Arsenic pollution is a worldwide issue. Nearly all arsenic is converted to arsine (AsH₃) under the reducing atmosphere required for the gasification process. Growing industrialization has increased AsH₃ emissions, for example, the ore smelting process leads to AsH₃ emissions. The conditions used in the ore smelting process are low temperature and micro-oxygen. A series of Hβ zeolites loaded on different metal oxides has been prepared using an impregnation method and tested for adsorption of arsine (AsH₃) under low temperature and micro-oxygen conditions. Based on the results obtained from the adsorbent optimization experiments, Hβ zeolite modified with Cu(NO₃)₂ (denoted as Cu/Hβ) was found to possess a significantly enhanced adsorption removal ability towards arsine. The effects of the impregnation concentration, calcination temperature, reaction temperature, and oxygen content on the AsH₃ removal process were investigated. The results indicate that adsorbents with 0.2 mol L⁻¹ Cu(NO₃)₂ after calcination at 400 °C have superior activity for AsH₃ removal. In addition, a breakthrough capacity of 43.7 mg AsH₃/g adsorbent at 60 °C as well as 1.0% oxygen was observed with Cu/Hβ for the AsH₃ adsorption process. The structure and surface properties of the Hβ zeolite samples were characterized by N₂-BET (N₂ adsorption/desorption), XRD (X-ray powder diffraction), XPS (X-ray photoelectron spectroscopy), and FTIR (Fourier transform infrared) spectroscopy. It is feasible that the exhausted Cu/Hβ can be regenerated by thermal desorption, and the adsorbents can be recycled at least two times with little capacity loss.

1. Introduction

Arsine (AsH₃) is a hydrophobic, very volatile, and highly poisonous gas, which plays an important role in the cycling of arsenic on earth. AsH₃ released in the air commonly arises from various sources such as the processes in which arsenic-containing metals react with acids, coal gasification, yellow phosphorus tail gas, and the burning of fossil fuels at high temperatures.³⁴ For example, ore smelting flue gas includes reducing gaseous pollutants such as AsH₃ and H₂S; however, arsenic emissions during the ore smelting process have not received adequate attention due to the micro-oxygen and low temperature conditions used; thus, these emissions have been easily overlooked despite their toxicity.²⁷ The toxicity of AsH₃ is about seven times higher than that of lewisite.⁷ AsH₃ can enter the body through skin, respiratory tract or the digestive tract, which can easily induce severe human health hazards including serious damage to the lungs, respiratory tract, bronchus, and kidneys as well as cancer.⁸ Thus, the concentration of AsH₃ in the workshop has been strictly limited in many countries. For instance, the permissible exposure limit of AsH₃ should be between 0.016 mg m⁻³ and 0.001 mg m⁻³, which has been defined by the American Committee of government in Health and the Ministry of Environmental Protection of the People’s Republic of China, respectively.⁹ Furthermore, synthesis gas can be used to produce C1 chemical products with the development of C1 chemical technology. However, the most important factors of synthesis catalyst poisoning is the existence of many impurities such as sulfur, phosphorus, arsenic, and cyanide in synthesis gas.¹⁰,¹¹ Therefore, the removal of AsH₃ has a profound significance.

In general, the methods for removing AsH₃ from air and off-gas include chemical adsorption, catalytic decomposition, combustion, and adsorption. However, catalytic decomposition and combustion are typically employed at high temperatures. Adsorption is one of the most mature and promising methods because of its ease of operation, flexible design, low temperature condition, and low-cost, and it is more appropriate for the removal of AsH₃ at low concentrations. Adsorption technology was chosen to accomplish the required removal of contaminants. Although numerous materials have been reported as adsorbents for the effective removal of AsH₃, high operating temperatures are typically required.¹²–¹⁸ For instance, Poulston et al. have reported that Pd can be used to modify Al₂O₃ for the adsorption of AsH₃ from simulated flue gas at temperatures
between 204 °C and 288 °C.9 Jiang et al. found that activated carbon modified with sulfonated cobalt phthalocyanine (CoPcS) and Cu(NO$_3$)$_2$ was able to adsorb AsH$_3$ efficiently, and the AsH$_3$ adsorption capacity was 35.7 mg g$^{-1}$ adsorbent at 60 °C and a 4% oxygen content.20 However, some shortcomings with the present activated carbons have been identified including their thermal instability.21 On the other hand, zeolite materials have been found to have broad applications in various fields including as a catalyst support as well as in the development of adsorbents due to their stable structures, large specific surface area, well-developed porous structure, and high thermal stability.22 However, the possibility of removing AsH$_3$ using zeolite dry adsorption has not been studied to date. Thus, Hf zeolite was chosen as the adsorbent support in this study.

