Additional index words. ethylene, 1-methylcyclopropene, quarantine

Abstract. ‘Oroblanco’ is an early-maturing pummelo-grapefruit hybrid (Citrus grandis Osbeck x C. paradisi Macf.). The fruit are usually picked and marketed while the peel color is still green; however, in some cases they can lose this green color during postharvest shipping and storage, which diminishes their commercial value. The effects of storage temperatures, gibberellic acid (GA), ethylene, and 1-methylcyclopropene (1-MCP) on the degreening of ‘Oroblanco’ fruit were examined. Storage temperature was critical for retaining fruit color: at 2°C the fruit remained green for a period up to 5 weeks, whereas at storage temperatures of 6, 12, and 20°C there was a progressive increase in the rate of degreening. Applications of GA, either as preharvest sprays or as postharvest dip treatments, effectively retained the green fruit color. Ethylene exposures up to 100 nL·L–1 for 3 days had only a slight effect on fruit degreening, and 1-MCP treatments up to 200 nL·L–1 for 16 hours had no effect at all. The slight influence of ethylene and the ineffectiveness of 1-MCP on fruit color change can not be attributed to difficulties in their application, since in the same experiments ethylene markedly induced peduncle abscission, and 1-MCP effectively inhibited this ethylene effect. Accordingly, ethylene had only a relatively small effect on the induction of chlorophyllase enzyme activity in green ‘Oroblanco’ peel tissue.

‘Oroblanco’ is a triploid pummelo-grapefruit hybrid that was generated in Riverside, Calif., by a cross between an acidless pummelo (Citrus grandis Osbeck) and a tetraploid grapefruit (Citrus paradisi Macf.) (Soost and Cameron, 1981). The general characteristics of the fruit are similar to those of ‘Marsh’ seedless white grapefruit, despite the fact that they have a higher percentage of total soluble solids (TSS) and a lower acid content. ‘Oroblanco’ also lacks the typical bitterness of grapefruit and instead has a special, sweet aroma that is more similar to pummelo (Soost and Cameron, 1981).

‘Oroblanco’ is an early-maturing cultivar, which, according to its internal characteristics, is ready for eating in October (Soost and Cameron, 1981; Traiber et al., 1984). Commercially, the fruit are usually picked between October and November and are exported from Israel, mainly to Japan, when the peel is still green. Unfortunately, in some cases the fruit color changes during postharvest shipping and storage, and as a result the fruit loses some of its commercial value.

Several preharvest and postharvest factors may affect the degreening of ‘Oroblanco’ fruit. Storage temperature is a major factor determining the rate of postharvest deterioration of commodities (Kader, 1992). In citrus, specifically, storage temperature is an important consideration in commercial fruit degreening (Grierson et al., 1986). Generally, increasing the temperature to 30°C enhances chlorophyll degradation, whereas somewhat lower temperatures of 23 to 25°C are optimal for carotenoid biosynthesis (Ahrens and Barmore, 1986; Jahn et al., 1973; Stewart and Wheaton, 1972). Thus, for ‘Oroblanco’ low storage temperatures should delay peel deterioration and chlorophyll loss while higher temperatures should enhance degreening.

Gibberellic acid (GA) is commonly used to delay senescence and loss of chlorophyll in various citrus fruits (Coggins et al., 1992; El-Otmani et al., 1990; Garcia-Luis et al., 1992; Greenberg et al., 1992; McDonald et al., 1997). In fact, GA sprays in the orchard are currently being used as a horticultural practice to prolong the harvest season and maintain the green color of ‘Oroblanco’ fruit (Greenberg et al., 1986).

Citrus fruits are nonclimacteric, and the precise role of endogenous ethylene in the regulation of fruit maturation and peel color change is not yet clearly understood. Nevertheless, exogenous ethylene is commonly being used for commercial degreening of citrus fruit (Grierson et al., 1986), and it is believed that the chemical acts by increasing chlorophyllase activity (Trebitsh et al., 1993). Studies with several ethylene inhibitors, such as 2,5-norbornadiene (NBD), silver nitrate, and 1-methylcyclopropene (1-MCP), have shown that by blocking the response of the fruits to endogenous ethylene it is possible to inhibit natural degreening in ‘Shamouti’ oranges (Goldschmidt et al., 1993; Porat et al., 1999).

