ABSTRACT
We consider two-machine routing open shop problem on a tree. In this problem, a transportation network with a tree-like structure is given, and each node contains some jobs to be processed by two mobile machines. Machines are initially located in the predefined node called the depot, have to traverse the network to perform their operations on each job (and each job has to be processed by both machines in arbitrary order), and machines have to return to the depot after performing all the operations. The goal is to construct a feasible schedule for machines to process all the jobs and to return to the depot in shortest time possible. This problem is known to be NP-hard even in the case when the transportation network consists of just two nodes. We propose an instance reduction procedure which allows to transform any instance of the problem to a simplified instance on a chain with limited number of jobs. The reduction considered preserves the standard lower bound on the optimum. We describe four possible outcomes of this procedure and prove that in three of them the initial instance can be solved to the optimum in linear time, thus introducing a wide polynomially solvable subclass of the problem considered. Our research can be used as a foundation to construct efficient approximation algorithms for the two-machine routing open shop on a tree.

1. Introduction
We consider the routing open shop problem, which is a natural combination of a well-known metric travelling salesman problem and a classical scheduling open shop problem. Metric TSP hardly needs an introduction. The open shop problem, introduced by Gonzalez and Sahni [12], can be described as follows. Sets $\mathcal{M} = \{M_1, \ldots, M_m\}$ of machines and $\mathcal{J} = \{J_1, \ldots, J_n\}$ of jobs are given and each machine $M_i$ has to perform an operation on each job $J_j$, this operation $O_{ji}$ requires $p_{ji} \geq 0$ time units to complete. Each machine has to process jobs in some sequence which is not given in advance but has to be chosen by a scheduler. Operations of the same job cannot be processed simultaneously. The goal is to construct a schedule of processing of all jobs, i.e. to specify non-negative starting and
completion times for each operation, such that the conditions above are satisfied and the maximum completion time (also referred to as the makespan) is minimized. Following the standard three-field notation for scheduling problems (see [17] for example), the open shop problem with \( m \) machines is denoted by \( Om\|C_{\text{max}} \). Notation \( O\|C_{\text{max}} \) is used when the number of machines is not bounded by any constant. The \( Om\|C_{\text{max}} \) problem is known ([12]) to be polynomially solvable in the case of two machines and is NP-hard for \( m \geq 3 \). The \( O\|C_{\text{max}} \) problem is strongly NP-hard. Moreover, unless \( P = NP \), no \( \rho \)-approximation algorithm for \( O\|C_{\text{max}} \) exists for any \( \rho < \frac{3}{4} \) [23].

Several algorithms for solving the two-machine problem \( O2\|C_{\text{max}} \) to the optimum were proposed over the last decades, for example, by Gonzalez and Sahni [12], Pinedo and Schrage [19] and de Werra [10]. All the known algorithms run in linear time and produce optimal schedules with different structures. An important property of the schedules produced by each of those algorithms (and therefore of the optimal schedule) is its so-called normality: the makespan of those schedules always coincides with the standard lower bound 
\[
\bar{C} = \max \left\{ \max_i \sum_{j=1}^n p_{ji}, \max_j \sum_{i=1}^m p_{ji} \right\}.
\]

Most of the classical scheduling models (open shop included) share the following disadvantage. It is supposed that each machine is able to start a new operation at the same moment when it completes the previous one. In a real-life environment that is not always possible. Usually jobs represent some material objects, therefore some delays between processing operations of two subsequent jobs may be unavoidable. Such delays can be machine-dependent, job- or sequence-dependent, and taking them into account can make the problem harder to investigate. Still, there is a number of papers considering scheduling problems with transportation delays (see [5,13,18,20], for example). However, the problem we are considering in this paper uses a different approach to model transportation delays.

We consider the routing open shop problem [4] which can be described as the open shop meeting the metric travelling salesman problem (TSP). Let the input of the TSP be given by an edge-weighted graph \( G \). Jobs from \( J \) are distributed between the nodes of \( G \), each node contains at least one job. Machines are mobile and are initially located at the predefined node referred to as the depot. Machines have to travel over the edges of \( G \), weights of the edges represent travel times for each machine. Any number of machines can travel over the same edge at the same time. Each machine has to visit each node of \( G \) (not necessary once), perform all the respective operations (under the feasibility constraints from the open shop problem) and return back to the depot after processing all the jobs. One has to construct a schedule, specifying starting and completion times for each machine's activity, which is either a performing of some operation or travelling over some edge of \( G \). Note that a machine has to arrive at some node to be able to process a job located at that node.

The makespan \( R_{\text{max}} \) of a schedule \( S \) for the routing open shop is the maximum completion time of machine's activity. (Note that \( R_{\text{max}} \geq C_{\text{max}} \) and those two values are different in case the last activity is a travelling of machine to the depot.) The goal is to construct a feasible schedule minimizing the makespan. The routing open shop problem with \( m \) machines is denoted by \( Rom\|R_{\text{max}} \) or \( Rom|G = X|R_{\text{max}} \) if we want to specify the structure \( X \) of the graph \( G \). In the latter case, we use either standard notation from graph theory, such as \( K_p \) for the complete graph with \( p \) nodes, or standard terms such as tree or chain.

The \( Rom\|R_{\text{max}} \) problem has a certain similarity to the so-called open shop with batch setup times (see [13], for example). In the latter problem jobs are partitioned into several groups referred to as batches, and a machine has to spend a pre-defined setup time.
when switching from one batch to another. Batches can correspond to sets of jobs from the same node in the routing open shop, and setup times correspond to travel times. However, there are two significant differences. First, setup times usually only depend on the destination batch (in terms of the routing scheduling problem that would mean that the travel time between nodes $u$ and $v$ depend only on $v$); second, there is no initial state of machines which can correspond to the depot. Including the depot into the picture makes the problem to be a generalization of a metric TSP, and it is worth mentioning that such combinations of hard discrete optimization problems get more attention during the last decades. For example, the routing scheduling model appeared independently while considering tasks arising both in production (see, e.g. [1,2]), so in the service industry [9,24].

The general routing open shop problem contains the metric TSP as a special case, moreover, the problem with a single machine is equivalent to the metric TSP and therefore is strongly NP-hard. On the other hand, the problem with zero travel times (or with $G = K_1$) is equivalent to the open shop problem and is NP-hard for $m \geq 3$. However, it is known, that the routing open shop problem remains NP-hard even in the simplest case $RO2|G = K_2|R_{\text{max}}$ with two machines and just two nodes of the transportation network [4]. On the other hand, FPTAS for such a case is described in [14].

Our research aims on the description of wide polynomially solvable cases of NP-hard problem $RO2||R_{\text{max}}$. A few such cases for the $RO2|G = K_2|R_{\text{max}}$ problem can be found in [8,14], see Sections 2–4 for details.

Although our research focuses on the two-machine version of the problem, the progress made in the study of the $ROm||R_{\text{max}}$ problem should be mentioned as well. A series of approximation algorithms for the $ROm||R_{\text{max}}$ problem was developed, starting with the $(m + 4)/2$-approximation [4]. The best-known algorithm up to date has the approximation ratio guarantee of $O(\log m)$ [15]. (An intriguing open question is whether an approximation algorithm with a constant approximation ratio exists for the $ROm||R_{\text{max}}$ problem.) A number of papers is devoted to the research of a special case with unit processing times [11,21,22].