The objective of this study was to investigate the adsorption behavior of the modified zeolite adsorbents under low temperature and micro-oxygen conditions and to explore the adsorption mechanism of AsH$_3$ adsorption removal. Herein, the adsorbents were prepared using an impregnation method, and the effects of the experimental conditions, including the types of impregnant, impregnation concentration, calcination temperature, reaction temperature, and oxygen content, were explored; this allowed us to obtain the optimal adsorption purification conditions for AsH$_3$. The pore structure properties of the Cu/Hf zeolite adsorbents before and after AsH$_3$ adsorption were measured using N$_2$-BET analysis. The phase and crystalline orientation of Cu/Hf were determined using XRD analysis. XPS was employed to evaluate the chemical states of the elements in Cu/Hf before and after AsH$_3$ adsorption. Functional group and chemical bonding in the Cu/Hf adsorbents were determined using FTIR spectroscopy.

2. Materials and methods

2.1 Sample preparation

Hf zeolite prepared from the commercial zeolite (99.99%, Nankai University Catalyst Co., Ltd., Tianjin, China) was used as a support material for metal adsorbents in our experiments. Cu(NO$_3$)$_2$, Fe(NO$_3$)$_3$·9H$_2$O, Zn(NO$_3$)$_2$·6H$_2$O, Ni(NO$_3$)$_2$·6H$_2$O, Mn(NO$_3$)$_2$, and Pb(AC)$_2$·3H$_2$O were used as impregnates to improve the adsorption performance of the Hf zeolite. M–Hf (M = metal) zeolites were prepared using an impregnation method. At first, the Hf zeolite was crushed and sieved with a 40–60 mesh size. The Hf zeolite support (10 ± 0.1 g) was washed three times with 150 mL of distilled water at 70 °C to remove the soluble impurities and then dried at 110 °C for 12 h. Subsequently, the Hf zeolite was impregnated with an aqueous Cu(NO$_3$)$_2$ solution (0.2 mol L$^{-1}$, 50 mL), an aqueous Fe(NO$_3$)$_3$·9H$_2$O solution (0.2 mol L$^{-1}$, 50 mL), an aqueous Zn(NO$_3$)$_2$·6H$_2$O solution (0.2 mol L$^{-1}$, 50 mL), an aqueous Ni(NO$_3$)$_2$·6H$_2$O solution (0.2 mol L$^{-1}$, 50 mL), an aqueous Mn(NO$_3$)$_2$ solution (0.2 mol L$^{-1}$, 50 mL) or an aqueous Pb(NO$_3$)$_2$ solution (0.2 mol L$^{-1}$, 50 mL) at ambient temperature. Then, impregnation was carried out under stirring for 24 h, and the adsorbent was filtered from the reaction solution. The filtered adsorbent was dried at 110 °C for 12 h followed by calcination in a muffle furnace at a specified temperature for 6 h. Finally, the resulting samples were cooled down to ambient temperature and denoted as Cu/Hf, Fe/Hf, Zn/Hf, Ni/Hf, Mn/Hf, and Pb/Hf.

2.2 Fixed-bed adsorption experiment

The model gas was composed of nitrogen with 70 ppm AsH$_3$, which was mixed in the mixer evenly with micro-oxygen and subsequently introduced into the adsorption bed unit. This adsorption reaction was conducted in a quartz columnar reactor with a 9 mm inner diameter and 60 mm length under atmospheric pressure. The AsH$_3$ breakthrough curves for AsH$_3$ removal were assessed using dynamic tests at temperatures between 20 and 80 °C with an oxygen content between 0% and 2%. Each sample (0.4 g) was added to the quartz column and exposed to the gas containing 70 ppm AsH$_3$ at a flow rate of 200 mL min$^{-1}$, and the experiment was stopped when the adsorbent was saturated. AsH$_3$ was adsorbed readily in potassium permanganate to avoid any safety problems. The concentration of AsH$_3$ was measured using a silver diethylthiocarbamate spectrophotometric method. The breakthrough time was defined as the time at which the AsH$_3$ outlet concentration reached 5% of the inlet concentration according to the breakthrough curves. The adsorption capacity of AsH$_3$ was calculated with the corresponding integral according to the following equation under various conditions of the breakthrough curves.23

