Abstract
Coronavirus disease 2019 (COVID-19) is a new type of respiratory infection that first emerged in December 2019 in Wuhan, Hubei, China. COVID-19 is caused by a new type of virus called severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). This study aims to determine the association of SNP CRP rs1800947 gene in suspected COVID-19 patients to length of stay at Al Ihsan Hospital, and Banten Hospital in June-November 2020. This study used data from 60 patients, all patients were suspect COVID-19. The subject was 29 COVID-19 people were confirmed, whereas 31 people were not. A statistics analysis due to pearson correlation and linear multi regression. This study found a significant association between the subject. The results of this study were the relationship between SNP rs1800947 and outcome, a fairly strong association level relationship was found in the SNP rs1800947 (p-value= 0.045, association= 0.537). The association between length of stay and CRP levels has a low level of association (p-value=0.015, association=0.378). The SNP genotype rs1800947 G had a longer treatment duration of 0.14778 days compared to the SNPrs1800947 C genotype. CRP levels showed that higher CRP levels increased the length of treatment compared to normal CRP levels. Where high CRP levels are at risk of 0.6330 days longer than normal CRP while very high CRP is at risk of 2.9561 days longer than Normal CRP levels. In general, the gene SNP rs1800947 and CRP levels, together affect the outcome of patients with suspected COVID-19.

Keywords
COVID-19, CRP levels, SNP rs180094, length of stay

Introduction
COVID-19 is a disease caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). COVID-19 can cause respiratory system disorders, ranging from mild symptoms, such as flu-like symptoms, to lung infections, such as pneumonia. COVID-19 was declared a Public Health Emergency of International Concern (PHEIC) by the World Health Organization (WHO) on January 30, 2020, and its status was later renewed to pandemic. There were 120,417,285 cases reported until March 15, 2021, with 1,419,455 cases reported in Indonesia, resulting in 38,426 deaths.

Some factors have been known to result in worse outcome in inflammatory diseases, including C-reactive protein (CRP). C-reactive protein (CRP) is an acute-phase protein, an early marker of inflammation or infection produced mainly in hepatocytes. CRP plays a role in inflammatory processes and the host immunological response to infection through complement pathways, apoptosis, phagocytosis, nitric oxide (NO) release, and production of cytokines. CRP level has drawn interest in recent research as diagnostic tools and progression model of infections in lower respiratory tract, pneumonia, and severity of COVID-19.

Single nucleotide polymorphisms (SNP) in the CRP gene show an association with CRP variability. The National Center for Biotechnology Information (NCBI) SNP Database (http://www.ncbi.nlm.nih.gov/SNP) contains more than 30 SNPs of the human CRP gene (as of July 2021). The most researched CRP gene variant is rs1800947, which features a guanine to cytosine substitution at position 1059. Variations in this region have been known to be related with alteration of serum CRP, and it is known to be a prognosis of the risk of some chronic diseases.

Until now, the relationship between the CRP level and SNP variability in COVID-19 patients has not been clearly highlighted. Despite this, the relationship between these factors and prognosis of the disease is urgently needed to immediately give the best intervention for patients admitted to hospital to decelerate progression of the disease. Moreover, these factors will also be useful to predict the outcome of suspected COVID-19 and confirmed positive cases. This study is aimed to scientifically evaluate the CRP level and SNP rs1800947 variability towards prognosis of disease in COVID-19 patients in comparison with confirmed negative cases with similar symptoms admitted to the hospital.

Methods
Patients
Patients admitted to Al-Ihsan Central Hospital, and Banten Central Hospital, Banten, West Java, Indonesia during July to November 2020 with following symptoms of respiratory tract infection: 1) high fever (≥38°C); 2) respiratory symptoms such as cough, runny nose, cold, shortness of breath, sore throat, or confirmed positive for pneumonia. There is no other cause based on a conclusive clinical picture. Further, patients also had to have: 1) history of traveling or staying in areas with reported transmission of COVID-19; or 2) contact with suspect and confirmed positive person. Patients were directly swabbed in nasopharynx at day of admission and samples were directly send to COVID-19 diagnostic laboratory for PCR test.

The study was conducted according to the guidelines of the Declaration of Helsinki, and approved by the Institutional Review Board (IRB) of our Institute (ethical approval code: 275/IJN6.KEP/ECEC/2020).