In this paper, we consider the problem $RO2|G = \text{tree}|R_{\text{max}}$ and describe several special cases which are solvable to the optimum in linear time, with the optimal makespan equal to the standard lower bound. The main special cases are formulated in terms of load distribution between the nodes, the formulation involves the definitions of an overloaded node and an overloaded edge (see Section 2) and is based on a special procedure of instance reduction and its properties (Section 3). For the sake of completeness, we also provide a couple of additional special cases for $RO2|G = \text{chain}|R_{\text{max}}$ problem formulated in terms of properties of the diagonal job, which plays important role in the Gonzalez-Sahni algorithm for the $O2||C_{\text{max}}$ problem (Theorem 2.7). These cases are elementary extensions of known classes for $RO2|G = K_2|R_{\text{max}}$ described by Kononov in [14] (see Theorem 2.5).

The structure of the remainder of the paper is as follows. Section 2 contains a detailed problem description, necessary notation and the formulation of known results we use. In Section 3, we describe the procedure of instance reduction, which is the main part of our algorithm. Polynomially solvable outcomes of the instance reduction procedure are described in Section 4, followed by the description of sufficient conditions of polynomial solvability in terms of the properties of the initial instance in Section 5. Concluding remarks and some open questions are given in Section 6.
2. Preliminary notes

Let us give a formal description of the routing open shop problem. A problem instance combines inputs from the metric TSP and the open shop problem in the following manner. A connected graph $G = (V, E)$ is given, a non-negative weight function $\tau : E \rightarrow \mathbb{Z}_{\geq 0}$ is defined. One of the nodes $v_0 \in V$ is chosen to be the depot. Jobs from the set $J = \{J_1, \ldots, J_n\}$ are distributed among the nodes from $V$. A set of jobs located at $v \in V$ is denoted by $J(v)$ and is non-empty for any node with possible exclusion of the depot. Machines from the given set $M = \{M_1, \ldots, M_m\}$ are initially located at the depot and each machine can travel over the edges of $G$, travel time of each machine over an edge $e \in E$ equal to $\tau(e)$. Any number of machines can travel over the same edge in any direction at the same time. Machines are allowed to visit each node multiple times and therefore we assume machines use the shortest paths while travelling from one location to another. Each machine $M_i$ has to perform an operation $O_{ji}$ on every job $J_j$. This operation takes $p_{ji} \in \mathbb{Z}_{\geq 0}$ time units and requires the machine to be at the location of $J_j$; while machine is in the node $v$, it can only process operations of jobs from $J(v)$. Different operations of the same job cannot be processed simultaneously, and each machine can process at most one operation at a time. Machines have to return to the depot after processing all the operations. We use notation $p_{ji}(I)$, $G(I)$, $\tau(I; e)$ and $J(I; v)$, if we want to specify a problem instance $I$.

A schedule $S$ can be described by specifying the starting time $s_{ji}$ for each operation $O_{ji}$:

$$S = \{s_{ji} | i = 1, \ldots, m, j = 1, \ldots, n\}.$$ 

The completion time of operation $O_{ji}$ in a schedule $S$ is denoted by $c_{ji}(S) = s_{ji} + p_{ji}$, notation $S$ is omitted when not needed.

Let $\text{dist}(v, u)$ denote the weighted distance between the nodes $v$ and $u$ (and vice versa), i.e. the minimal total weight of edges belonging to some chain connecting $v$ and $u$. So $\text{dist}(v, u)$ is the shortest time needed for a machine to reach $u$ from $v$. We also use notation $\text{dist}(I; v, u)$ for a specific instance $I$.

**Definition 2.1:** A schedule $S$ for an instance $I$ is referred to as feasible if it satisfies the following conditions:

1. If $i_1 = i_2$ or $j_1 = j_2$ (but not both) then

$$ (s_{i_1j_1}, c_{i_1j_1}) \cap (s_{i_2j_2}, c_{i_2j_2}) = \emptyset. $$

2. If operation of job $J_j \in J(v)$ is the first to start by machine $M_i$ then

$$ s_{ji} \geq \text{dist}(I; v_0, v). $$

3. If machine $M_i$ processes operation $O_{ji}$ before the processing of an operation $O_{ji'}$, $J_j \in J(v)$, and $J_{j'} \in J(v')$, then

$$ s_{ji} \geq c_{ji} + \text{dist}(I; v, v'). $$

Condition 1 means that intervals of processing of dependent operations (i.e. operations of the same job or of the same machine) do not overlap. Conditions 2 and 3 mean that machine cannot start an operation before it reaches its location.
Suppose an operation of job $J_j \in \mathcal{J}(v)$ is the last to be processed by machine $M_i$ in some schedule $S$. Then we define the release time of machine $M_i$ as

$$R_i(S) = c_{ji}(S) + \text{dist}(v, v_0).$$

The makespan of schedule $S$ is $R_{\text{max}}(S) = \max_i R_i(S)$. The goal is to find a feasible schedule minimizing the makespan.

For some problem instance $I$, we use the following notation:

- $\ell_i(I) = \sum_{j=1}^n p_{ji}(I)$ — the load of machine $M_i$;
- $\ell_{\text{max}}(I) = \max_i \ell_i(I)$ — the maximal machine load;
- $d_j(I) = \sum_{i=1}^m p_{ji}(I)$ — the length of job $J_j$;
- $d_{\text{max}}(I; v) = \max_{j \in \mathcal{J}(v)} d_j(I)$ — the maximal job length at node $v$;
- $\Delta(I; v) = \sum_{j \in \mathcal{J}(v)} d_j(I)$ — the load of node $v$;
- $\Delta(I) = \sum_{v \in \mathcal{V}} \Delta(I; v)$ — the total load of instance $I$;
- $T^*(I)$ — the optimum of the underlying TSP, i.e. the length of the shortest a cyclic route visiting each node at least once;
- $R^*_{\text{max}}(I)$ — the optimal makespan.

We omit $I$ from the notation in case when it does not lead to a confusion.

The following standard lower bound on the optimum for the routing open shop problem was introduced in [3]:

$$\bar{R}(I) = \max \left\{ \ell_{\text{max}}(I) + T^*(I), \max_{v \in \mathcal{V}} (d_{\text{max}}(I; v) + 2\text{dist}(I; v_0, v)) \right\}. \quad (1)$$

Note that $\bar{R}$ coincides with $\bar{C}$ in case when all edges have zero weight or $G = K_1$ (in this case our problem is reduced to the classical open shop problem).

Our study is focused on the case of two machines. In this case, we use simplified notation for the operations of each job $J_j$: $a_j$ and $b_j$ instead of $O_{j1}$ and $O_{j2}$, respectively. Moreover, we use the same notation ($a_j$ and $b_j$) for operations’ processing times whenever it does not lead to a confusion.

We use the following definitions inherited from [16].

**Definition 2.2:** A feasible schedule $S$ for a problem instance $I$ is referred to as normal if $R_{\text{max}}(S) = \bar{R}(I)$. Instance $I$ is normal if it admits construction of a normal schedule.

A class of instances is normal if it consists of normal instances only. A normal class $\mathcal{K}$ is referred to as efficiently normal if there exists a polynomial time algorithm for solving any instance from $\mathcal{K}$ to the optimum.

