The evolution of a closed Friedmann universe filled by a tachyon scalar field with a trigonometric potential and cold dark matter (CDM) is investigated. A subset of the evolutions consistent to 1\sigma confidence level with the Union 2.1 supernova data set is identified. The evolutions of the tachyon field are classified. Some of them evolve into a de Sitter attractor, while others proceed through a pseudo-tachyonic regime into a sudden future singularity. Critical evolutions leading to Big Brake singularities in the presence of CDM are found and a new type of cosmological evolution characterized by singularity avoidance in the pseudo-tachyon regime is presented.

\section{I. INTRODUCTION}

The discovery of the cosmic acceleration \cite{1} has generated a lot of interest in Friedmann cosmological models with various kinds of exotic forms of matter, collectively known as dark energy \cite{2}. Unsurprisingly, some of these models allow for novel type of singularities (occurring in finite time), which can be either strong or weak \cite{3,4,5,6}.

In particular, the Big Rip singularity occurs at infinite scale factor, diverging Hubble parameter $H$ and diverging $H^2$. This singularity is strong according to both Tipler's \cite{7} and Krółak's \cite{8} definition. Some other singularities are alike, but they occur at finite scale factor (FSF). The FSF singularity \cite{8,9} is also strong according to Krółak's definition, but is classified as weak according to Tipler's definition.

The sudden future singularity (SFS), discovered many years ago \cite{10}, is characterized by both a finite scale factor and a finite Hubble parameter, while only $H$ diverges \cite{11}. As consequence the energy density is finite, while the pressure diverges at SFS. The geodesic equation (containing only $H$) remains regular at SFS, such that point particles will pass through the singularity. However for an infinitesimally short time the tidal forces in the geodesic deviation equation become infinite due to the diverging $H$. The SFS singularity is weak in both Tipler's and Krółak's definitions, hence it has been conjectured that finite object may also cross this singularity \cite{3}.

A subclass of the SFS singularities is the Big Brake, introduced in Ref. \cite{12} as emerging in the presence of a particular tachyonic scalar field (i.e. Born-Infeld-type field). Such a singularity is characterized by a full stop in the expansion, occurring at finite scale factor and vanishing energy density, augmented by a diverging deceleration and pressure. There is also the w-singularity \cite{8,13}, when both the pressure and energy density vanish, however their ratio, the barotropic index $w$ diverges, is also weak in both definitions.

Interesting features of the SFS singularities have been found on the example of the flat Friedmann universe filled with a combination of cold dark matter (dust) and tachyonic field, the latter obeying a particular potential of trigonometric functions \cite{12}. The model possesses two surprising features. First, for certain model parameter range, at some stage of the cosmological evolution, the tachyonic field is constrained to transform into another Born-Infeld-type field, the pseudo-tachyon. Secondly, in this regime the universe unavoidably evolves into the SFS.

In this model in the absence of the dust component the SFS singularity represents a Big Brake. Confrontation with type Ia Supernovae (SNIa) data showed that the allowed cosmological evolutions can reach either the Big Brake or the de Sitter attractor \cite{13}. Further, in Ref. \cite{16} it was proven that the Big Brake singularity is traversable, and the evolution continues through a collapsing universe into a Big Crunch.

When the dust component is included, the SFS cannot be a Big Brake anymore \cite{17}. Indeed, the universe reaches the singularity with a finite but nonzero $H$. Its traversability is guaranteed by certain changes in the matter properties \cite{14,18}, imposed by the requirement of a smooth passage through the SFS. These changes lead to the notion of the quasi-tachyonic Born-Infeld-type field, a phantom field \cite{19} with negative energy density. A thorough confrontation of these models with SNIa, baryonic acoustic peaks, and cosmic microwave background temperature anisotropy power spectrum did not disrule the evolutions leading to either the de Sitter attractor or to the SFS \cite{20}.