In the current study, we have evaluated the effects on the postharvest degreening of ‘Oroblanco’ citrus fruit of different storage temperatures, preharvest and postharvest GA applications, and exposure of the fruit to various concentrations of ethylene and 1-MCP.

Materials and Methods

Effect of temperature and length of storage. ‘Oroblanco’ fruit were harvested in October from local orchards, and their commercial color was evaluated immediately. Sixty fruit from each of three locations (replications) were selected, and a circle was drawn on the surface of each with a black marker. The hue angle of the peel within this circle was measured with a Minolta chroma meter (model CR-200; Minolta, Ramsey, N.J.), as described elsewhere (McGuire, 1992). The hue angle of these fruit at harvest was ≈122°; a hue angle of 120° represents green color, whereas 90° represents yellow. From each replicate 15 fruit were randomly selected for storage at 2, 6, 12, or 20°C for 5 weeks at 90% relative humidity. Hue angle at the marked location was subsequently measured weekly.

Effect of GA applications and 1-MCP and ethylene treatments. Prior to the October harvest, certain trees were sprayed twice during the months of August and September with 10 mg L–1 of GA (Machtshem, Israel) containing 0.05% Triton-B (Agan, Israel) as a surfactant. The fruit from some of these trees were also treated with GA postharvest by dipping for 20 s in 100 mg L–1 of GA in tap water with 0.15% BB5 (CTS, Israel) as a surfactant in a combination treatment. A third treatment received only the postharvest dip. Along with an untreated control, all fruit were stored for 5 weeks at 20°C, and hue angle was measured weekly at a marked location. Each treatment consisted of 15 fruit replicated three times.

In a similar test, fruit were placed in sealed 30-L plastic tanks and treated for 16 h with 1-MCP at 20, 100, or 200 nL·L–1 or for 3 d with ethylene at concentrations of 10, 40, or 100 µL·L–1. In both cases the exposure to the gas was carried out at 21°C. The concentrated

stock of 1-MCP (3000 µL·L⁻¹) was a gift from Prof. E.C. Sisler (Univ. of North Carolina). The required final concentrations of 1-MCP and ethylene were obtained by injecting appropriate amounts of the gases into the experimental tanks. Along with an untreated control, all fruit were stored for 5 weeks at 20 °C, and hue angle was measured weekly at a marked location. Each treatment consisted of 15 fruit replicates three times.

To validate the efficacy of 1-MCP and ethylene, some fruit that had been treated as above with 1-MCP (20, 100, or 200 nL·L⁻¹) for 16 h were subsequently kept for 3 d in air or exposed to 10 µL·L⁻¹ of ethylene over that time period. The abscission of the fruits’ peduncle was subsequently measured after 4 weeks of storage at 20 °C. Fifteen fruit per treatment were tested from each of three replications.

Chlorophyllase activity. Extraction of the chlorophyllase enzyme and its activity were assayed as described in detail by Trebisth et al. (1993). Briefly, the flavedo from 10 green fruit (hue angle of peel = 118 to 122°) or yellow fruit (hue angle of peel = 100 to 105°) was removed and homogenized in 50 mM Tris-HCl (pH 8.0), and centrifuged at 12,000 g for 10 min. The pellet was homogenized in acetone at −15 °C for the preparation of an acetone powder. For the determination of chlorophyllase activity, 20 mg of acetone powder were stirred for 30 min at 37 °C with 20 mL of a solution of 5 mM potassium phosphate (pH 7.0), 0.24% Triton X-100, and 0.24% Triton X-100. The extract was filtered through glass wool and centrifuged again at 12,000 g for 10 min, and the supernatant was collected. To measure chlorophyllase activity, 0.2-mL aliquots of the enzyme were incubated at 37 °C for up to 60 min in 2.8 mL of a solution of 100 mM sodium phosphate (pH 7.0), 0.24% Triton X-100, and 0.2 µmol of chlorophyll-a dissolved in 100% acetone. The reaction was stopped by transferring 0.5 mL of the reaction mixture to centrifuge tubes containing acetone/hexane/10 mM KOH, at ratios of 4:6:1 (by volume), and after phase separation, chlorophyllide-a in the acetone phase was determined spectrophotometrically at 667 nm. The experiment was repeated three times.

