(Dated: December 24, 2020)

The recent interest into the Brownian gyrator has been confined chiefly to the analysis of Brownian dynamics both in theory and experiment despite the applicability of general cases with definite mass. Considering mass explicitly in the solution of the Fokker–Planck equation and Langevin dynamics simulations, we investigate how inertia can change the dynamics and energetics of the Brownian gyrator. In the Langevin model, the inertia reduces the nonequilibrium effects by diminishing the decline of the probability density function and the mean of a specific angular momentum, \( j_\theta \), as a measure of rotation. Another unique feature of the Langevin description is that rotation is maximized at a particular anisotropy while the stability of the rotation is minimized at a particular anisotropy or mass. Our results suggest that the Langevin dynamics description of the Brownian gyrator is intrinsically different from that with Brownian dynamics. In addition, \( j_\theta \) is proven to be essential and convenient for estimating stochastic energetics such as heat currents and entropy production even in the underdamped regime.

I. INTRODUCTION

On account of its simplicity and efficiency, Brownian dynamics has been adopted in a series of recent studies to describe biological systems such as chromosomes [1], primary cilia [2, 3], membrane fluctuations [4, 5], and actin-myosin networks [6–8]. In many cases, characteristic directed currents in configuration space reveal the violation of detailed balance originating from thermal nonequilibrium (see the rotational probability currents in steady state in Refs. [3, 9, 10]). Studies of such biological nonequilibrium systems through Brownian dynamics have expanded our understanding of fluctuation theorems [11–14] and the thermodynamic uncertainty relation [15–19].

The choice of Brownian dynamics may be appropriate in describing such systems because it reduces simulation cost when long-time configurational dynamics are the main interest and short-time movements do not change the results significantly. However, the development of the related theory and experiments is moving our concern to faster motions that could result in crucial differences. Observation of short-time dynamics have become available at greater time resolutions so that we are able to examine a number of theoretical results based on Langevin dynamics, where the memory effect caused by the inertia of a particle is relevant [20–23]. Moreover, systems in low-density environments (e.g., rarefied gas [20]) or at large scales such as flocks of birds [24], schools of fish [25], vibrobots [26], and various mesoscale organisms [27–29] should be addressed by Langevin dynamics including the inertial term to more realistically catch their characteristics. Normally, Langevin dynamics correspond to larger masses, lower frictions, and shorter time scales compared to Brownian dynamics.

Though Brownian dynamics is an overdamped limit of Langevin dynamics, neglecting the inertial term is not always successful even in longer time scales. There have been reports that the overdamped approximation fails in a spatially inhomogeneous temperature field [30, 31] or in the presence of a magnetic field [32, 33]. While studies to explain the inertial effects have shown that inertia qualitatively changes the system dynamics of a motility-induced phase separation [34] as well as the dynamical states and translational motion of a self-propelled particle [35–39], the effects of inertia on rotational motion and system energetics have been less considered; thus, how inertia affects the dynamics and energetics of a wider range of nonequilibrium systems, including the Brownian gyrator, still remains unclear.

In this paper, we investigate inertial effects on the dynamics and energetics of the Brownian gyrator [40], which is a two-dimensional (2D) model treating the rotational motion of a particle in contact with two different heat baths and in an anisotropic harmonic potential. This model is widely used not only because it is exactly solvable but also because it can be interpreted as a bead-spring model of an internally driven assembly in biological systems [3, 41, 42]. However, the absence of the inertial term in Brownian dynamics bears some critical limitations. First, even though the concept of the Brownian gyrator has been realized (as the overdamped limit) in recent experiments with stochastic electronic and colloidal systems [43–47], it is still possible to further develop the idea to more general experiments where the particle has considerable mass. In that case, there is lack of research with which to compare the results. Regarding the rotational motion of a particle in nonequilibrium steady state (NESS), a curl of probability currents and a cycling frequency of the Brownian gyrator has been studied [48–51], but most related reports have not considered particle

inertia. In this respect, including the inertial term, i.e., adopting Langevin dynamics, will be beneficial for clarifying the actual rotational motion of a particle in NESS. Our results here reveal that consideration of inertia remarkably changes the probability density of the particle and its rotational motion. Further, we derive the relation between the energetics and the rotational motion in the underdamped regime and show that energetic quantities can be inferred from dynamical properties.