$$X = \left( \frac{Q}{Q_0 C_0} - \frac{Q}{Q_0} \int_0^t C dt \right) \left/ m \right.$$  

where $X$ is the adsorption capacity in mg g$^{-1}$, $Q$ denotes the gas flow rate in m$^3$ min$^{-1}$, $t$ represents the adsorption time in minutes, $C_0$ represents the adsorption column entrance mass concentration of AsH$_3$ in mg m$^{-3}$, $C$ represents the adsorption column outlet mass concentration of AsH$_3$ in mg m$^{-3}$, and $m$ is the mass of adsorption in g obtained from the breakthrough curves.

2.3 Sample characterization

The pore size distribution, specific surface area, and pore volume of the samples were measured using the nitrogen adsorption/desorption isotherms obtained at 77 K using a NOVA 2000e (Quanta chrome instruments) surface area analyzer. The specific surface area was determined using the Brunauer–Emmett–Teller (BET) equation. The pore size distribution was evaluated using the Barrett–Joyner–Halenda (BJH) method. X-ray diffraction (XRD) patterns were obtained using a Rigaku diffractometer (D/MAX-2200), which was operated under the conditions of 36 kV and 30 mA using Ni-filtered CuK$_\alpha$ radiation ($\lambda = 0.15406$ nm) at a rate of 5° min$^{-1}$ from 20 = 5°–80°. X-ray photoelectron spectroscopy (XPS) was carried out using an ESCALAB 250 spectrometer, in which the X-ray source was operated with an Al-K$_\alpha$ radiation source with a photoenergy of $h\nu = 1361$ eV. The core-level binding energy of the C 1s peak (284.8 eV) was used for calibration. Fourier transform infrared (FTIR) spectroscopy spectra were obtained using the
KBR pellet technique via a Thermo spectrometer in the wavenumber range between 4000 and 300 cm\(^{-1}\).

3. Results and discussion

3.1 Characterization of the samples

3.1.1 \( \text{N}_2 \)-BET analysis. The structural parameters of the H\(\beta \) zeolite, Cu/H\(\beta \), and Cu/H\(\beta \)-AsH\(_3\) (Cu/H\(\beta \)) after the adsorption of AsH\(_3\) and the same expression corresponding to the corresponding meaning) were obtained from the nitrogen adsorption/desorption experiments, and the results are shown in Fig. 1. The pore size distribution curves are plotted in Fig. 2. The BET surface area, micro- and total-pore volume, and average pore radius of the samples are summarized in Table 1.

According to the IUPAC classification, the nitrogen adsorption–desorption isotherms of all the samples studied belong to the IUPAC type IV classification, suggesting that the adsorbents are mesoporous materials, and the capillary condensation phenomenon may occur in their pore channels.

As illustrated in Fig. 1, the \( \text{N}_2 \) adsorption capacity of the plain H\(\beta \) zeolite seems to be greater than that of the Cu/H\(\beta \) and Cu/H\(\beta \)-AsH\(_3\) samples; this is probably because the pores of Cu/H\(\beta \) and Cu/H\(\beta \)-AsH\(_3\) are partially covered by the active ingredient, and the surface area reduces. Furthermore, the hysteresis loop shifts in the relative pressure range of 0.4–1.0, which is a typical characteristic of mesoporous structures. It is considered that the position of the inflection point of \( P/P_0 \) relates to a diameter in the mesoporous range, and the sharpness of the step shows the uniformity of the mesoporous size distribution.

The pore size distribution curves in Fig. 2 show that all the samples have pores in the radius range of 1.5–4.5 nm; this further confirms that all the samples are mesoporous. It can also be observed that the volume of the mesopores decreases in the order of H\(\beta \) zeolite > Cu/H\(\beta \) > Cu/H\(\beta \)-AsH\(_3\). This is because the pores are blocked by the active ingredients during the impregnation process and the products after the reaction; this ultimately leads to a decrease in the pore volume.