CRP levels
CRP levels were measured using enzyme-linked immunosorbent assay (ELISA) with samples from blood drawn during admission. CRP ELISA kit (Epithod® 616 CRP Test Kit) was used for this purpose. CRP was classified into three categories based on Landry et al.. Normal: CRP level of 3–10 mg/L; high: CRP level of 10–100 mg/L; and very high: CRP level >100 mg/L.

SNP rs1800947 variations
Blood samples were extracted using a magnetic bead-based method with a commercially available kit (MagMAX™ Viral/Pathogen Nucleic Acid Isolation Kit, A42352). SNP rs1800947 were detected using polymerase chain reaction (PCR) method using PCR kit (MyTaq™ HS Red Mix, BIO-25048) according to manufacturer’s protocol with following primers, forward: 5’-GATCTGTGTAGTCTGAGAAACCTCT 3’; reverse: 5’-GAGGATCCAGACACGAGACAGTG 3’. Later, the DNA was sequenced using Sanger sequencing for detection of SNP variations.

Statistical analysis
A statistical analysis by Pearson correlation and linear multi-regression was performed. Regression analysis is an analysis used to describe the relationship between an independent variable on dependent variable that can be declared as a form of mathematical model.
Linear regression equation models in general:

\[ Y = \beta_0 + \beta_1 X_1 + \ldots + \beta_i X_i \]

In the category variable with a nominal/ordinal measurement scale to facilitate the analysis process requires conversion to numerical forms using dummy variables that take binary numbers 1 and 0.

Suppose for the X2 variable CRP content with two normal, and high categories, two dummy variables are formed: \( X_{2(1)} = 1 \) for high levels, 0 for others.

**Results**

This study used data from 60 patients, all patients were suspect COVID-19. Patients were divided into two groups: 29 positive patients (COVID-19 (+)) and 31 unconfirmed patients (COVID-19 (−)). The mean age was 48 years in both groups. Male patients were more prevalent in COVID-19 (+) compared with the COVID-19 (−) group. The COVID-19 (+) group was found to have twice as many patients with comorbidities as the non-COVID group, however the results were not significant due to the small sample size. More patients with low nutritional status were found in the non-COVID group. The distribution of patients for each CRP level was balanced for each group. Genotype variation (G>C) was found in balance for each group (Table 1).

The results in Table 2 show how large the association between lengths of stay for CRP levels, SNPs rs1800947. From the results of this study, the association between length of stay and CRP levels has a low level of association (p-value = 0.015, association = 0.378). A fairly strong association level relationship was found in SNP rs1800947 (p-value = 0.045, association = 0.537). This means that if the subject has a CG gene mutation, the length of stay will be longer. Results for confounding variables, very low association rates were found in the age group, and comorbid diabetes mellitus. Meanwhile, low association levels were found in gender, comorbid hypertension, and heart disease.

Regression analysis is an analysis used to explain the relationship between an independent variable on the dependent variable which can be expressed as a form of mathematical model. The results obtained from the regression analysis (Table 3) for the SNP genotype rs1800947 G, the length of treatment was 0.14778 days longer than the SNP rs1800947 C genotype, and the CRP levels in general showed that the higher the CRP level, the longer the treatment compared to

**Table 1. Subject demographic.**

| Variable          | Value or number of patients | Risk ratio | p-value  |
|-------------------|-----------------------------|------------|----------|
|                   | COVID-19 (+) (n = 29) | COVID-19 (−) (n = 31) |          |          |
| Age (year±st.dev) | 48±10.3 [47(26–64)] | 48.6±20.4 [47.5 (0–86)] | 0.880    |          |
| Gender            | Male 21 (72.4%) | 15 (48.4%) | 1.50 [0.47–0.99] | 0.060    |
|                   | Female 8 (27.6%) | 16 (51.6%) | REFERENCE |          |
| Comorbidity       | Hypertension 7 (24.1%) | 4 (12.9%) | 1.87 [0.61–5.73] | 0.270    |
|                   | Heart disease 3 (10.3%) | 1 (3.2%) | 0.80 [0.20–3.28] | 0.760    |
|                   | Diabetes mellitus 2 (6.9%) | 1 (3.2%) | 2.14 [0.20–22.34] | 0.530    |
| CRP level         | Normal 17 (41.4%) | 17 (54.8%) | REFERENCE |          |
|                   | High 12 (58.6%) | 14 (45.2%) | 0.92 [0.51–1.64] | 0.770    |
| Genotype          | Rs1800947 | | | |
|                   | C 22 (75.9%) | 25 (80.6%) | REFERENCE | |

*CRP levels: Normal: 3–10 mg/L, high: >10 mg/L.*
normal CRP levels. Where high CRP levels are at risk of 0.6330 days longer than normal CRP while very high CRP is at risk of 2.9561 days longer than normal CRP levels (Table 4).