The present work represents a continuation of the series of papers \cite{12,13,14,15,20}, investigating the consequences of the introduction of a tiny positive curvature, which remains compatible with the recent Planck data \cite{21,22}. As will be shown, the addition of the curva-
ture term enriches the velocity phase space of the possible cosmological evolutions, adding to it regimes which were impossible to realize in the flat model. We study these regimes numerically and show the existence of a critical behavior in the formation of the singularities in the framework of these tachyonic cosmological models. Such critical phenomena were well-known in the numerical study of gravitational collapse of a scalar field [23] and of various other fields (as reviewed in Ref. [24]), with the critical evolutions separating black-hole reaching evolutions from those which do not lead to black hole formation.

The structure of the paper is as follows. In Section II we introduce the equations of the tachyonic cosmology in the presence of dust and curvature. In Section III we confront the luminosity distance-redshift relation with the supernova data. In Section IV we investigate numerically the dynamics and give the classification of all possible regimes, with emphasis on the new types of evolutions. The results are summarized in the Conclusions.

The units are chosen as \( c = 1 \) and \( 8\pi G/3 = 1 \).

II. A MIXTURE OF DUST AND TACHYONIC FIELD IN A FRIEDMANN UNIVERSE

We consider a Friedmann universe

\[
\begin{align*}
\text{d}s^2 &= \text{d}t^2 - a^2(t) \left( \frac{1}{1 - Kr^2} \text{d}r^2 + r^2 \text{d}\theta^2 + r^2 \sin^2 \theta \text{d}\phi^2 \right),
\end{align*}
\]

with cosmological time \( t \), comoving radial distance \( r \), polar and azimuthal angles \( \theta \) and \( \phi \), unnormalized curvature index \( K > 0 \), or \( 0 < K \) and scale factor \( a(t) \). The combined energy momentum tensor is an ideal fluid with energy density \( \rho \) and pressure \( p \). The dynamics of the scale factor is governed by the Raychaudhuri equation:

\[
\dot{H} - \frac{K}{a^2} + \frac{3}{2}(\rho + p) = 0,
\]

and the change in the energy density by the continuity equation:

\[
\dot{\rho} + 3H(\rho + p) = 0.
\]

The overdot denotes time derivative and \( H \equiv \dot{a}/a \) is the Hubble parameter. The first integral of the system [22-23] is the Friedmann equation:

\[
H^2 + \frac{K}{a^2} = \rho.
\]

We assume that the Friedmann universe is filled with a mixture of tachyonic field and cold dark matter (CDM). The mixture of the two ideal fluid components (distinguished by \( m \) and \( T \) subscripts) is characterized by \( \rho = \rho_m + \rho_T \) and \( p = p_T \), where

\[
\rho_m = \frac{\rho^*}{a^3},
\]

with integration constant \( \rho^*_m \). The evolution of the homogeneous tachyonic field \( T(t) \) follows from the Lagrangian density [25]

\[
L_T = -\sqrt{-g}V(T) \sqrt{1 - g^TT^2},
\]

with \( s = \dot{T} \). Variation with respect to the metric gives its energy density

\[
\rho_T = \frac{V(T)}{\sqrt{1 - s^2}},
\]

and pressure

\[
p_T = -V(T) \sqrt{1 - s^2}.
\]

As \( w = p/\rho = s^2 - 1 \), in principle the tachyonic field can mimic dark energy. The particular case of a trigonometric tachyonic potential [12]

\[
V = \frac{\Lambda\sqrt{1 - (1 + k)y^2}}{1 - y^2},
\]

with

\[
y = \cos \left[ \frac{3}{2} \sqrt{\Lambda (1 + k)} T \right],
\]

\( \Lambda > 0 \) and \( -1 < k < 1 \) model parameters further leads to interesting behavior, including a smooth passage into the \( s > 1 \) regime and a sudden future singularity which can be passed through by geodesics which then bounce back into a recollapse [12-20].

Note that the system is invariant under the simultaneous changes \( (y \rightarrow -y, s \rightarrow -s) \). This yields a double coverage of the dynamics in these velocity phase space variables.