The goal of this paper is to describe wide efficiently normal classes for the RO2|G = tree|R_{\text{max}} problem. Below we describe a few such classes known from previous research.

The first efficiently normal class of instances of RO2|G = $K_2$|R_{\text{max}} is due to Kononov [14] and its description is based on the so-called diagonal job, which can be defined as follows.
**Definition 2.3:** The diagonal job of an instance of the $O_2\|C_{\text{max}}$ (or $RO_2\|R_{\text{max}}$) problem is such a job $J_r \in \mathcal{J}$ that

$$r = \arg \max_j \{\min\{a_j, b_j\}\}.$$  

We also need the following

**Definition 2.4:** A feasible schedule $S$ if referred to as early if no operation $O_{ji}$ can start earlier than at $s_{ji}(S)$, providing that the sequences of operations of each job and each machine from $S$ are preserved, without violating the feasibility.

Note that any early schedule is uniquely defined by sequences of operations of each job and each machine.

**Theorem 2.5 (Kononov, [14]):** A class of instances of the $RO_2|G = K_2|R_{\text{max}}$ problem satisfying at least one of the following properties of the diagonal job $J_r$ is solvable to the optimum in linear time:

1. $J_r \in \mathcal{J}(v_0)$,
2. $d_r \geq \ell_{\text{max}}$.

The proof of Theorem 2.5 is based on properties of the Gonzalez-Sahni algorithm for open shop problem $O_2\|C_{\text{max}}$ [12]. This proof can be easily extended on a problem $RO_2|G = \text{chain}|R_{\text{max}}$ under the following conditions:

1. the depot $v_0$ is one of the terminal nodes of chain $G$,
2. job $J_r$ is located at some terminal node of $G$.

To present this proof, we use the following Gonzalez-Sahni formulation, similar to that described in [14].

| Gonzalez-Sahni algorithm [12] |
|--------------------------------|
| **Input:** An instance $I$ of $O_2\|C_{\text{max}}$ problem.  |
| **Output:** An optimal schedule for $I$.  |
| **Step 1.** Partition the set of jobs $\mathcal{J}$ into two subsets: |
| $\mathcal{J}_A = \{J|a_j \leq b_j\}$, $\mathcal{J}_B = \{J|a_j > b_j\}$.  |
| **Step 2.** Let $J_r$ be a diagonal job. Without loss of generality assume $J_r \in \mathcal{J}_A$.  |
| **Step 3.** Choose enumerations of operations from $\mathcal{J} \setminus \{J_r\}$ ($\mathfrak{A}$ and $\mathfrak{B}$ for machines $M_1$, $M_2$ respectively) in the following way: |
| 3.1. If $d_r < \ell_{\text{max}}$ then $\mathfrak{A} = \mathfrak{B}$ is a concatenation of arbitrary enumerations of $\mathcal{J}_A \setminus \{J_r\}$ and $\mathcal{J}_B$,  |
| 3.2. If $d_r \geq \ell_{\text{max}}$ then both $\mathfrak{A}$ and $\mathfrak{B}$ are arbitrary and independent.  |
| **Step 4.** Construct an early schedule in the following manner: |
| 4.1. Machine $M_1$ processes operation of jobs from $\mathcal{J} \setminus \{J_r\}$ according to $\mathfrak{A}$, then $a_r$;  |
| 4.2. Machine $M_2$ processes $b_r$, then operations of jobs from $\mathcal{J} \setminus \{J_r\}$ according to $\mathfrak{B}$;  |
| 4.3. Operations of all jobs except $J_r$ are processed first by $M_1$, then by $M_2$.  |
Lemma 2.6 ([12]): The Gonzalez-Sahni algorithm runs in $O(n)$ time and obtains a normal schedule for any instance of $O2\|C_{\text{max}}$.

Theorem 2.7: Let $I$ be an instance of the $RO2|G = \text{chain}|R_{\text{max}}$ problem with $J_r$ being a diagonal job, $G$ is a chain $(v_0, \ldots, v_g)$. Then any of the following conditions implies $I$ is normal and an optimal schedule for $I$ can be found in $O(n)$:

1. $J_r \in \mathcal{J}(v_0)$,
2. $J_r \in \mathcal{J}(v)$ and $d_r \geq \ell_{\text{max}}$.

Proof: The algorithm for $RO2|G = \text{chain}|R_{\text{max}}$ is based on the Gonzalez-Sahni algorithm and its properties. The key fact is that operations of jobs from each of the sets $J_A$ and $J_B$ (Step 3) can be processed in an arbitrary order, and we show that it is possible to choose the order in such a way that each machine is guaranteed to take an optimal route. Thus the algorithm of building an optimal schedule in both cases has the following structure:

- Choose a specific orders $\mathfrak{A}$ and $\mathfrak{B}$ for operations of non-diagonal jobs to apply at Step 3 of Gonzalez-Sahni algorithm.
- Build a schedule $S_{\text{GS}}$ ignoring travel times using Gonzalez-Sahni algorithm.
- “Insert” travel times into $S_{\text{GS}}$ to obtain a schedule for the initial $RO2\|R_{\text{max}}$ problem instance.

Hereafter we assume without loss of generality that $J_r \in J_A$, and use notation $J_A(v) = J_A \cap \mathcal{J}(v) \setminus \{J_r\}$ ($J_B(v) = J_B \cap \mathcal{J}(v)$) for each $v \in V$. Let us specify the orders $\mathfrak{A}$ and $\mathfrak{B}$ for both cases of the Theorem.

Case 1. Let $\mathfrak{A} = \mathfrak{B}$ be a concatenation of arbitrary enumerations of $J_A(v_0), J_A(v_1), \ldots, J_A(v_g), J_B(v_g), \ldots, J_B(v_0)$. The structure of the resulting schedule is shown in Figure 1. Thick arcs represent multiple precedence constraints: not between the two blocks, but between respective operations of the same job.

Case 2. Let $\mathfrak{A}$ be a concatenation of arbitrary enumerations of $\mathcal{J}(v_0), \mathcal{J}(v_1), \ldots, \mathcal{J}(v_g) \setminus \{J_r\}$, and $\mathfrak{B}$ be a concatenation of arbitrary enumerations of $\mathcal{J}(v_g) \setminus \{J_r\}, \mathcal{J}(v_{g-1}), \ldots, \mathcal{J}(v_0)$ (see Figure 2). A thick dashed line represents the connection between operations of the diagonal job: $c_{r2} = s_{r1}$.

Note that in both cases the orders $\mathfrak{A}$ and $\mathfrak{B}$ comply with the Gonzalez-Sahni algorithm, hence the schedule built is normal. Now it is sufficient to observe that inserting travel times into those schedules does not introduce extra delay intervals into their structure.

The second normal class of instances of $RO2|G = K_2|R_{\text{max}}$ was introduced in [8] and is based on the following

Definition 2.8: A node $v$ is referred to as superoverloaded if jobs from $\mathcal{J}(v)$ can be partitioned into three subsets $\mathcal{J}_1, \mathcal{J}_2, \mathcal{J}_3$ such that

1. $\forall k \in \{1, 2, 3\} \sum_{j \in \mathcal{J}_k} d_j \leq \bar{R} - 2\text{dist}(v_0, v)$,
2. $\forall k \neq l \in \{1, 2, 3\} \sum_{j \in \mathcal{J}_k \cup \mathcal{J}_l} d_j > \bar{R} - 2\text{dist}(v_0, v)$. 
Such a partition is referred to as irreducible one.

