Abstract

Numerous technological applications of Ni-based Zr and Hf intermetallic alloys promoted comprehensive studies in Zr$_8$Ni$_{21}$ and Hf$_8$Ni$_{21}$ by perturbed angular correlation (PAC) spectroscopy, which were not studied earlier until this report. The different phases produced in the samples have been identified by PAC and X-ray diffraction (XRD) measurements. Using $^{181}$Hf probe, two non-equivalent Zr/Hf sites have been observed in both Zr$_8$Ni$_{21}$ and Hf$_8$Ni$_{21}$ compounds. From present PAC measurements in Zr$_8$Ni$_{21}$, a component due to the production of Zr$_7$Ni$_{10}$ by eutectic reaction from the liquid metals is also observed. The phase Zr$_7$Ni$_{10}$, however, is not found from the XRD measurement. In Zr$_8$Ni$_{21}$, while the results do not change appreciably up to 973 K exhibit drastic changes at 1073 K. In Hf$_8$Ni$_{21}$, similar results for the two non-equivalent sites have been found but site fractions are in reverse order. In this alloy, a different concentrating phase, possibly due to HfNi$_3$, has been found from PAC measurements but is not found from XRD measurement. Density functional theory (DFT) based calculations of electric field gradient (EFG) and asymmetry parameter ($\eta$) at the sites of $^{181}$Ta probe nucleus allowed us to assign the observed EFG fractions to the various lattice sites in (Zr/Hf)Ni$_{34}$Ni$_{21}$ compounds.

1. Introduction

Intermetallic binary alloys between the two elements of A (Hf/Zr/Ti) and B (Fe/Co/Ni) have many technological applications. They have properties like superior strength, corrosion resistance, hydrogen storage capacity, ferromagnetism and have applications in space craft industry, fuel cell etc. The Zr-Ni alloys, particularly, have excellent hydrogen storage properties and have applications in Ni-metal hydride (MH) rechargeable batteries as a negative electrode [1-3]. The gaseous hydrogen storage characteristics of four intermetallic compounds in the Zr-Ni system viz. Zr$_9$Ni$_{11}$, Zr$_7$Ni$_{10}$, Zr$_8$Ni$_{21}$ and Zr$_2$Ni$_7$ were compared by Joubert et al. [1]. It was found that hydrogen storage capacities in hydrogen atoms per metal atom (H/M) for these four compounds are 0.93 (10 bar), 1.01 (10 bar), 0.34 (25 bar) and 0.29 (25 bar), respectively, at room temperature and the storage capacities for Zr$_8$Ni$_{21}$, Zr$_2$Ni$_7$ are completely reversible. The hydrogen reversible capacities for Zr$_9$Ni$_{11}$ and Zr$_7$Ni$_{10}$ are 50% and 77%, respectively. The electrochemical properties of Zr$_9$Ni$_{11}$, Zr$_7$Ni$_{10}$ and Zr$_8$Ni$_{21}$ were studied by Ruiz et al. [2,3] and Nei et al. [4,5]. It was found [3] that Zr$_8$Ni$_{21}$ alloy had a better charge/discharge performance than Zr$_7$Ni$_{10}$ and Zr$_9$Ni$_{11}$. A detailed review on the electrochemical properties of various compounds of Zr-Ni system for application of these materials in Ni-MH battery was reported by Young et al. [4]. The intermetallic compound ZrNi$_5$ was reported to have strong ferromagnetic properties by Drulis et al. [5]. A. Amamou [6] reported the electronic structure of various compounds in the Zr-Ni system, namely, Zr$_9$Ni, ZrNi, Zr$_8$Ni$_{21}$ and ZrNi$_5$. Both magnetic and structural properties of the A$_x$B$_y$ compounds can be studied experimentally by the nuclear technique of perturbed angular correlation (PAC), which uses a suitable radioactive isotope (usually $^{181}$Hf) to characterize the materials. Using this technique, different intermetallic compounds in the Zr-Ni system have recently been studied, namely, ZrNi$_5$ [10], Zr$_8$Ni$_{21}$ [11] and ZrNi [12]. From the studies in ZrNi$_5$ system [9,10], however, no magnetic interaction was found, in contradiction with the result from previous measurements by Drulis et al. [7].