III. TEST WITH SUPERNOVAE DATA

The evolution of the Friedmann universe is determined by the initial conditions \( H_0 = H(z = 0), y_0 = y(z = 0), s_0 = s(z = 0), (z \) is the redshift), the present values of the cosmological parameters

\[
\Omega_m = \frac{\rho^*_m}{a^3 H^2_0}, \quad \Omega_K = \frac{-K}{a^2 H^2_0},
\]

associated to the CDM and the curvature, and the model parameters \( \Lambda, k \). The parameter \( \Omega_K \) is constrained by observations to 95% confidence level: \(-0.0065 \leq \Omega_K \leq 0.0012 \) by WMAP data [27] and \(-0.019 \leq \Omega_K \leq 0.011 \) by Planck data (see fifth column in Table 5 of [22]). In what follows we set \( \Omega_m = 0.315 \) (supported by the cosmic microwave anisotropies measured by the Planck satellite [21, 22], \( k = 0.44 \), \( H_0 = 70 \text{ km/sec/Mpc} \) and we analyze both \( \Omega_K = -0.0065 \) and 0 (the former being compatible with \( K > 0 \), the latter representing a spatially flat
universe). The Friedmann equation represents a constraint among $y_0$, $s_0$ and $\Lambda$, thus only the first two are varied. The confrontation of the tachyonic model with the Union 2.1 SNIa data set through a $\chi^2$-test as described in Ref. [15] relies on fitting with the computed luminosity distance ($d_L$)-redshift relation. A dimensionless luminosity distance $d_L = H_0 d_L$ is given by

$$\sqrt{-\Omega_K} \frac{d_L}{1 + z} = \chi(z) \text{ for } K = 0,$$

(12)

$$\sqrt{-\Omega_K} \frac{d_L}{1 + z} = \sin(\chi(z)) \text{ for } K > 0,$$

(13)

with

$$\frac{d\chi(z)}{dz} = \frac{-\sqrt{-\Omega_K}}{H}.$$  

(14)

($\dot{H} = H/H_0$) We show the fit on Fig 1. The contours refer to the 68.3% (1σ) and 95.4% (2σ) confidence levels.

Thus the introduction of the curvature does not hamper the compatibility of the model with the SNIa observations.

IV. VELOCITY PHASE SPACE

The $y^2 < 1/(1+k)$ , $s^2 < 1$ domain of the velocity phase space represents proper tachyonic fields, characterized by the Lagrangian, energy density, pressure and potential. A subset of the initial conditions $y_0$, $s_0$ allow the universe to evolve outside this regime through the corner points $y, s = \pm 1$ where the potential $V$ vanishes, as described in Ref. [12].

Note that in the Lagrangian $W$ absorbs the imaginary factor arising from the change of sign in the equation of state $w = s^2 - 1$. The expressions of the energy density and pressure are also unchanged in the pseudo-tachyonic regime. Rewriting the Lagrangian, the energy density and pressure in terms of $W$ however manifestly shows that all these quantities stay real:

$$L_P = \sqrt{-g} W \sqrt{g^{tt} s^2 - 1},$$

(16)

$$\rho_P = \frac{W(T)}{\sqrt{s^2 + 1}},$$

(17)

$$p_P = W(T) \sqrt{s^2 - 1}.$$  

(18)

The pressure is positive, thus the expansion of the universe slows down in this regime.

Further evolution to $s \to -\infty$ leads to SFS, arising for finite values of $z$, $\dot{H}$ and $W$ and $\rho_P \to 0$, $p_P \to \infty$. As was shown in Ref. [13] the evolution can be continued smoothly across these soft singularities at the price of a sudden change of the Lagrangian, which will represent a quasi-tachyonic field:

$$L_Q = \sqrt{-g} W \sqrt{g^{tt} s^2 + 1},$$

(19)

$$\rho_Q = \frac{-W(T)}{\sqrt{s^2 + 1}},$$

(20)

$$p_Q = W(T) \sqrt{s^2 + 1}.$$  

(21)

Note that $w_Q = p_Q/\rho_Q = -(s^2 + 1) \neq w$, thus the quasi-tachyon is a phantom with negative energy density.