It was proved in [8] that any instance of $RO2|G = K_2|R_{\text{max}}$ containing a superoverloaded node is normal, and the optimal schedule for such an instance can be built in linear time providing that an irreducible partition is known. We provide an elementary extension of this result on the special case with $G = \text{chain}$ in Section 4.

Unfortunately the verification of existence of an irreducible partition is NP-complete [8] and therefore the problem of obtaining of such a partition is NP-hard. However, there is a description ([8]) of a sufficient condition for a node to be superoverloaded, together with a polynomial time procedure of obtaining of an irreducible partition.

**Theorem 2.9 ([8]):** Let $\Delta(v) > \frac{3}{2}(\bar{R} - 2\text{dist}(v_0, v)) + d_{\text{max}}(v)$. Then $v$ is superoverloaded, and an irreducible partition can be obtained by the following procedure.

**Procedure Partition.**

Let $\mathcal{J}(v) = \{J_1, \ldots, J_k\}$.

**Step 1.** Find minimal $x > 1$ such that $\sum_{j=1}^{x} d_j > \frac{1}{2}(\bar{R} - 2\text{dist}(v_0, v))$.

Set $\mathcal{J}_1 = \{J_1, \ldots, J_x\}$ and $X = \sum_{j=1}^{x} d_j$.

**Step 2.** Find minimal $y > x$ such that $\sum_{j=x+1}^{y} d_j > \bar{R} - 2\text{dist}(v_0, v) - X$.

Set $\mathcal{J}_2 = \{J_{x+1}, \ldots, J_y\}$.

**Step 3.** Set $\mathcal{J}_3 = \{J_{y+1}, \ldots, J_k\}$.

This procedure runs correctly if for each job $J_j \in \mathcal{J}(v)$ its length $d_j \leq \frac{1}{2}(\bar{R} - 2\text{dist}(v_0, v))$. The condition of Theorem 2.9 implies that inequality, and also guarantees the irreducibility of the partition obtained. In general case the procedure Partition still may be applied if a special treatment for 'long' jobs (with $d_j > \frac{1}{2}(\bar{R} - 2\text{dist}(v_0, v))$, if any) is provided. We describe the following version of the procedure guaranteed to run correctly in any case.
**Procedure** Partition 2.0.

Let \( J(v) = \{J_1, \ldots, J_k\} \).

**Step 0.** If \( J(v) \) contains long jobs, rearrange the enumeration of jobs to comply with the following conditions:
0.1. \( J_1 \) is a long job,
0.2. \( J_2 \) is also a long job unless there are no more long jobs except for \( J_1 \).

**Step 1.** Find minimal \( x > 1 \) such that \( \sum_{j=1}^{x} d_j > \frac{1}{2}(R - 2\text{dist}(v_0, v) + d_{\text{max}}(v)) \).
   If no such \( x \) exists, set \( x = k \).
   Set \( J_1 = \{J_1, \ldots, J_x\} \) and \( X = \sum_{j=1}^{x} d_j \).
   If \( x = k \), set \( J_2 = J_3 = \emptyset \) and STOP.

**Step 2.** Find minimal \( y > x \) such that \( \sum_{j=x+1}^{y} d_j > \bar{R} - 2\text{dist}(v_0, v) + d_{\text{max}}(v) - X \).
   If no such \( y \) exists, set \( y = k \).
   Set \( J_2 = \{J_{x+1}, \ldots, J_{y}\} \).
   If \( y = k \), set \( J_3 = \emptyset \) and STOP.

**Step 3.** Set \( J_3 = \{J_{y+1}, \ldots, J_k\} \).

Clearly, each step of the procedure requires \( O(n) \) time. However, without the conditions of Theorem 2.9, we cannot guarantee that the partition obtained by the procedure Partition 2.0 is irreducible. Note how we use this procedure in our algorithm in the next section.

### 3. Instance reduction procedure

In this section, we study some general properties of an instance of RO\(2\|R_{\text{max}} \) and describe the reduction procedure which helps to reduce the number of jobs and to simplify the graph structure preserving the standard lower bound \( \bar{R} \). One of the important properties of the procedure is its reversibility: any feasible schedule for a reduced instance can be treated as a feasible schedule for the initial instance with the same makespan. In general case, this procedure can increase the optimal makespan. However, in the next sections, we prove that for our special cases of \( RO2|G = \text{tree}|R_{\text{max}} \) the instance reduction procedure also preserves the optimum. Therefore, it can be used as a main part of an exact algorithm for solving the initial instance.

The procedure is based on two types of instance transformation: *job aggregation* and *terminal edge contraction*. The first one is described in detail in [7], while the second was used in [6] for a certain generalization of the routing open shop problem. We provide all the necessary details below.

**Definition 3.1:** Let \( I \) be an instance of the problem \( ROM\|R_{\text{max}} \) with graph \( G = (V; E) \), and \( K \subseteq J(I; v) \) for some \( v \in V \). Then we say that instance \( I' \) is obtained from \( I \) by *aggregation* of jobs from \( K \) if

\[
J(I'; v) = J(I; v) \setminus K \cup \{J_K\}, \quad \forall i = 1, \ldots, m, \quad p_{j_K; I'} = \sum_{j \in K} p_{ji}(I),
\]

\[
\forall u \neq v \quad J(I'; u) = J(I; u).
\]

(Here \( j_K \) is some new job index. A job \( J_K \) is to replace the set of jobs \( K \).) An instance \( \tilde{I} \) obtained from \( I \) by a series of job aggregations is referred to as an *aggregation* of \( I \).
The idea behind the job aggregation is easy: to partition jobs into some number of groups and treat each group as a new job with processing times equal to the total processing times of the jobs combined. Similar approach is used in de Werra’s algorithm for the $O2∥C_{\text{max}}$ problem [10].

It is easy to observe that any feasible schedule for any aggregation $\tilde{I}$ can be treated as a feasible schedule for the initial instance $I$: one just needs to replace an aggregated operation with a sequence of operations of jobs from $K$ to be processed in any order with no idle time. Therefore, $R^*_{\text{max}}(I) \geq R^*_{\text{max}}(\tilde{I})$. Also as soon as we obtained a new job $J_{jk}$ in $\mathcal{J}(I'; v)$, it is possible that $d_{jk} > d_{\text{max}}(I; v)$, so job aggregation can lead to the growth of the standard lower bound. Specifically, (1) implies

$$\overline{R}(I') > \overline{R}(I) \text{ if and only if } d_{jk} > \overline{R}(I) - 2\text{dist}(v_0, v).$$

(2)

We use job aggregation to simplify the instance preserving the standard lower bound. Such an aggregation is referred to as a valid one. An instance with no further legal job aggregation possible is called irreducible.

A natural question arises, if it is possible to perform a valid job aggregation of a whole set $\mathcal{J}(I; v)$ for some $v \in V$. To answer that question, we use the following definition from [7].