Detailed information on the textural properties of these samples is provided in Table 1. As illustrated in Table 1, when compared with H\(\beta \) zeolite, the Cu/H\(\beta \) and Cu/H\(\beta \)-AsH\(_3\) samples show that the impregnation process causes a decrease in the volume of pore radius in the range of 1.5–4.5 nm. The surface areas of the Cu/H\(\beta \) and Cu/H\(\beta \)-AsH\(_3\) samples were found to be 10.8% and 36.8% lower, and the volumes of the samples seemed to decrease by 12.8% and 39.3%, respectively.

As is well known, the presence of a large pore size is considered as fundamental for zeolite materials used in the field of adsorbents. These pore structures can provide more adsorption sites. Moreover, the AsH\(_3\) molecules can easily pass through the pore structures and enter the interior of the H\(\beta \) zeolite; this is beneficial to improve the amount of AsH\(_3\) adsorption on the H\(\beta \) zeolite.

3.1.2 XRD analysis. The phase and crystalline orientation of the H\(\beta \) zeolite and Cu/H\(\beta \) samples with different impregnation concentrations calcined at 400 °C were determined by XRD, as shown in Fig. 3. It can be seen that comparatively weak changes are detected at a lower impregnation concentration (<0.2 mol L\(^{-1}\)). This was probably because the concentration of Cu(NO\(_3\))\(_2\) was very low on the surface of the H\(\beta \) zeolite, and the Cu species on the H\(\beta \) adsorbent were highly dispersed on the surface of the samples. In addition, H\(\beta \) zeolite is non-crystalline and its background peak is obvious, whereas the amount of

| Cu/H\(\beta\)-AsH\(_3\) | 263.4                                   | 0.0730                                   | 0.1271                                   | 2.4291                        |
metal oxide is far less than that of zeolite. However, the peaks tend to become more intense upon increasing the impregnation concentration (0.2–0.4 mol L⁻¹). As shown in Fig. 3, peaks with strong intensity appear at 2θ = 35.4, 38.7, and 61.5°. These diffraction peaks matched with CuO, which was used as the active component and existed in the Hβ zeolite, and the amount of CuO increased upon increasing the Cu(NO₃)₂ impregnation concentration from 0.2 to 0.4 mol L⁻¹. Cu(NO₃)₂, Cu(OH)₂, and CuCO₃ can be transformed into CuO under the calcination conditions, and CuO can enhance the adsorption activity. Although the content of CuO is highest at 0.4 mol L⁻¹, the active sites will be occluded by overfull metal oxides, which decrease the adsorption activity. Simultaneously, it can be seen from the Fig. 3 that the characteristic diffraction peaks of the Hβ zeolite with strong intensity appear at 2θ = 7.7, 22.5, 25.4, 27.1, 28.7, 29.7, and 43.5°, indicating that the crystal form of the modified Hβ zeolite remains intact. The calcination process also appears to have no effect on the sample pore structure; this indicates that the Hβ zeolite has good thermal stability.

3.1.3 X-ray photoelectron spectroscopic analysis. To ascertain whether the adsorption mechanism was associated with Cu²⁺ and As³⁻, XPS analysis was employed to examine the composition of the elements Cu and As in the fresh and exhausted adsorbents to determine the valence states of Cu and As on the adsorbent surface. As shown in Fig. 4, a new peak (As 2p) was seen on the Cu/Hβ–AsH₃ adsorbents, suggesting that AsH₃ was adsorbed on the adsorbents. In addition, in the case of after AsH₃ adsorption, the XPS survey spectra exhibited prominent peaks, which included Cu 2p, O 1s, and C 1s, which obviously diminished. These phenomena may result from the involvement of these elements in AsH₃ adsorption, thus leading to a change in the intensity of these elemental peaks.