In order to formulate the dynamical equations with dimensionless variables, we normalize the potentials as

$$\dot{V} = \Omega_L \sqrt{\frac{1 - (1 + k)y^2}{1 - y^2}},$$

(22)

$$\dot{W} = \Omega_L \sqrt{\frac{(1 + k)y^2 - 1}{1 - y^2}}.$$  

(23)

(i.e. $\Omega_L = \Lambda/H_0^2$, $\dot{V} = V/H_0^2$, $\dot{W} = W/H_0^2$).
The dimensionless variables $z(t)$ and $\hat{H}(t)$ evolve as

$$\frac{dz}{dt} + (1 + z)\hat{H} = 0 , \quad (24)$$

$$\frac{d\hat{H}}{dt} + \frac{3}{2}(\dot{\rho}_m + \dot{\rho} + \dot{\hat{p}}) + \Omega_K (1 + z)^2 = 0 , \quad (25)$$

with $\dot{t} = H_s t$. Eq. (24) follows from the definition of $z$, while Eq. (25) is the Raychaudhuri equation. Here $\dot{\rho}_m = \Omega_m (1 + z)^3$ is the normalized density of the dust, while $\dot{\rho}$ stands for either of the normalized densities

$$\dot{\rho}_T = \frac{\dot{V}}{\sqrt{1 - s^2}} , \quad (26)$$

$$\dot{\rho}_P = \frac{\dot{W}}{\sqrt{s^2 - 1}} , \quad (27)$$

$$\dot{\rho}_Q = \frac{-\dot{W}}{\sqrt{s^2 + 1}} , \quad (28)$$

holding for the tachyonic, pseudo-tachyonic or quasi-tachyonic regime, respectively. Similarly, $\dot{\rho}$ denotes one of the normalized pressures

$$\dot{\rho}_T = -\dot{V}\sqrt{1 - s^2} , \quad (29)$$

$$\dot{\rho}_P = \dot{W}\sqrt{s^2 - 1} , \quad (30)$$

$$\dot{\rho}_Q = \dot{W}\sqrt{s^2 + 1} . \quad (31)$$

The dynamics of the tachyonic field $y(t)$ emerges from the definition of $s$ as

$$\frac{dy}{dt} + \frac{3}{2}s\sqrt{\Omega_\Lambda (1 + k)(1 - y^2)} = 0 , \quad (32)$$

while the evolution of $s(t)$ in the tachyonic, pseudo-tachyonic and quasi-tachyonic regimes are given by the following Euler-Lagrange equations:

$$\frac{ds}{dt} + (1 - s^2)\left(3\dot{H}s + \frac{\dot{V}_T}{V}\right) = 0 , \quad (33)$$

$$\frac{ds}{dt} + (1 - s^2)\left(3\dot{H}s - \frac{\dot{W}_T}{W}\right) = 0 , \quad (34)$$

$$\frac{ds}{dt} + (1 + s^2)\left(3\dot{H}s - \frac{\dot{W}_T}{W}\right) = 0 . \quad (35)$$

In the neighborhood of the soft singularity $y$ can be approximated as

$$y_P = y_S + \frac{\sqrt{6}}{2}\sqrt{1 - y_S^2} \times \sqrt{\Omega_\Lambda (1 + k)}\sqrt{\frac{1}{H_S}\sqrt{1 - t_S}} , \quad (36)$$

$$y_Q = y_S - \frac{\sqrt{6}}{2}\sqrt{1 - y_S^2} \times \sqrt{\Omega_\Lambda (1 + k)}\sqrt{\frac{1}{H_S}\sqrt{t - t_S}} . \quad (37)$$

(These formulas are analogous to Eqs. (30) and (50) of Ref. [18] presented in terms of the original tachyonic variable $T$, and they hold for the upper right strip of Fig. 2 where $y_P > y_S > y_Q$.) The two expressions coincide at the singularity. In the quasi-tachyonic regime the Hubble variable decreases, reaching zero at some point which is followed by a recollapse through the same type of singularity to the pseudo-tachyonic regime, ending in a Big Crunch. This was always the case for $K = 0$ [16].

Due to the extra gravitational attraction represented by $\Omega_K < 0$ however some of the pseudo-tachyonic evolutions do not reach the singularity, avoiding the quasi-tachyonic regime. Instead the recollapse into a Big Crunch commences earlier. These two types of evolutions are separated by a critical trajectory when the soft singularity is reached exactly with $\hat{H} = 0$. In what follows we will investigate this criticality.