**Definition 3.2:** A node $v \in V$ of an instance $I$ of the problem $ROm∥R_{\text{max}}$ is referred to as overloaded if

$$\Delta(I; v) > \overline{R}(I) - 2\text{dist}(v_0, v).$$

Otherwise the node is called underloaded.

Note that Definition 2.8 implies $\Delta(v) > \frac{3}{2}(\overline{R} - 2\text{dist}(v_0, v))$, therefore any superoverloaded node is overloaded as well.

The job aggregation of the set $\mathcal{J}(I; v)$ is valid if and only if the node $v$ is underloaded. Therefore, any node containing single job is an underloaded one.

By $L_V(I)$ we denote the number of overloaded nodes in an instance $I$. It was proved in [7] that for every instance $I$ of the $RO2∥R_{\text{max}}$ problem $L_V(I) \leq 1$. Further in this section we prove a more general result (Proposition 3.5).

Now let us describe the terminal edge contraction operation.

**Definition 3.3:** Let $v \in V \setminus \{v_0\}$ be some terminal node in graph $G$, containing a single job $J_j$ in an instance $I$ of the $ROm∥R_{\text{max}}$ problem. Let $e = [v, u] \in E$ be the edge incident to $v$. By the contraction of the edge $e$ we understand the following instance transformation:

$$\mathcal{J}(I'; u) \triangleq \mathcal{J}(I; u) \cup \{J_j\}; \ p_{ji}(I') \triangleq p_{ji}(I) + 2\tau(e); \ G(I') \triangleq G(I) \setminus \{v\}.$$

In other words, job $J_j$ is translated from $v$ to $u$, while its operations’ processing times increase by $2\tau(e)$ each. After that translation node $v$ is obsolete (contains no jobs) and to be removed from $G$.

Consider an instance $I'$ obtained from $I$ by the contraction of edge $e$. Any feasible schedule for $I'$ can be treated as a feasible schedule for the initial instance $I$. One just needs to
replace a scheduled interval of a new operation $O_{ji}$ with three consecutive intervals: travelling of the machine $M_i$ over the edge $e$ to the node $v$, performing of the old operation $O_{ji}$, and travelling back to the node $u$.

Note that an edge contraction increases each machine load by $2 \tau(e)$ while decreasing $T^*$ by the same amount, therefore preserving the sum $\ell_{\text{max}} + T^*$. However the length of $J_j$ increases by $2m \tau(e)$ which might lead to the growth of the standard lower bound. We want to avoid that. Consider the two-machine case of our problem. The following definition describes the exact condition, under which an edge contraction increases $\tilde{R}$.

**Definition 3.4:** Let $v \in V \setminus \{v_0\}$ be some terminal node in graph $G$, containing a single job $J_j$ in instance $I$ of the $RO_2\|R_{\text{max}}$ problem. Let $e = [v, u] \in E$ be the edge incident to $v$. The edge $e$ is referred to as overloaded if

$$d_j(I) + 4\tau(e) > \tilde{R}(I) - 2\text{dist}(I; v_0, u),$$

and underloaded otherwise.

(Note that we could perform a contraction of an overloaded edge — meaning that the edge is terminal, the respective terminal node is not the depot and contains a single job — but this would increase the standard lower bound. In the case the edge contraction cannot be performed, the edge is neither overloaded nor underloaded.)

For any problem instance $I$, we denote the number of overloaded edges by $L_E(I)$. The following property of any instance of $RO_2\|R_{\text{max}}$ is fundamental for the procedure of instance reduction.

**Proposition 3.5:** Let $I$ be an instance of the problem $RO_2\|R_{\text{max}}$. Then $L_V(I) + L_E(I) \leq 1$.

**Proof:** As proved in [7], any instance of $RO_2\|R_{\text{max}}$ contains at most one overloaded node, so $L_V(I) \leq 1$. Let us prove, that $I$ contains at most one overloaded edge. Note that (1) implies

$$\Delta(I) = \ell_1(I) + \ell_2(I) \leq 2(\tilde{R}(I) - T^*(I)).$$

Let $v$ and $v'$ be two different terminal nodes with single job in each, $J_j$ and $J_{j'}$ respectively; $e = [u, v]$ and $e' = [u', v']$ be the edges incident to $v$ and $v'$, respectively, and both edges are overloaded. (Note that there is a possibility that $u = u'$.) Due to the metric property of distances we have

$$T^* \geq \text{dist}(v_0, u) + \text{dist}(v_0, u').$$

From (3) we have

$$d_j + 4\tau(e) > \tilde{R} - 2\text{dist}(v_0, u); \quad d_{j'} + 4\tau(e') > \tilde{R} - 2\text{dist}(v_0, u'),$$

and therefore

$$\Delta \geq d_j + d_{j'} > 2\tilde{R} - 2\text{dist}(v_0, u) - 2\text{dist}(v_0, u') - 4\tau(e) - 4\tau(e').$$

Consider a graph $G' = G \setminus \{v, v'\}$. Let $T'^*$ be the optimum of the TSP on $G'$. Then due to the fact that edges $e$ and $e'$ are terminal,

$$T^* = T'^* + 2\tau(e) + 2\tau(e').$$
Indeed, in order to visit terminal nodes, one needs to travel twice over their respective incident edges. Combining (6), (5) and (7), we obtain the inequality
\[
\Delta > 2\bar{R} - 2T^* - 4\tau(e) - 4\tau(e') \geq 2\bar{R} - 2T^*.
\]
By contradiction with (4) we have \(L_E(I) \leq 1\).

Now suppose \(L_V(I) = L_E(I) = 1\). Let \(e = [u, v]\) be the overloaded edge, \(v \neq v_0\) is terminal node with single job \(J_j\). Note that node \(v\) is underloaded as it contains a single job. Let \(v' \neq v\) be the overloaded node. Then, by Definitions 3.2 and 3.4 we have
\[
\Delta(v') > \bar{R} - 2\text{dist}(v_0, v'), \quad (8)
\]
\[
d_j + 4\tau(e) > \bar{R} - 2\text{dist}(v_0, u). \quad (9)
\]
By using reasoning similar to that of (5) and (7), we deduce
\[
T^* \geq \text{dist}(v_0, v') + \text{dist}(v_0, u) + 2\tau(e).
\]
Using this inequality, together with (8) and (9), we obtain
\[
\Delta \geq \Delta(v') + d_j > 2\bar{R} - 2\text{dist}(v_0, v') - 2\text{dist}(v_0, u) - 4\tau(e) \geq 2\bar{R} - 2T^*,
\]
contradicting (4). This concludes the proof of the Proposition. ■

The idea of the following instance reduction procedure is simple. First, we aggregate jobs in all the underloaded nodes to obtain single job in each, then contract all the underloaded edges, and repeat this step until there is no underloaded edge and each underloaded node contains exactly one job. Second, we deal with the only overloaded node (if any), using the Procedure Partition 2.0 and aggregation of the obtained job sets. This way we transform the initial instance, preserving the standard lower bound. The instance obtained is irreducible. Moreover, any further operation of terminal edge contraction would increase the standard lower bound.

Note that the reduction procedure is not used for solving a problem instance, but to simplify it and consequently verify its properties. Depending on the outcome of the procedure (see Lemma 3.6), we further decide, whether the instance belong to the efficiently normal subclass we announced (see Theorem 4.3). The simplification procedure is described in detail in Table 1.