Fig. 5 shows the XPS spectra of the core-level binding energies in Cu 2p (b) before and after the adsorption of AsH₃ as well as As 2p (a) after the adsorption of AsH₃. The XPS data of the Cu 2p and As 2p spectra and their possible statuses before and after AsH₃ adsorption are listed in Table 2. As noted in Fig. 5 and Table 2, the main Cu 2p x̅ peak centers are located at 935.5 eV in the presence of a small satellite peak centers located at 943.9 eV and assigned to CuO,²⁷ which is consistent with the XRD results shown in Fig. 3. In addition, the XPS analysis of As 2p for Cu/Hβ–AsH₃ was also conducted to clarify the reaction products. Fig. 5 illustrates that the As 2p peak is centered at 1328.2 eV, indicating the possible presence of As₂O₅.²⁸ The As species appearing in Cu/Hβ–AsH₃ are likely to be formed via an oxidation process. Freshly prepared Cu/Hβ adsorbent shows no signs of As species, whereas after adsorption, it clearly contains As species.

On the basis of the abovementioned XPS results, it was confirmed that Cu(NO₃)₂ played a very important role in the AsH₃ adsorption process, in which AsH₃ seemed to be fixed on the surface of the zeolite. There is no doubt that a higher quantity of As₂O₅ has been formed on the Cu/Hβ sample when compared with the case of the plain Hβ zeolite. These results suggest that Cu/Hβ may participate in the catalytic oxidation reaction during the process when zeolite adsorbs AsH₃.

3.1.4 Infrared spectroscopy analysis. To further understand the changes in the functional groups and chemical bonds of the samples before and after the adsorption of AsH₃, FTIR spectroscopy has been carried out. The FTIR spectra of the samples are presented in Fig. 6. It was notable that the peaks at 3438.45, 1632.44, 1382.23, 1228.71, 1095.78, 789.33, 620.58, 568.13, and 464.25 cm⁻¹ appeared in the spectra of both the Cu/Hβ and Cu/Hβ–AsH₃ samples; this suggested that they possessed similar functional groups or chemical bonds on their surface.

In Fig. 6, we can see a broad strong adsorption band at 3438 cm⁻¹, which can be attributed to the r(O–H) stretching vibrations of water or phenolic hydroxyl groups associated with hydrogen bonds and carboxylic groups.²⁹–³¹ The broad band centered at 1632 cm⁻¹ can be assigned to the δOH bending vibration of H₂O molecules in the interlayer spaces.³² The band
at around 1382 cm\(^{-1}\) was the IR characteristic peak of NO\(_3\)^–, which originated from (Cu(NO\(_3\))\(_2\)) used in the adsorbent preparation process. It may be inferred that a small amount of nitrate may not decompose during the calcination step performed at 400 °C for 6 h. Another broad peak in the 700–1200 cm\(^{-1}\) region with a maximum at about 1095.78 cm\(^{-1}\) and a weak shoulder peak appearing at about 1228.71 cm\(^{-1}\) can be assigned to C–O vibrations of alcohol groups. The band at 620 cm\(^{-1}\) was assigned to coupled Al–O and Si–O out-of-plane vibrations. The spectra of the samples have absorption bands characteristic of amorphous silica (790 cm\(^{-1}\)), which confirm that the zeolite structure is not decomposed. The bands appearing below 600 cm\(^{-1}\) can be assigned to the M–OH and M–O lattice vibration modes, and the peaks observed at 464.25 cm\(^{-1}\) and 568.13 cm\(^{-1}\) are due to \(\delta\)(CuO) vibrations. The abovementioned results are consistent with the conclusions obtained from the XRD patterns; the characteristic feature of the zeolite has not been destroyed and CuO is formed at a calcination temperature of 400 °C. The IR spectra of the adsorbents (Cu/Hβ-400 °C, Cu/Hβ-400 °C–AsH\(_3\)) are similar; however, in the case after AsH\(_3\) adsorption, the vibrations at 3438.45, 1632.44, and 1228.71 cm\(^{-1}\) (corresponding to O–H, \(\delta\)OH, and C–O, respectively) have been obviously diminished. This may be a result of the involvement of these functional groups and chemical bonds in the AsH\(_3\) adsorption process, thus leading to a change in the intensity of these functional groups.