Considering the important applications of Zr$_8$Ni$_{21}$, Zr$_9$Ni$_{11}$ and Zr$_7$Ni$_{10}$ as described above, we have done detailed PAC measurements in Zr$_8$Ni$_{21}$ and Hf$_8$Ni$_{21}$ intermetallic compounds. To the best of our knowledge, there is no measurement by PAC technique to characterize these materials. From previous studies [13], a pure single phase Zr$_8$Ni$_{21}$ was not found to be produced by arc melting preparation. It was found [13] that Zr$_9$Ni$_{21}$ was not formed congruently from the liquid. The
Zr$_2$Ni$_7$ was first solidified from the liquid and then reacted with the remaining liquid to form Zr$_8$Ni$_{13}$ alloy peritectically. The Zr$_2$Ni$_{10}$ was formed eutectically from Zr$_8$Ni$_{21}$. The two other phases viz. Zr$_2$Ni$_7$ and Zr$_7$Ni$_{13}$ were produced along with Zr$_8$Ni$_{21}$ and were confirmed by scanning electron microscopy (SEM)/X-ray energy dispersive spectroscopy (EDS) compositional mapping and transmission electron microscopy (TEM) [13]. However, in the present report, we have studied both Zr$_8$Ni$_{13}$ and Hf$_6$Ni$_{21}$ to identify and characterize the different phases produced in these compounds. The secondary phases of small fractions that are produced along with the main phase can be determined quite accurately by this technique. The structural and compositional stability of Zr$_8$Ni$_{13}$/Hf$_6$Ni$_{21}$ phases have been studied by temperature dependent PAC measurements.

The crystal structure of Zr$_8$Ni$_{13}$ is known to be triclinic [14] and is isotropic to that of Hf$_6$Ni$_{21}$ [13]. The lattice parameters of Zr$_8$Ni$_{13}$ are $a=6.476$ Å, $b=8.064$ Å, $c=8.594$ Å, $\alpha=75.15^\circ$, $\beta=68.07^\circ$ and $\gamma=75.23^\circ$ as determined by X-ray diffraction analysis.

In the PAC technique [16-18], the angular correlation of a $\gamma$-$\gamma$ cascade in a suitable probe nucleus is perturbed by the interaction of the probe nuclear moments with the electric field gradients/magnetic fields generated at the probe site due to surrounding charge distribution. The crystalline electric field gradient (EFG) and the internal magnetic field in a magnetic material can be determined by the PAC technique if the values of electromagnetic moments of the intermediate level of the probe nucleus are known. As the EFG depends on the charge distribution of the probe-nucleus environment, the temperature evolution of the lattice properties such as crystallographic structure, imperfections or defects, can be monitored by applying PAC technique over a wide temperature range. The combination of PAC measurements and ab-initio calculations proved to be an excellent method to study the structural phase stabilities and the localization of the impurities in the host lattice [19,20]. In this paper, results of temperature dependent PAC measurements (77-1073 K) in both Zr$_8$Ni$_{13}$ and Hf$_6$Ni$_{21}$ as well as DFT calculations are reported. The calculated EFG values at the $^{181}$Ta impurity sites are compared with experimental results.

## 2. Experimental details

The intermetallic compounds Zr$_8$Ni$_{13}$ and Hf$_6$Ni$_{21}$ were prepared by arc melting in an argon atmosphere. Stoichiometric amounts of high purity metals procured from M/S Alfa Aesar were used to prepare the samples. The purity of Zr (excluding Hf), Hf (excluding Zr) and Ni metals used were 99.2%, 99.95% and 99.98% respectively. For each sample, the constituent metals were alloyed homogeneously by repeated melting and then activated by remelting with a piece of $^{181}$Hf metal. The $^{181}$Hf metal was prepared by thermal neutron capture of natural $^{180}$Hf metal in the Dhruva reactor, Mumbai using a flux $\sim 10^{13}$ cm$^{-2}$s$^{-1}$. In both cases, shiny globule samples were formed and these were then sealed in evacuated quartz tubes for high temperature measurements. Different inactive samples of Zr$_8$Ni$_{13}$ and Hf$_6$Ni$_{21}$ were prepared similarly for XRD measurements. The X-ray powder diffraction measurements have been carried out using the Rigaku X-ray diffractometer TTRAX-III and Cu K$_\alpha$ radiation.