The numerical evolution of the dynamical equations yields seven types of trajectories $I, IIa, IIIa, IIIb, IV$, and $V$, represented on the upper panel of Fig. 2. The lower panel magnifies out the pseudo-tachyonic evo-

![FIG. 2: (Color online) Upper panel: The numerical evolution of the dynamical equations yields seven type of trajectories (I, IIa, IIb, IIIa, IIIb, IV and V), separated by separatrices (red). Lower panel: the pseudo-tachyonic evolutions of the upper right corner. We chose $\Omega_\Lambda = 0.8$.](image)
of dust are (4) and (6).

The trajectories of type I originate from the Big Bangs $(y, s) = (1, \sqrt{1 + 1/k})$ and $(y, s) = (-1, -\sqrt{1 + 1/k})$ in pseudo-tachyonic regime, then evolve into the tachyonic regime towards a de Sitter expansion, represented by the origin $(y, s) = (0, 0)$. The trajectories of type IIa originate from the lines $s = \pm 1$ representing Big Bang singularities, then evolve from the pseudo-tachyonic regime, through the corner points into the tachyonic era, where they also reach the de Sitter attractor. The trajectories of type IIIb are similar, but they never cross into the pseudo-tachyonic regime.

The trajectories of type IIIa and IIIb also originate in Big Bangs at the lines $s = \pm 1$, pass through the tachyonic regime and through the cornerpoint into a pseudo-tachyonic regime, followed by a collapse into a Big Crunch (on the $y = \pm 1$ line). The difference between them is shown on Fig. 2. While IIIa reaches the soft singularity, evolves through a short quasi-tachyonic regime in which the universe start to recollapse towards a second soft singularity, those of type IIIb never reach a soft singularity.

The trajectories of type IV originate in a Big Bang located in the pseudo-tachyonic regime $(y = \pm 1$ line), evolve into the tachyonic regime, then return into a pseudo-tachyonic regime, pass twice through soft singularities (with a short quasi-tachyonic period), finally collapse into a Big Crunch. The trajectories of type V are born in the Big Bang singularities on the lines $s = \pm 1$, after which they mimic the evolution of the trajectories of type IV following their second passage into a pseudo-tachyonic regime.

On Fig. 3 we represent all types of trajectories which will reach a pseudo-tachyonic regime in the future (types IIIa, IIIb, IV and V). From among these IIIa, IV, V pass twice through soft singularities, with an intercalated quasi-tachyonic regime, while those of type IIIb never reach a soft singularity. We also determined numerically the critical evolutions separating these two types of behaviors. They are the evolutions leading to Big Brake type singularities in the presence of dust.

**V. CONCLUDING REMARKS**

In this paper we have expanded previous studies of a tachyonic cosmological model with trigonometric potential and dust exhibiting a rather rich spectrum of possible evolutions, by including curvature. As expected, a positive curvature could counterbalance the influence of the dust (manifesting itself in a positive $H$ and nonvanishing energy density at the SFS), in the sense that it can compensate for the nonzero energy density at the SFS. When the curvature term is strong enough, it stops the expansion before the encounter with the SFS, preventing its formation. If the curvature term is less strong, then the cosmological SFS is still formed, followed by the transition to the quasi-tachyonic regime, but its slowing-down effect is expected to reduce the duration of this regime as compared to the flat case.

We have shown by numerical methods that it is possible to have a particular balance between curvature and dust effects, leading to critical evolutions, represented by the curves (4) and (6) on Fig. 3. When such a critical evolution is realized, the universe reaches exactly a Big Brake singularity, which was forbidden in the flat case. The critical evolutions reaching a traversable Big Brake separate evolutions into SFS from completely regular ones. In this sense they resemble the criticality of singularity-forming in gravitational collapse. This criticality is a new feature of tachyonic cosmologies, induced by curvature. The possibility to reach a Big Brake type singularity when dust is present is the second new feature of the closed Friedmann universes with the tachyonic field.