### 3.2 Performance of the adsorbents

#### 3.2.1 The effects of modifiers on AsH\(_3\) adsorption

Hβ zeolites modified with six metal precursors via impregnation were used to investigate the adsorption performance towards AsH\(_3\). Their adsorption capacities were determined and

| Table 2 The XPS results of the Cu 2p and As 2p spectra, and their possible statuses before and after AsH\(_3\) adsorption |
|---|---|---|---|
| Element status | Cu/Hβ | Cu/Hβ–AsH\(_3\) | As\(_2\)O\(_3\) |
| Cu 2p\(_{3/2}\), 935.31 | Cu 2p\(_{3/2}\) sat, 943.64 | Cu 2p\(_{3/2}\) sat, 944.28 | As 2p\(_{3/2}\), 1328.15 |
| fwhm (eV) | 4.198 | 4.628 | 4.932 | 3.174 |
| Doublet separation (eV) | 8.33 | 8.54 | 8.54 | 100 |
| Calculated As percentage (%) | — | — | — | — |
compared in dynamic removal capacity tests with AsH₃. The breakthrough curves for AsH₃ on the abovementioned adsorbents are displayed in Fig. 7. It can be seen that AsH₃ has been removal effectively after the adsorption treatment, whereas their breakthrough curves have significant differences in their adsorption performance as AsH₃ adsorbents. The breakthrough times of the adsorbents increased in the following sequence: Hβ zeolite < Mn/Hβ < Ni/Hβ < Fe/Hβ < Pb/Hβ < Cu/Hβ. The Cu/Hβ sample showed a significant improvement towards AsH₃ adsorption with a breakthrough time of 390 min and a breakthrough capacity of 37.1 mg g⁻¹. The impregnation of Cu(NO₃)₂ leads to an increase in both the breakthrough time and the amount of AsH₃ adsorbed by the Hβ zeolite. It can be deduced that the excellent adsorption performance of the Cu/Hβ adsorbent may be attributed to the active groups formed upon the introduction of Cu(NO₃)₂, which will add to the physical adsorption sites and lead to a strong chemical adsorption process.

3.2.2 The effects of the Cu²⁺ impregnation concentration on AsH₃ adsorption. The impregnation concentration of active components in the process of preparing the adsorbent is one of the most principal factors that affect the removal efficiency in the AsH₃ adsorption process. Different concentrations of Cu(NO₃)₂ solutions ranging from 0.05 to 0.4 mol L⁻¹ were used to obtain Cu/Hβ adsorbents with various metal loading amounts. Fig. 8 shows how the Cu²⁺ impregnation concentration affects the AsH₃ breakthrough at different impregnation concentrations of 0.05, 0.1, 0.2, and 0.4 mol L⁻¹. It was found in Fig. 8 that the adsorption efficiency of the modified Hβ zeolite was influenced by the concentration of Cu(NO₃)₂ in the following sequence: 0.2 mol L⁻¹ > 0.1 mol L⁻¹ > 0.4 mol L⁻¹ > 0.05 mol L⁻¹ > Hβ zeolite. The corresponding breakthrough capacities were 37.1 mg g⁻¹, 33.3 mg g⁻¹, 27.6 mg g⁻¹, and 22.8 mg g⁻¹, which changed with the impregnation concentration. It can be deduced that a lower concentration of Cu²⁺ cannot provide a sufficient number of active groups, and a higher concentration may cause the blockage of the micropores in the adsorbent and a decrease in the specific surface area. Therefore, 0.2 mol L⁻¹ was selected as the optimal impregnation concentration for the Cu/Hβ adsorbent preparation process.

To evaluate the performance of the adsorbents, the actual Cu metal loadings of adsorbents were measured using inductively coupled plasma (ICP) analysis. As the impregnation concentration of Cu(NO₃)₂ was increased from 0.05 to 0.4 mol L⁻¹, the copper element loading amount increased linearly. The sample of copper-exchanged zeolite with better efficiency was impregnated with 0.2 mol L⁻¹ Cu²⁺ and had a Cu loading amount of 10.87 wt%.