The TDPAC technique measures the effect of perturbations of $\gamma$-$\gamma$ angular correlation of the probe nucleus through the hyperfine interaction. In the present case, the probe $^{181}$Hf substitutes the Zr atom in Zr$_8$Ni$_{21}$ and is a constituent element in Hf$_6$Ni$_{21}$. In the $\beta^-$ decay of $^{181}$Hf, it populates the 615 keV excited level of $^{181}$Ta which emits two successive $\gamma$ rays, 133 and 482 keV passing through the 482 keV level with a half-life 10.8 ns and a spin angular momentum $I=5/2^+$ [21]. The angular correlation of the 133-482 keV cascade is perturbed by the extranuclear electric field gradients.

The perturbation function $G_2(t)$ for the electric quadrupole interaction in a polycrystalline material is given by [16]

$$G_2(t) = S_{20}(\eta) + \sum_{i=1}^{3} S_{2i}(\eta) \cos(\omega_i t) \exp(-\delta \omega_i t) \exp\left(\frac{-(\omega_i \tau_\gamma)^2}{2}\right)$$

(1)

The frequencies $\omega_i$ correspond to transitions between the sub-levels of the intermediate state that arise due to nuclear quadrupole interaction (NQI). The parameter $\delta$ is the frequency distribution width (Lorentzian damping) which takes care of the chemical inhomogeneities in the sample and $\tau_\gamma$ is the time resolution of the coincidence set up. Due to the presence of various non-equivalent sites, the perturbation factor $G_2(t)$ can generally be expressed as

$$G_2(t) = \sum_i f_i G_2^i(t),$$

(2)

where $f_i$ is the site fraction of the $i$-th component. A fitting to eqn. (1) determines the maximum component $V_{zz}$ of the electric field gradient from the measured quadrupole frequency $\omega_Q$ given by

$$\omega_Q = \frac{eQV_{zz}}{4I(2I-1)\hbar},$$

(3)

where $Q$ is the nuclear quadrupole moment of the 482 keV intermediate state (2.36 b). For an axially symmetric EFG ($\eta = 0$), $\omega_Q$ is related to $\omega_1$, $\omega_2$ and $\omega_3$ by

$$\omega_Q = \omega_1/6 = \omega_2/12 = \omega_3/18.$$  

(4)

The principal EFG components obey the relations

$$V_{xx} + V_{yy} + V_{zz} = 0 \quad \text{and} \quad V_{zz} \geq V_{yy} \geq V_{xx}.$$  

(5)

The EFG can therefore be designated by two parameters only viz. $V_{zz}$ and $\eta$. The asymmetry parameter $\eta$ is defined as

$$\eta = \frac{(V_{xx} - V_{yy})}{V_{zz}}, \quad 0 \leq \eta \leq 1.$$  

(6)

The TDPAC spectrometer used for present measurements was a four detector LaBr$_3$(Ce)-BaF$_2$ set up with crystal sizes $38\times25.4$ mm$^2$ for LaBr$_3$(Ce) and $50.8\times50.8$ mm$^2$ for BaF$_2$. The 133 keV $\gamma$-rays were selected in LaBr$_3$(Ce) detectors. Standard slow-fast coincidence assemblies were employed to collect data at 180° and 90°. Typical prompt time resolution (FWHM) = 800
results from ab-initio calculations by density functional theory. The frequency components at room temperature have been obtained by comparing with our PAC results in HfNi. The TDP AC spectra of ZrNi are produced, it is not observed from the sample is shown in Table 1: Results of PAC measurements in ZrNi121

| Temperature (K) | Component | \( \omega_0 \) (Mrad/s) | \( \eta \) | \( \delta \) (%) | \( \phi \) (%) | Assignment |

* after measurement at 1073 K

ps was obtained for the 181Hf energy window settings. The perturbation function \( G_2(t) \) is found from the four coincidence spectra at 180° and 90°. Details of the experimental set up and data analysis can be found in reference [22].