Fruit quality after commercial quarantine and long-term storage. A second type of storage experiment compared a short, cold method that simulates a commercial quarantine treatment against the Mediterranean fruit fly (Ceratitis capitata) (Wiedemann) with long-term storage. Untreated control fruit were compared with those sprayed as above with GA in the orchard and also with fruit sprayed with GA in the orchard and then after harvest exposed to 200 nL·L⁻¹ of 1-MCP for 16 h. For the short quarantine storage, fruit were held for 3 weeks at 2 °C followed by 1 week at 12 °C to simulate commercial treatment; long-term storage lasted 11 weeks at 12 °C. Following these storage regimes, the fruit were transferred to market conditions at 20 °C prior to evaluation. Each of four replications consisted of 25 fruit per treatment. At the end of storage, hue angle (initially averaging 121.3°) was reevaluated. The percentage of total soluble solids (TSS) in the fruit juice was determined with a refractometer, and the percentage of acidity was measured by titration to pH 8.3 with 0.1 N NaOH. Fruit were weighed before and after storage to assess weight loss, and the percentages of fruit that decayed or were injured by the chill temperatures were recorded at the end of each storage period.

Statistical analysis. Student–Newman–Keuls one-way analysis of variance (ANOVA) tests on ranks were performed using the SigmaStat statistical software (Jandel Scientific Software, San Rafael, Calif.). In addition, regression analysis according to the General Linear Model (GLM) procedure was performed using the SAS statistical analysis programs (SAS Institute, Cary, N.C.).

Results

Effect of storage temperature on fruit degreening. Following storage at 2 °C, there was only a very slight change in the color of ‘Oroblanco’ fruit, whereas at 6, 12, and 20 °C, there was a progressive increase in the rate of degreening (Fig. 1). At 20 °C, the fruit remained green during the first 2 weeks of storage but then began to change color very rapidly. A regression analysis of fruit color across time for each storage temperature showed that storage at 2 °C was significantly different from all of the other storage temperatures at P < 0.01. Storage at 6 and 12 °C was also significantly different from storage at 20 °C at the same level of significance. There was no significant difference between storage temperatures of 6 and 12 °C.

Effect of GA applications on fruit degreening. Both preharvest and postharvest applications of GA significantly retained the green color of ‘Oroblanco’ fruit and markedly reduced the rate of degreening as compared to untreated fruit (Fig. 2). A regression analysis of fruit color across time for each treatment has shown that the various preharvest, postharvest, and combined preharvest and postharvest GA application treatments were all significantly different from the untreated control.
Effects of 1-MCP and ethylene on fruit degreening. There was no effect of 1-MCP on the color of ‘Oroblanco’ fruit (Fig. 3). On the other hand, exposure to exogenous ethylene immediately caused fruit to yellow very slightly, but the accelerated effect lasted no more than 2 weeks after the ethylene treatment (Fig. 4). A regression analysis of fruit color across time for each concentration of ethylene showed that the various ethylene treatments were significantly different from the untreated control at \( P < 0.01 \). The various ethylene concentrations were not significantly different among themselves, however.

The lack of an effect with 1-MCP and the minimal effect with ethylene could not be attributed to application difficulties, since in the same experiments ethylene markedly increased peduncle abscission, and 1-MCP inhibited this ethylene effect (Table 1). Chlorophyllase activity was higher in green fruit than in already degreened yellow fruit (Table 2); however, exogenous ethylene had only a moderate effect (1.7-fold in green fruit and 2.3-fold in yellow fruit) on the induction of chlorophyllase activity.