Let us illustrate this procedure on a small instance with transportation network from Figure 3 and job data from Table 2. Job data contains the description of jobs of type \(J_j(a_j, b_j)\), with each node's load calculated in the last row. For this instance, we have \(T^* = 28\) and \(\ell_1 = \ell_2 = 28\). As soon as each job length (and even node's load) is smaller than \(l_{\text{max}}\), we have \(R = \ell_{\text{max}} + T^* = 56\). We can also observe that for each node \(v\) we have \(\Delta(v) + 2\text{dist}(v_0, v) < \bar{R}\), therefore all the node are underloaded. After performing Step 1 of the procedure we will obtain an instance with a single job at each node (see Table 3).

Let us perform Step 2. Consider terminal node \(v_1\). The edge \([v_1, v_2]\) is underloaded as soon as \(d_3 + 4\tau([v_1, v_2]) + 2\text{dist}(v_2, v_0) = 5 + 4 + 2 = 11 < \bar{R}\). After the edge contraction (Step 2.2.2), we have modified job \(J_3(6, 3)\) translated to node \(v_2\), so \(\Delta(v_2)\) is now 15. The node \(v_2\) is still underloaded, so we perform job aggregation (Step 2.2.3), see Table 4. Further contractions of terminal edges is show in Table 5. Terminal nodes are eliminated in order \(v_2, v_3, v_5, v_7, v_8, v_6\). After the last contraction the node \(v_4\) becomes overloaded, Step 3 does nothing and the procedure stops. The initial instance is reduced to a simple instance with two nodes \(v_0\) and \(v_4\) with three jobs.
Table 1. The simplification procedure Reduction.

| INPUT: An instance \( I \) of the problem \( RO2|R_{\max} \). |
| OUTPUT: A simplified irreducible instance \( \tilde{I} \). |

**Step 1.** For each underloaded \( v \in V \) perform the job aggregation of \( J(v) \).

**Step 2.** For each terminal node \( v \neq v_0 \):

1. \( e = [u, v] \) (\( e \) is incident to \( v \), \( u \) is adjacent to \( v \)),
2. If \( e \) is underloaded then
   2.1. Let \( J_j \) is the only job in \( J(v) \),
   2.2. Perform the contraction of \( e \),
   2.3. If \( u \) is underloaded then perform the job aggregation of \( J(u) \).

**Step 3.** If some \( v \in V \) is overloaded then

1. Obtain sets \( J_1, J_2, J_3 \) by application of the Partition 2.0 to node \( v \),
2. For each non-empty set \( J_k \) perform the job aggregation of \( J_k \),
3. If an aggregation of two obtained jobs in \( J(v) \) with the smallest length is valid then perform that aggregation.

Figure 3. A sample transportation network.

Table 2. Job data for a sample instance.

| \( v \)  | \( v_0 \) | \( v_1 \) | \( v_2 \) | \( v_3 \) | \( v_4 \) | \( v_5 \) | \( v_6 \) | \( v_7 \) | \( v_8 \) |
|--------|--------|--------|--------|--------|--------|--------|--------|--------|--------|
| Jobs:  | \( J_1(1, 2) \) | \( J_2(4, 1) \) | \( J_3(1, 1) \) | \( J_4(1, 1) \) | \( J_5(1, 1) \) | \( J_6(1, 1) \) | \( J_7(2, 1) \) | \( J_8(5, 2) \) | \( J_9(1, 1) \) | \( J_{10}(2, 1) \) | \( J_{11}(3, 2) \) | \( J_{12}(1, 4) \) | \( J_{13}(2, 3) \) | \( J_{14}(1, 5) \) |
| \( \Delta(v) \) | 10   | 5    | 6    | 3    | 9    | 3    | 5    | 5    | 11 |

Table 3. Job data for a sample instance after Step 1.

| \( v \)  | \( v_0 \) | \( v_1 \) | \( v_2 \) | \( v_3 \) | \( v_4 \) | \( v_5 \) | \( v_6 \) | \( v_7 \) | \( v_8 \) |
|--------|--------|--------|--------|--------|--------|--------|--------|--------|--------|
| Jobs:  | \( J_{12}(4, 6) \) | \( J_3(4, 1) \) | \( J_{4,5,6}(3, 3) \) | \( J_7(2, 1) \) | \( J_{8,9}(6, 3) \) | \( J_{10}(2, 1) \) | \( J_{11}(3, 2) \) | \( J_{12}(1, 4) \) | \( J_{13,14}(3, 8) \) |
| \( \Delta(v) \) | 10   | 5    | 6    | 3    | 9    | 3    | 5    | 5    | 11 |

Note that the procedure Reduction obtains a reversible instance in \( O(n) \) time. Indeed, Step 1 requires \( O(n) \) time. Step 2 is repeated once for each terminal node (and total number of nodes is not greater than \( n \)), and takes constant amount of time for a single edge contraction. Step 3 is also linear, as its running time is majorized by that of the procedure Partition 2.0.

The following Lemma describes all possible variants of the reduced instance for the problem \( RO2|G = tree|R_{\max} \).
Table 4. Performing Steps 2.2.2 and 2.2.3 for $v_1$.

| $v$: | $v_0$ | $v_2$ | $v_3$ | $v_4$ | $v_5$ | $v_6$ | $v_7$ | $v_8$ |

| $\Delta(v)$: | 40 |

Lemma 3.6: Let $I$ be an instance of RO2$| G = \text{tree}| R_{\text{max}}$ and $\bar{I}$ is obtained from $I$ by the procedure Reduction. Then $\bar{R}(\bar{I}) = \bar{R}(I)$ and the graph $G(\bar{I})$ satisfies exactly one of the following conditions:

1. $G(\bar{I})$ has a single node $v_0$;
2. $G(\bar{I})$ is a chain connecting $v_0$ with an overloaded node $v$ and each node contains only one job except $v$ which contains two or three jobs;
3. $G(\bar{I})$ is a chain connecting $v_0$ with a node $v$ with single job at each node, and the edge incident to $v$ is overloaded.

Proof: Each job aggregation used in the Procedure is valid and, therefore, does not grow the standard lower bound. Terminal edge contractions are applied only to underloaded edges, therefore, $\bar{R}(\bar{I}) = \bar{R}(I)$.

Consider the case $G(\bar{I}) \neq K_1$. Note that Steps 1 and 2.2.3 guarantee that each underloaded node in $\bar{I}$ contains exactly one job. Therefore, each terminal node in $G(\bar{I})$ is either $v_0$, or overloaded, or incident to an overloaded edge. By Proposition 3.5 the graph $G(\bar{I})$ contains at most two terminal nodes (one of which is the depot) and hence is a chain. Step 2 of the procedure continues until we have no more underloaded terminal edges. Therefore, a terminal edge is contracted unless it is overloaded, or incident to the depot, or incident to
an overloaded node. As soon as the first and the third options are mutually exclusive, the Lemma follows.