**Discussion**

Several studies have confirmed that serum CRP levels are an important marker for clinical diagnosis and severity assessment in pneumonia, and one study found that rs1800947 is closely linked to CRP expression. SNP rs1800947
only has two alleles, which shows substitutional mutations from one other nucleotide, at rs1800947 only found alleles G and C in the population. CRP plasma levels were shown to be lower in C-allele carriers than in GG homozygotes in previous studies. The rs1800947 polymorphism's C-allele explained 6.2 per cent of the variation in CRP levels. An interesting point of this study was the number of C-allele carriers was very large, 24.1% for Covid-19 (+) and 19.4% for Covid-19 (–).

The majority of SNPs have no association to illness or functional problems. However, if SNPs are positioned on a gene or regulator area (promoter, enhancer, etc.), they can impact the function of genes involved in the disease mechanism. Another study found that the impact of the CRP gene polymorphism rs1800947 may differ. Because the rs1800947 polymorphism is silent, the mechanism underlying the expressed CRP levels could be the linkage disequilibrium of the rs1800947 polymorphism with other functional variants both within and outside the CRP gene. Alternatively, it's possible that this polymorphism changes the kinetics of CRP translation, resulting in varying CRP levels throughout the body.

Patients with COVID-19, increased CRP correlates with damage in the lungs, so CRP can be an important indicator to predict severity and mortality in patients with COVID-19 who are hospitalized. These results are in line with previous research conducted by Wang et al., showed that in the early stages of COVID-19 disease, CRP levels were positively correlated with pulmonary lesions. CRP levels can describe the severity of the disease and should be used as the main indicator for disease monitoring. Significant increase in CRP levels and erythrocyte sedimentation rate in the early stages of severe COVID-19 patients. CRP has also been associated with disease progression and has shown good performance in predicting severity in the early stages of COVID-19 disease.

CRP is an acute-phase protein produced by the liver in response to increased levels of inflammatory cytokines, especially Inteleukin-6 (IL-6) and tumor necrosis factor α (TNF-α). CRP levels are known to increase in response to tissue damage, infection and inflammation and their concentration will increase in the circulation during inflammatory events. CRP is not only a marker of inflammation but also plays an active role in the inflammatory process. Patients with COVID-19 show higher leukocyte counts and elevated levels of pro-inflammatory cytokines such as IL-6, IL-10, granulocyte colony stimulating factor (G-CSF), monocyte chemoattractant protein 1 (MCP1), macrophage inflammatory protein (MIP)1α, and TNF-α. IL-6 level is also related to the severity of the patient's condition, the more severe the patient's condition, the higher the level of IL-6 and this will stimulate the liver to produce CRP.

Nonetheless, certain substantial limitations of this study should be mentioned, such as its small sample size, but we had enough power to detect significant differences between the differences we identified. Therefore, our results should eventually be confirmed. However, the findings suggest that CRP levels, and the SNP rs180094 also may play a role in disease prognosis. This research can be used as a reference for researchers who will research similar things as well as a reference for COVID-19 examinations in the future.

**Conclusions**

The association between length of stay and CRP levels has a low level of association (p-value = 0.015, association = 0.378). A fairly strong association level relationship was found in the SNP rs1800947 (p-value = 0.045, association = 0.537). The SNP genotype rs1800947 G was 0.2677 days faster than the SNP genotype rs1800947 C in patients with confirmed COVID-19 (+). In general, CRP levels show that the higher the CRP levels, the longer the length of treatment compared to Normal CRP levels. Where high CRP levels are at risk of 1.3928 days longer than normal CRP while very high CRP is at risk of 4.1087 days longer than Normal CRP levels in confirmed COVID-19 (+) patients.