3. PAC results

3.1 ZrNi121

The XRD powder pattern of ZrNi121 sample is shown in figure 1. The X-ray analysis has been carried out using the known crystallographic data of ZrNi121 [12]. The XRD spectrum shows no other peaks except for ZrNi121 and this sample is, therefore, found to be produced in an almost pure single component phase. If any small contaminating phases like ZrNi10 or ZrNi17 are produced, is not observed from the XRD powder pattern.

The TDPAC spectra of 181Ta in the as prepared sample of ZrNi121 are shown in figure 2. From PAC measurements, three frequency components at room temperature have been obtained (Table I). The components 1 and 3 have been attributed to ZrNi121 by comparing with our PAC results in HfNi21 and results from ab-initio calculations by density functional theory (discussed later). The component 2 has been attributed to ZrNi10. This follows from the previous X-ray EDS and SEM/TEM results reported by Shen et al. [13]. The characteristic frequency and \( \eta \) for this component are distinctly different than those found in ZrNi17 [11]. Moreover, assignment of this component can be supported from our PAC measurements in ZrNi110 [23] where, a component similar to this was found. It is found that three frequency components are required to fit the spectra in the temperature range 77-737 K with no appreciable change in parameters (Table I). Variations of \( \omega_0, \eta, \phi \) and site fraction (f) with temperature for the two components of ZrNi121 are shown in figure 3.

At 473 K, however, the PAC spectrum gives two components. The component ZrNi121 does not exist at this temperature. In the temperature range 473-973 K, no appreciable changes in results are observed (Table II). But at 1073 K, a drastic change in PAC spectrum is found. At this temperature, the predominant component (~68%) produces a sharp decrease in quadrupole frequency and asymmetry parameter shows a value equal to
zero. This possibly indicates a change in local environment of the probe. The component due to Zr$_7$Ni$_{10}$, on the other hand, remains almost unchanged.

To understand the change in PAC spectrum at 1073 K, we have repeated the PAC measurement at room temperature. In the re-measured spectrum at 298 K, the predominant component (~70%) produces values of $\omega_0 \sim 57$ Mrad/s, $\eta \sim 0$. At the remeasured room temperature, it is found that the major component of Zr$_8$Ni$_{21}$ found initially at room temperature reappears with a much smaller fraction (Table 1). One additional new component is observed with a very small fraction which can be assigned to Zr$_2$Ni$_7$ by comparing with the previous result in Zr$_2$Ni$_7$ [11]. From SEM/X-ray EDS measurement [13] also, Zr$_2$Ni$_7$ was found in a sample of Zr$_8$Ni$_{21}$ annealed at 1233 K.

We have performed XRD measurement in a sample of Zr$_8$Ni$_{21}$ annealed at 1073 K for two days. The XRD spectrum (Fig. 1) shows peaks mainly due to Zr$_8$Ni$_{21}$. This indicates that no major structural or compositional phase transformation occurs at 1073 K.

Possible explanation for the predominant component observed at 1073 K and subsequently at room temperature is the following. Probably, the probe $^{181}$Hf was not settled well at the position of Zr$_8$Ni$_{21}$ and at 1073 K, these probe atoms got enough energy to go out from the position. The major component is, therefore, observed due to the Hf probe itself.