Commercial storage experiments. To evaluate the inhibitory effects of GA and 1-MCP on the degreening of these fruit under commercial storage conditions, fruit were stored under temperature regimes that simulated a short quarantine treatment and a long-term storage treatment. GA treatments alone and the combination of GA plus 1-MCP delayed fruit degreening under both storage regimes (Table 3). However, the further exposure of GA-treated fruit to 1-MCP did not have any additional effect on the loss of green coloration when compared with fruit that were treated only with GA.

During the short quarantine treatment, in which the fruits were held for 3 weeks at 2°C, the untreated control fruit had degreened only slightly from an initial hue angle of 121.3°. Nevertheless, GA significantly inhibited fruit degreening and the fruit remained completely green (Table 3). After the long-term storage treatment, the untreated control fruit became completely yellow, whereas the GA treatment inhibited the rate of degreening, and the fruit remained greenish-yellow. Apart from the effects of GA on the retention of peel color, neither GA nor 1-MCP had any effect on internal fruit quality characteristics such as TSS and acid content, nor on postharvest storage performance. Differences in weight loss

*Hue angle at harvest was 121.3°; an angle below 115° is considered unacceptable by the market. Data are means of measurements taken from 100 fruit for each treatment. Different letters within a column indicate significant differences at \( P < 0.05 \), according to a Student–Newman–Keuls one-way ANOVA test on ranks.

*Fruits were kept in air or were exposed to 10 μL·L⁻¹ ethylene for 3 d.

---

**Fig. 3.** Effect of 1-methylcyclopropene (1-MCP) on the degreening of ‘Oroblanco’ fruit. Fruit were kept untreated, or were exposed to 20, 100 or 200 nL·L⁻¹ of 1-MCP for 16 h then stored for 5 weeks at 20°C. Data are means for 45 fruit from three separate experiments. Green = 120°, yellow = 90°.

**Fig. 4.** Effect of ethylene on the degreening of ‘Oroblanco’ fruit. Fruit were kept untreated, or were exposed to 10, 40, or 100 μL·L⁻¹ of ethylene for 3 d then stored for 5 weeks at 20°C. Data are means for 45 fruit from three separate experiments. Green = 120°, yellow = 90°.
were nonsignificant within storage regimes and averaged 3.5% and 6.7% after short- and long-term storage, respectively. There was no decay or chilling injury after either treatment (data not shown).

Discussion

Low-temperature storage and GA treatments significantly reduced the degreening of ‘Oroblanco’ fruit. A hue angle below 115° is unacceptable in the marketplace. To maintain a green-colored fruit with a hue angle above 115°, we suggest as a commercial practice that the fruit should be treated with GA, either as preharvest sprays in the orchard or as postharvest dips, followed by storage at 2 °C. However, since ‘Oroblanco’ fruit, as well as their grapefruit and pummelo parents, are sensitive to chilling injuries (Chalutz et al., 1985; Waks et al., 1988), the duration of cold storage should not exceed 4 to 5 weeks, which is not sufficiently long to promote chilling damage. Periods of 8 and 12 weeks at 2 °C, however, can cause severe chilling injuries (Chalutz, personal communication).

Surprisingly, ethylene had just a slight effect and 1-MCP had no effect at all on the color of ‘Oroblanco’ fruit. These findings are inconsistent with the well-known behavior of many other citrus cultivars, in which ethylene is commonly used to enhance fruit degreening (Cohen, 1978; Grierson et al., 1986). To the best of our knowledge, the only other case in which ethylene was relatively ineffective in promoting degreening was in regreened ‘Valencia’ oranges (Eaks, 1977). In that case, ethylene accelerated chlorophyll loss, but at a relatively low rate, so that the visual changes in fruit color were very small (Eaks, 1977). In a similar manner, ethylene had only a relatively small effect on the increase in chlorophyllase activity in ‘Oroblanco’ peel: 1.7- to 2.3-fold as compared with an 11.4-fold increase observed in ethylene-treated ‘Valencia’ oranges (Trebitsh et al., 1993). Therefore, the ethylene treatment of ‘Oroblanco’ fruit was probably insufficient to promote a remarkable effect on chlorophyllase activity.