As soon as the procedure Reduction preserves $\bar{R}$, we have the following property: if the reduced instance $\tilde{I}$ is normal, then the initial instance $I$ is normal as well, and any normal (and hence optimal) schedule for $\tilde{I}$ can be easily transformed into an optimal schedule of $I$. Obviously $\tilde{I}$ is normal in case 1 of Lemma 3.6: the problem is reduced to a classical $O2\|C_{\text{max}}$ and a normal schedule can be built by the Gonzalez-Sahni algorithm (Lemma 2.6). Therefore a class of instances of $RO2|G = \text{tree}|R_{\text{max}}$, for which the procedure Reduction contracts the initial tree into a single node is efficiently normal and can be solved in three steps: Reduction, Gonzalez-Sahni algorithms and restoring a schedule for the initial instance. In the next Section, we prove similar properties for case 3 and (under a certain condition) for case 2.

4. Easy solvable cases on a chain

In this section, we establish the normality of two special cases of $RO2|G = \text{chain}|R_{\text{max}}$. In both cases, we assume that the instance is irreducible, the depot is one of the ends of $G$, while the other end is either incident to an overloaded edge (which corresponds to a case 3 of Lemma 3.6) or contains exactly three jobs (which is a special subcase of a case 2 of Lemma 3.6). A trivial corollary of those results is Theorem 4.3 providing a formulation of efficiently normal subcases for the $RO2|G = \text{tree}|R_{\text{max}}$ in terms of the outcome of the procedure Reduction applied to an instance of the problem.

In this Section, we construct early schedules using partial orders of the operations, according to the remark to the Definition 2.4. Necessary partial orders are referred to as schemes and are described graphically. Auxiliary nodes $S$ and $F$ represent start and finish moments of a schedule.

**Lemma 4.1:** Let $I$ be an instance of $RO2|G = \text{chain}|R_{\text{max}}$, with $G(I)$ being a chain $(v_0, \ldots, v_g), g \geq 1$, each node $v_p$ contains a single job $J_p$ and the edge $[v_{g-1}, v_g]$ is overloaded. Then one can build a normal schedule $S$ for $I$ in linear time.

**Proof:** Let $T = \text{dist}(v_0, v_{g-1})$ and $\mu = \tau([v_{g-1}, v_g])$. Then $T^* = 2(T + \mu)$. As soon as the edge $[v_{g-1}, v_g]$ is overloaded, we have

$$d_g + 4\mu > \bar{R} - 2T.$$

Therefore, (4) implies

$$\sum_{j=0}^{g-1} d_j + 2T = \Delta - d_g + 2T < 2\bar{R} - 2T^* - \bar{R} + 2T + 4\mu + 2T = \bar{R}. \quad (10)$$

Let $S$ be the early schedule built according to the scheme from Figure 4. Following a well-known fact from project planning, the makespan of the schedule $S$ coincides with the length
**Figure 4.** A scheme of an optimal schedule for an instance with overloaded edge.

of a critical path in graph from Figure 4:

\[
R_{\text{max}}(S) = \max \left\{ \ell_1 + T^*, \ell_2 + T^*, d_g + 2\text{dist}(v_0, v_g), \sum_{j=0}^{g-1} d_j + 2T \right\}.
\]

From (1) and (10), we obtain \( R_{\text{max}}(S) = \bar{R}(I) \), concluding the proof.

**Lemma 4.2:** Let \( I \) be an irreducible instance of RO2|\( G = \text{chain} | R_{\text{max}} \), with \( G(I) \) being a chain \((v_0, \ldots, v_g), g \geq 1, \) and \( v_g \) contains three jobs, while each underloaded node \( v_p \) contains a single job \( J_p, p = 0, \ldots, g - 1. \) Then one can build a normal schedule \( S \) for \( I \) in linear time.

**Proof:** Let \( J(v_g) = \{J_\alpha, J_\beta, J_\gamma\}. \) Let \( T = \text{dist}(v_0, v_g), \) then we have \( T^* = 2T. \)

Without loss of generality we may assume

\[ a_\alpha \leq \min\{a_\gamma, b_\gamma, b_\alpha\} \] (11)

(this can be achieved by renumeration of machines and/or jobs \( J_\alpha, J_\gamma \)).

As soon as \( I \) is irreducible we have

\[ d_\alpha + d_\beta > \bar{R} - 2\text{dist}(v_0, v_g) = \bar{R} - T^*. \] (12)

Together (4) and (12) imply

\[ \sum_{j=0}^{g-1} d_j + d_\gamma + T^* < \bar{R}. \] (13)

Consider the early schedules \( S_1 \) and \( S_2 \) built according to the schemes from Figures 5 and 6, accordingly.

By the reasoning similar to that of the proof of Lemma 4.1, using (11) we have

\[
R_{\text{max}}(S_1) = \max \left\{ \ell_1 + T^*, \ell_2 + T^*, \sum_{j=0}^{g-1} d_j + d_\gamma + T^*, T^* + a_\alpha + a_\beta + b_\beta \right\}.
\]

We prove that at least one of \( S_1 \) and \( S_2 \) is normal. Assume otherwise. Then \( R_{\text{max}}(S_1) > \bar{R} \) together with (1) and (13) imply

\[
R_{\text{max}}(S_1) = T^* + a_\alpha + a_\beta + b_\beta, \] (14)
Figure 5. A scheme of the schedule $S_1$.

Figure 6. A scheme of the schedule $S_2$.

and $R_{\text{max}}(S_2) > \bar{R}$ implies

$$R_{\text{max}}(S_2) = T^* + \sum_{j=0}^{g-1} d_j + b_\gamma + \max\{a_\gamma, b_\alpha\} + a_\alpha.$$

By the assumption (11), we have

$$R_{\text{max}}(S_2) \leq T^* + \sum_{j=0}^{g-1} d_j + b_\gamma + a_\gamma + b_\alpha. \tag{15}$$

Therefore, by (4)

$$R_{\text{max}}(S_1) + R_{\text{max}}(S_2) = 2T^* + \sum_{j=0}^{g-1} d_j + d_\alpha + d_\beta + d_\gamma = 2T^* + \Delta \leq 2\bar{R},$$

hence both $S_1$ and $S_2$ are normal. Lemma is proved by contradiction. \[\square\]

Now we are ready to declare the main result of this section.

**Theorem 4.3:** Let $I$ be an instance of the RO2|\text{G = tree}|R_{\text{max}}$ problem, $\tilde{I}$ is obtained from $I$ by Reduction procedure and one of the following conditions is true:

1. $G(\tilde{I}) = K_1$,
2. $G(\tilde{I})$ contains an overloaded edge,
3. $G(\tilde{I})$ contains an superoverloaded node.

Then one can build a normal schedule $S$ for $I$ in linear time.
Proof: Straightforward from Lemmas 3.6, 4.1 and 4.2.

Theorem 4.3 can be seen as a description of efficiently normal class of instances of $RO2|G = \text{tree}|R_{\text{max}}$, formulated in terms of the outcome of the Procedure Reduction. In the next section, we suggest a formulation of sufficient conditions of efficient normality in terms of the properties of the initial instance (Theorem 5.3).

5. Sufficient conditions of polynomial solvability

Consider an instance $I$ of the $RO2|G = \text{tree}|R_{\text{max}}$ problem. Let us introduce some notation and definitions convenient for the description of the further results.