The electric field gradients in metal and intermetallic compound are found to vary with temperature following $T$ or $T^{3/2}$ relationship [24]. In Zr$_8$Ni$_{21}$, it is found that quadrupole frequencies vary with $T^{3/2}$ for both components. For the predominant site Zr$_8$Ni$_{21}$(1) (present up to 973 K), the results are fitted by

$$\omega_0(T) = \omega_0(0)[1 - \beta T^{3/2}].$$

A least squares fitting gives results $\omega_0(0)=78.2(1)$ Mrad/s and $\beta=5.9(1)\times10^{-6}$ K$^{-3/2}$.

3.2 Hf$_8$Ni$_{21}$

The powder XRD pattern of Hf$_8$Ni$_{21}$ is shown in figure 4. The spectrum is fitted using the known crystallographic data of Hf$_8$Ni$_{21}$ [15]. The X-ray analysis shows that there are no other peaks except for HfNi$_{21}$ and this sample is also found to be produced in an almost pure single component phase. No contaminating phase is obtained from the XRD powder pattern.

The TDPAC spectra of $^{181}$Ta in Hf$_8$Ni$_{21}$ are shown in figure 5. The spectrum at room temperature produces four interaction frequencies. The first two components at room temperature with site fractions 63% and 21% (Table 2) are found to be quite similar to the components found in Zr$_8$Ni$_{21}$. The third weak component can possibly be attributed to HfNi$_3$ produced along with Hf$_8$Ni$_{21}$. L. Bsenko [29] reported the decomposition of Hf$_8$Ni$_{21}$ to HfNi$_3$ eutectoidally at 1175±10°C. This component has been found in the whole temperature range. The assignment of HfNi$_3$ in Hf$_8$Ni$_{21}$ can be supported also from our PAC measurements in HfNi$_3$ [26] where a similar component to this was found. A very weak component (~5%) found at room temperature can be attributed to Hf probe which is not settled in the compound. From our temperature dependent PAC measurements, it is found that all four components exist in the temperature range 77-673 K. The component 4 is not observed at 773 K and the minor site of Hf$_8$Ni$_{21}$ (Hf$_8$Ni$_{21}$(1)) disappears at 873 K. A drastic change in PAC spectrum is observed at 1073 K where the tentatively assigned HfNi$_3$ component suddenly increases at the expense of Hf$_8$Ni$_{21}$ (Table 2). The component due to Hf$_8$Ni$_{21}$ reduces to only 15%. At this temperature, a new frequency component (component 3) is observed which probably can be attributed to Hf$_2$Ni$_7$ by comparing its values with the results reported in the analogous compound Zr$_2$Ni$_7$ [11].

After measurement at 1073 K, a re-measurement at 298 K is carried out. In the re-measurement, HfNi$_3$ is found to be predominant (~62%) which appeared as a minor fraction (~10%) initially at room temperature. Here, no component due to Hf$_8$Ni$_{21}$ is observed. A small component fraction of Hf$_8$Ni$_{21}$ found at 1073 K and absence of this fraction at re-measured room temperature indicates that Hf$_8$Ni$_{21}$ is not a stable phase approximately above 1000 K. It is found also that, the component due to Hf probe atom re-appears at this temperature with a higher component fraction (~25%). The quadrupole frequency and asymmetry parameter for this component ($\omega_0=50.8$
Figure 2: TDPAC spectra in Zr$_8$Ni$_{21}$ at different temperatures. Left panel shows the time spectra and the right panel shows the corresponding Fourier transforms. The PAC spectrum designated by 298° K is taken after the measurement at 1073 K. The two sets of arrows in each Fourier spectrum (up to 373 K) correspond to two non-equivalent $^{181}$Ta sites in Zr$_8$Ni$_{21}$. Arrows shown in the Fourier spectra at 1073 and 298° K correspond to Hf.
Figure 3: Variations of quadrupole frequency ($\omega_Q$), asymmetry parameter ($\eta$) and site fraction ($f$) with temperature for the two non-equivalent $^{181}$Ta sites in Zr$_8$Ni$_{21}$. Variation of $\delta$ is shown for the component Zr$_8$Ni$_{21}$(1).