3.2.3 The effects of the calcination temperature on AsH₃ adsorption. The calcination temperature used in the adsorbent preparation process is one of the key factors that can influence the AsH₃ removal efficiency and adsorption capacity. It has a great effect on the activation, grain distribution, crystal formation, pore volume, porosity, pore size distribution, and stability of the modified Hβ zeolite. The calcination temperature can influence the decomposition of the metal salts and relates to the redistribution and aggregation of products on the zeolite surface. Fig. 9 shows the AsH₃ adsorption breakthrough curves of the Cu/Hβ samples calcined at 200, 300, 400, and 500 °C when the impregnation concentration of Cu(NO₃)₂ is 0.2 mol L⁻¹. As observed from Fig. 9, a too low or too high calcination temperature is disadvantageous for AsH₃ adsorption. The adsorption efficiency at different calcination temperatures increased in the following order: Cu/Hβ-200 °C < Cu/Hβ-300 °C < Cu/Hβ-500 °C < Cu/Hβ-400 °C. Low temperature does not result in enough Cu(NO₃)₂ decomposition to form a sufficient amount of CuO and further effects the dispersion of CuO on the surface of the zeolite support. In contrast, a high temperature can decompose the active substances and destroy the pore structure, which will finally affect the adsorptive
properties of the modified zeolite. Based on the above-mentioned analysis, 400 °C was found to be the optimal calcination temperature for AsH₃ adsorption.

3.2.4 The effects of the reaction temperature on AsH₃ adsorption. The reaction temperature was also closely investigated in this study. The low temperature of the system cannot provide sufficient heat to activate the gas molecules; thus, the gas and the active substances cannot be directly involved in the chemical reaction on the zeolite. All kinds of gases can be adsorbed via physical adsorption on any adsorbent. However, physical adsorption, which is produced only by weak van der Waals forces between the gas phase and solid phase, is usually reversible and without selectivity. The AsH₃ breakthroughs observed on the Cu/Hβ bed at 20, 40, 60, and 80 °C are illustrated in Fig. 10. Notably, it is found that the reaction temperature is one of the most critical factors that can affect the removal efficiency of AsH₃. As shown in Fig. 10, the AsH₃ removal efficiency was significantly enhanced upon increasing the reaction temperature. However, when the temperature reaches a certain point (60 °C), the effect of a further increase in the reaction temperature on the AsH₃ adsorption efficiency is no longer observed. Physical adsorption, chemical adsorption, and catalytic oxidation are expected to play a role during the removal process of AsH₃ on Cu/Hβ. Temperature has an influence on all the abovementioned mechanisms; a higher temperature promotes catalytic oxidation and chemical adsorption but definitively inhibits physical adsorption. From the experiments, it can be concluded that the optimal reaction temperature for Cu/Hβ is 60 °C, at which the AsH₃ adsorption capacity reaches 43.7 mg of AsH₃/[g of Cu/Hβ].

3.2.5 The effects of the oxygen content on AsH₃ adsorption. The effect of oxygen content on the AsH₃ breakthrough for Cu/Hβ at 60 °C is presented in Fig. 11, and the AsH₃ adsorption experiments have been conducted at an oxygen content maintained at 0%, 0.5%, 1.0%, 1.5%, and 2.0%. The oxygen content is another important factor that influences the adsorption efficiency of AsH₃, and a supplement of trace oxygen can help reach a better removal efficiency. The increase in oxygen content can combine lattice oxygen with AsH₃ on the adsorbent surface, improve the mixture’s total air speed, and avoid the influence of external diffusion. This makes the AsH₃ molecules overcome the resistance of diffusion and enter the pore channels of the modified zeolite. Thus, the AsH₃ molecules can fully contact the active substances in the pores, react with each other, and improve the adsorption efficiency. As illustrated in Fig. 11, the adsorption efficiency is significantly improved upon increasing the oxygen content, but no apparent efficiency increase is observed when the oxygen content is higher than 1.0%.

Fig. 9 The AsH₃ breakthrough curves obtained for the samples prepared at different calcination temperatures at 60 °C with 1.0% O₂ (AsH₃ inlet concentration = 200 mg m⁻³ and impregnation concentration = 0.2 mol L⁻¹).

Fig. 10 The AsH₃ breakthrough curves obtained for a Cu/Hβ fixed bed as a function of the reaction temperature in the presence of 1.0% O₂ (AsH₃ inlet concentration = 200 mg m⁻³, impregnation concentration = 0.2 mol L⁻¹ and calcination temperature = 400 °C).