**Definition 5.1:** Let $G = \langle V; E \rangle$ be a subtree of $G$. We define the weight of $G$ as
\[
W(G) = \sum_{v \in V} \Delta(v) + 4 \sum_{e \in E} \tau(e).
\]

It is easy to observe that $W(G)$ is preserved by any operation of job aggregation and terminal edge contraction (and therefore by the Procedure Reduction). Moreover, if during the Reduction some subtree $G'$ is completely contracted into a node $v$, then in the instance $\tilde{I}$ obtained we have $\Delta(\tilde{I}; v) = W(G')$.

**Notation 2:**
- Let $v \neq v_0$ and $e = [u, v] \in E$ — the edge, incident to $v$ in the chain connecting $v_0$ and $v$. Then $G_v$ is the connected component of $G \setminus \{e\}$ containing $v$. In other words, $G_v$ is a subtree of $G$ induced by the set of all nodes $u$ such that $v$ belongs to a chain connecting $v_0$ and $u$. For the sake of completeness let $G_{v_0} = G$.
- Let $e \in E$. Then by $v(e)$ we denote the node incident to $e$ such that $e$ belongs to a chain connecting $v_0$ and $v(e)$.
- $B_{G'}(v)$ — the set of all nodes of $G'$, adjacent to $v$.

**Proposition 5.2:** Let $W(G_v) \leq \bar{R} - 2\text{dist}(v_0, v)$. Then during the Reduction procedure no node from $G_v$ becomes overloaded.

**Proof:** It is sufficient to prove that any tree $G_v$ with such a property cannot contain an overloaded node. Assume otherwise, let some $u \in G_v$ be overloaded. Then by Definition 3.2
\[
\Delta(u) > \bar{R} - 2\text{dist}(v_0, u) \geq \bar{R} - 2\text{dist}(v_0, v) \geq W(G_v),
\]
which contradicts with Definition 5.1.

The next Theorem describes an efficiently normal class of instances of $RO2|G = \text{tree}|R_{\text{max}}$.

**Theorem 5.3:** Suppose an instance $I$ of the $RO2|G = \text{tree}|R_{\text{max}}$ problem satisfies at least one of the following properties:

1. The depot $v_0$ is overloaded.
(2) \( \forall v \in B_G(I)(v_0) \ W(v) \leq \bar{R} - 2\tau ([v_0, v]) \).

(3) There exists \( e \in E \) such that

\[
W \left( G_{v(e)} \right) \in \left( \bar{R} - 2\text{dist}(v_0, v) - 2\tau (e), \bar{R} - 2\text{dist}(v_0, v) \right].
\] (16)

(4) There exists \( v \neq v_0 \) such that

(4.1) \( \forall u \in B_G(v) \ W(G_u) \leq \bar{R} - 2\text{dist}(v_0, u) \), and

(4.2) \( W(G_v) > \frac{3}{2}(\bar{R} - 2\text{dist}(v_0, v)) + M \), there

\[
M = \max \left\{ d_{\max}(v), \max_{u \in B_G(v)} \left( W(G_u) + 4\tau ([v, u]) \right) \right\}.
\]

Then a normal schedule for \( I \) can be built in linear time.

**Proof:** It is sufficient to prove that such an instance \( I \) satisfy the conditions of Theorem 4.3.

(1) By Lemma 3.6 the only possible outcome of the Reduction procedure is that \( G \) is contracted into \( v_0 \), and we have condition 1 of Theorem 4.3.

(2) Let us prove that in this case the initial tree is contracted by the Reduction procedure either into \( v_0 \) or into a chain containing an overloaded edge. By Proposition 5.2, in this case each of the subtrees \( G_v \), \( v \in B_G(v_0) \) is either contracted into \( v \) or there occurs an overloaded edge. In the later case, we have condition 2 of Theorem 4.3, otherwise each of \( G_v \) is contracted into \( v \), and after that \( v \) is underloaded. Any further reduction can only end up either with \( v_0 \) or a link with overloaded edge (if any of the edges incident to \( v_0 \) become overloaded). Either way we have one of the conditions 1, 2 of Theorem 4.3.

(3) Let us prove that condition (16) guarantees that the Reduction procedure will end up with a chain containing an overloaded edge. Indeed, by (16) and Proposition 5.2, the tree \( G_{v(e)} \) is either contracted into \( v(e) \) or an overloaded edge occurs during the process and we have the claim. In the first case, we obtain \( \Delta (v(e)) = W(G_{v(e)}) \), by (16) \( v(e) \) is underloaded, and hence all the jobs from \( J(v(e)) \) are aggregated into a single job \( J_x \) of length \( d_x = \Delta (v(e)) \) during the Reduction. Let \( e = [u, v] \). From (16), we have

\[
d_x > \bar{R} - 2\text{dist}(v_0, v) - 2\tau (e) = \bar{R} - 2\text{dist}(v_0, u) - 4\tau (e),
\]

and by Definition 3.4, the edge \( e \) is overloaded.

(4) Suppose that no overloaded edge occurs during the Reduction of subtree \( v \). By condition 4.1 and Proposition 5.2, \( G_v \) is contracted into overloaded node \( v \). The value \( M \) equals the maximal job length in \( J(v) \) after the reduction prior to Step 3 of the Reduction procedure: indeed, for each \( u \in B_G(v) \) all jobs from \( G_u \) are reduced into a single job of length \( W(G_u) \), which is further translated into \( v \) while its length becomes \( W(G_u) + 4\tau ([v, u]) \) by the contraction of edge \([v, u]\). Now by condition 4.2 set of jobs from \( J(v) \) satisfy the Theorem 2.9, an as soon as Step 3 of the Reduction procedure is an application of the Procedure Partition 2.0 (see Section 2), all the jobs from \( J(v) \) are aggregated into exactly three jobs, and \( v \) is superoverloaded. Hence the reduced instance satisfies condition 3 of Theorem 4.3.
6. Conclusion

We described the instance reduction procedure and proved that any instance with $G = \text{tree}$ can be reduced to a chain preserving the standard lower bound. We may distinguish four outcomes of that procedure: Lemma 3.6 describes three, but the second one actually consists of two: with two and three jobs at the overloaded node. We cannot guarantee the normality of the initial instance only in one of that four outcomes (with two jobs in the overloaded node). However it would be of interest to find out, how often does such an abnormal outcome occur, and therefore, how justified the use of term “normal” in this context is. This might be a subject for an experimental study.

On top of that we suggest the following directions for future investigation.

Problem 1. Find new normal (or efficiently normal) classes of instances of the RO2|$G = \text{cycle}$|$R_{\text{max}}$ problem.

Problem 2. Determine whether RO2|$G = \text{tree}$|$R_{\text{max}}$ is strongly NP-hard.

Notes on contributors

I. D. Chernykh is a senior researcher from Sobolev Institute of Mathematics, Novosibirsk, Russia. He received his M.S. in Novosibirsk State University in 1996 and Russian analogue of a Ph.D. degree (candidate of sciences) in 2001. His main area of research interest lies within machine scheduling, including but no limited to the design of efficient approximation algorithms and computer-aided proofs.

E. V. Lgotina is a second year master student at Novosibirsk State University, Faculty of Mechanics and Mathematics, studying for Master’s degree in Mechanics and Mathematical Modelling. Along with her studies, she carries out scientific research in two different scientific areas. For the last five years, she has been investigating optimal localization problems for various routing open shop models. She also has research experience in hydraulic fracturing, in particular, she works on interpretation of the minifrac.