Figure 5: TDPAC spectra in Hf$_8$Ni$_{21}$ at different temperatures. Left panel shows the time spectra and the right panel shows the corresponding Fourier transforms. The PAC spectrum designated by 298° K is taken after the measurement at 1073 K. The two sets of arrows in each Fourier spectrum (up to 773 K) correspond to two different $^{181}$Ta sites in Hf$_8$Ni$_{21}$. Two sets of arrows in the Fourier spectrum at 298° K correspond to HfNi$_3$ and Hf.
Figure 6: Variations of quadrupole frequency ($\omega_Q$), asymmetry parameter ($\eta$) and site fraction $f(\%)$ with temperature for the two non-equivalent $^{181}$Ta sites in Hf$_8$Ni$_{21}$. Variations of $\delta$ is shown for the site Hf$_8$Ni$_{21}^{(2)}$.

Figure 7: Models of four types of cells used in this study
cycles were performed via a tetrahedron method [30], using the vector used in the plane wave expansion. All atomic sphere radii and WIEN2k simulation package [28], based on the full potential generalized gradient approximation (GGA) parametrized by Perdew-Burke-Ernzerhof (PBE) [29]. In our calculations the muffin-tin radii for Zr, Ni and Ta (Hf) were 2.3, 2.2 and 2.4 a.u., respectively. The cut-off parameter $R_{MT}K_{max}$ for limiting the number of plane waves was set to 7.0, where $R_{MT}$ is the smallest value of all atomic sphere radii and $K_{max}$ is the largest reciprocal lattice vector used in the plane wave expansion.

The Brillouin zone integrations within the self-consistency cycle were performed via a tetrahedron method [30], using 18 $k$ points in the irreducible wedge of the Brillouin zone (4x3x3 mesh). The atomic positions were relaxed according to Hellmann-Feynman forces calculated at the end of each self-consistent cycle, with the force minimization criterion 2 mRy/ a.u. In our calculations the self-consistency was achieved by demanding the convergence of the integrated charge difference between last two iterations to be smaller than $10^{-5}$. Both Zr$_3$Ni$_2$ and Hf$_3$Ni$_2$ crystallize in the triclinic P1 type structure, which possesses 15 non-equivalent crystallographic positions [14, 15], 4 for Zr (Hf) atoms and 11 for Ni atoms. All Zr (Hf) non-equivalent positions have the same point group symmetry $2i$ and 3 Zr and 12 Ni atoms as nearest neighbors, except Zr(3), which has 2 Hf and 13 Ni. Each of the four non-equivalent Zr (Hf) atoms in the unit cell, stated in references [14, 15] was replaced by Ta subsequently (figure 7, [31]) preserving the point group symmetry around original atom and then electric field gradients at thus created Ta positions were calculated using the method developed in reference [32].

The usual convention is to designate the largest component of the EFG tensor as $V_{zz}$. The asymmetry parameter $\eta$ is then given by $\eta = (V_{xx} - V_{yy})/V_{zz}$, where $V_{zz}$ $\geq V_{yy}$ $\geq V_{xx}$. The calculated EFGs in the pure compounds as well as at Ta probe positions in the investigated compounds are given in Table 3.

It can be observed that there is not much difference in the EFG values for four non-equivalent Zr positions in the pure Zr$_3$Ni$_2$ compound. EFG is the smallest at Zr1 and the largest at Zr3. This trend is preserved also for the electric field gradients calculated at the corresponding Ta positions, but the EFGs are now about 2.5 times larger. In the pure Hf$_3$Ni$_2$ compound, EFG values are about doubled, as compared to the corresponding ones for Zr$_3$Ni$_2$, but the $\eta$ values are similar. Here, also, introduction of Ta atom at one of the non-equivalent Hf sites, leads to increased EFG values.