Fig. 11 The AsH₃ breakthrough curves obtained for a Cu/Hβ fixed bed at 60 °C as a function of the oxygen content (AsH₃ inlet concentration = 200 mg m⁻³, impregnation concentration = 0.2 mol L⁻¹ and calcination temperature = 400 °C).
3.3 Thermal regeneration

Heating the adsorbents and then blowing with a nitrogen flow were performed in the spent adsorbent regeneration experiments. The Cu/Hβ–AsH₃ sample was first reactivated for 4 h under hot air and washed with distilled water to a constant pH after cooling down to room temperature. The second step was to dry the sample at 110 °C for 5 h. Finally, the dried sample was heated at 300 °C for 3 h under N₂ at a flow rate of 30 mL min⁻¹ in the tube furnace and then cooled down to room temperature. Fig. 12 shows the AsH₃ breakthrough behavior of Cu/Hβ, which has been used in the AsH₃ breakthrough test with subsequent thermal regeneration (the sample is referred to as Cu/Hβ-R1, Cu/Hβ-R2, and Cu/Hβ-R3). The generation efficiency of adsorbents and the regeneration time were the two key parameters used to investigate the adsorbent regeneration performance. When compared with that of fresh Cu/Hβ, the adsorption behaviors of the spent adsorbents (Cu/Hβ-R1) were similar and the breakthrough time remained as long as 430 min. However, Cu/Hβ-R2 and Cu/Hβ-R3 displayed a shorter breakthrough time than Cu/Hβ-R1. Despite the adsorption reaction being carried on for 290 min, the adsorption efficiency of Cu/Hβ-R3 for AsH₃ still remained above 95%. This result indicated that the regeneration thermal desorption was effective, and the Cu/Hβ zeolite adsorbent could be recycled at least two times with a slight loss in capacity.

3.4 Identification of the AsH₃ adsorption mechanism

Considering all the characterization results, the Hβ zeolite is a highly efficient adsorption material. The addition of copper to the zeolite and the formation of a CuO active phase upon calcination at high temperatures allowed the removal of AsH₃ in an efficient manner.

Based on the XRD, XPS, and infrared spectroscopy analysis results, a reaction model for AsH₃ adsorption over the copper-exchanged zeolite adsorbent was proposed. The reaction involves (1) the reaction of adsorbed AsH₃ and CuO, and the generation of Cu⁺, As, and oxygen vacancies; (2) O₂ activation on the oxygen vacancies and formation of surface activated oxygen or lattice oxygen; (3) the reaction of As and surface activated oxygen or lattice oxygen and the formation of As₂O₅; and (4) the newly generated Cu⁺ and oxygen vacancies involved in the successive cycles.

Considering the abovementioned discussion, the AsH₃ adsorption process can be divided into the following steps:

\[
\text{AsH}_3 + \text{CuO} \rightarrow \text{As} + \text{Cu}_2\text{O} + \text{H}_2\text{O} \tag{1}
\]

\[
\text{As} + \text{O}_2 \rightarrow \text{As}_2\text{O}_3 \tag{2}
\]

\[
\text{Cu}_2\text{O} + \text{O}_2 \rightarrow \text{CuO} \tag{3}
\]

A possible total chemical reaction formula on the zeolite surface was proposed as follows:

\[
2\text{AsH}_3 + 4\text{O}_2 \rightarrow \text{As}_2\text{O}_3 + 3\text{H}_2\text{O} \tag{4}
\]

4. Conclusions

The Hβ zeolite loaded with metal salts has been prepared using an impregnation method and tested for AsH₃ removal. When compared with other adsorbents, the Cu/Hβ sample exhibited a significant improvement for AsH₃ adsorption with a breakthrough time of 390 min. In this study, we found that the best breakthrough capacity was 43.7 mg As₂O₃/g Cu/Hβ adsorbent at 60 °C with 1.0% oxygen content on Cu/Hβ, which was prepared via calcination at 400 °C using an impregnation concentration of Cu(NO₃)₂ of 0.2 mol L⁻¹.

The Cu(NO₃)₂ impregnation likely results in the formation of surface functional groups, which significantly contribute to the pronounced increase in the AsH₃ adsorption capacity. The XRD and BET results revealed that a crystalline phase of CuO was formed on the zeolite surface and affected the specific surface area and pore structure. In addition, the XPS results showed that the products of AsH₃ adsorption were As₂O₅ species, which were accumulated on the zeolite surface and had a negative effect on the adsorption activity. It is feasible that the spent Cu/Hβ can be regenerated via thermal desorption, and the adsorbents can be recycled at least two times with a small amount of capacity loss.