## 5. Discussion

In the temperature range 77-373 K, Zr$_3$Ni$_2$ PAC spectra consist of three frequency components. A uniform conversion from the measured quadrupole frequencies to the EFGs is achieved by demanding the convergence of the integrated charge difference between last two iterations to be smaller than $10^{-5}$. Both Zr$_3$Ni$_2$ and Hf$_3$Ni$_2$ crystallize in the triclinic P1 type structure, which possesses 15 non-equivalent crystallographic positions [14, 15], 4 for Zr (Hf) atoms and 11 for Ni atoms. All Zr (Hf) non-equivalent positions have the same point group symmetry $2i$ and 3 Zr and 12 Ni atoms as nearest neighbors, except Zr(3), which has 2 Hf and 13 Ni. Each of the four non-equivalent Zr (Hf) atoms in the unit cell, stated in references [14, 15] was replaced by Ta subsequently (figure 7, [31]) preserving the point group symmetry around original atom and then electric field gradients at thus created Ta positions were calculated using the method developed in reference [32].
using the value of $2.36\times10^{-24}$ cm$^2$ for the quadrupole moment of $^{181}$Hf. By comparing the measured results for the EFGs and asymmetry parameters with the calculated ones, components 1 and 3 (Table 1) are attributed to the two non-equivalent Zr sites in Zr$_8$Ni$_{21}$. The measured values of EFGs (8.7×10$^{-21}$ V/m$^2$ and 11.3×10$^{-21}$ V/m$^2$) and η (0.80 and 0.73) at 77 K are in excellent agreement with the calculated values for the two Zr sites in Zr$_8$Ni$_{21}$. However, as Ta doped Zr$_8$Ni$_{21}$ has four non-equivalent crystallographic positions with similar EFG and asymmetry parameter (Table 3), in order to explain preferential site occupation, we performed ab initio total energy calculations for Ta doped Zr$_8$Ni$_{21}$ and found that the configuration obtained when Ta replaces Zr(3) position has the lowest formation energy, about 0.013 eV lower than the structure when Ta is at Zr(1) position. The formation energies of the remaining two configurations are about 0.1 eV higher.

At 1073 K, there is a drastic change of PAC spectrum in Zr$_8$Ni$_{21}$. At this temperature, EFG for the predominant component produces a zero value of η. A similar change in $^{181}$Ta PAC spectra with increasing temperature above 650 K was observed in TiPd$_2$ compound and was explained with the shift of Ta atom from Ti to Pd lattice site, but in our case, DFT calculations excluded that possibility, as all of the non-equivalent Ni sites in Zr$_8$Ni$_{21}$ has η which differs from zero. We find a resemblance of EFG and η for the component 1 in Zr$_8$Ni$_{21}$ at re-measured room temperature and component 4 in Hf$_8$Ni$_{21}$ with the calculated values for Ta in pure Hf metal (6.7×10$^{-21}$ V/m$^2$ and η = 0).

The PAC spectrum for Hf$_8$Ni$_{21}$ at room temperature consists of four components. The first two components with the EFG values $11.1\times10^{-21}$ V/m$^2$ and $9.0\times10^{-21}$ V/m$^2$ and the corresponding asymmetry parameters 0.62 and 0.73 (at 77 K) obviously correspond to the two different Hf positions in Hf$_8$Ni$_{21}$ (Table 3). The measured results show that quadrupole frequencies for the two corresponding sites in Zr$_8$Ni$_{21}$ and Hf$_8$Ni$_{21}$ vary in similar manner with temperature.

6. Conclusion
We have presented the time differential perturbed angular correlations measurements and DFT calculations to determine the electric field gradients in Zr$_8$Ni$_{21}$ and Hf$_8$Ni$_{21}$ intermetallic compounds. Our results indicate that during the preparation of Zr$_8$Ni$_{21}$ by arc melting, other phases like Zr$_7$Ni$_{10}$ can also be formed. The same goes for Hf$_8$Ni$_{21}$, in which HfNi$_3$ compound was detected. In both Zr$_8$Ni$_{21}$ and Hf$_8$Ni$_{21}$, EFGs for two non-equivalent sites of Zr/Hf vary following $T^{3/2}$ relationship with temperature. Temperature dependent PAC measurement show that Hf$_8$Ni$_{21}$ is probably not a stable phase above 1000 K.