This paper is organized as follows. Section II introduces the Brownian gyrator and its nonequilibrium features through Brownian dynamics, which we call the overdamped model. Section III describes how the inertial term in Langevin dynamics changes the system dynamics mainly concerning the rotational motion, which we call the inertial model. Section IV clarifies how the stochastic energetics relates to rotational motion in the underdamped regime.

II. OVERDAMPED MODEL

A. Tilted PDF and rotational motion

In the overdamped model, we consider a particle moving in a 2D plane with the position \( \mathbf{x} = (x_1, x_2)^T \) and neglect the inertial term. The particle undergoes an anisotropic harmonic potential, \( U(\mathbf{x}) = \frac{1}{2} \mathbf{x}^T \mathbf{U} \mathbf{x} \) where \( U = (u \ k \ -k u) \) with \( u < k \), and it contacts with two different heat baths at temperature \( T_1 \) and \( T_2 \) (< \( T_1 \)); see Fig. 1(a). Then, the Langevin equation for this model can be written as

\[
\gamma \dot{\mathbf{x}}(t) = -\nabla_x U(\mathbf{x}(t)) + \mathbf{\xi}(t),
\]

where \( \gamma \) is the Stokes friction coefficient and \( \mathbf{\xi} \equiv (\xi_1, \xi_2)^T \) is a Gaussian white noise satisfying \( \langle \xi_i(t) \rangle = 0 \) and \( \langle \xi_i(t) \xi_j(t') \rangle = 2 \gamma T_i \delta_{ij} \delta(t - t') \). The angle bracket \( \langle \cdot \rangle \) stands for the ensemble average. We set Boltzmann’s constant \( k_B = 1 \) and all parameters are dimensionless.

To obtain the probability density function (PDF) and the probability current, we consider the associated Fokker–Planck equation given by

\[
\frac{\partial p(\mathbf{x}, t)}{\partial t} = -\nabla_\mathbf{x} \cdot \mathbf{j}_\mathbf{x}(\mathbf{x}, t),
\]

where the probability current \( \mathbf{j}_\mathbf{x}(\mathbf{x}, t) \) is defined by

\[
\mathbf{j}_\mathbf{x}(\mathbf{x}, t) = -\left[ \frac{1}{\gamma} \nabla_x U(\mathbf{x}) + \mathbf{D} \cdot \nabla_x \right] p(\mathbf{x}, t).
\]

Here, the diffusion matrix is given as \( \mathbf{D} \equiv \frac{1}{2} \begin{pmatrix} T_1 & 0 \\ 0 & T_2 \end{pmatrix} \). The first term on the right-hand side of Eq. (3) is the drift current determined by potential \( U(\mathbf{x}) \), and the second term is the diffusion current of the system [52].

We calculate the steady-state PDF \( p(\mathbf{x}) \) using the method in Appendix A. The covariance matrix in the steady-state \( \mathbf{C}_{\mathbf{x} \mathbf{x}} \) for \( \mathbf{x} \) defined as \( \langle \mathbf{x} \mathbf{x}^T \rangle \) is given by

\[
\mathbf{C}_{\mathbf{x} \mathbf{x}} = \frac{1}{2k(2 - u^2)} \begin{pmatrix} 2T_1 k^2 (T_2 - T_1) u^2 & -T_1 + T_2 \kappa u \\ -T_1 + T_2 \kappa u & 2T_2 k^2 (T_1 - T_2) u^2 \end{pmatrix},
\]

and \( p(\mathbf{x}) \) is

\[
p(\mathbf{x}) = \frac{1}{2\pi \sqrt{\det \mathbf{C}_{\mathbf{x} \mathbf{x}}}} \exp \left( -\frac{1}{2} \mathbf{x}^T \mathbf{C}^{-1}_{\mathbf{x} \mathbf{x}} \mathbf{x} \right).
\]

Inserting \( p(\mathbf{x}) \) into Eq. (3), we can easily obtain the probability current \( \mathbf{j}_\mathbf{x}(\mathbf{x}) \). When \( T_1 \neq T_2 \) and \( u \neq 0 \), \( \mathbf{j}_\mathbf{x}(\mathbf{x}) \) has a non-zero value, which implies that the system is in NESS. The rotational property of \( \mathbf{j}_\mathbf{x}(\mathbf{x}) \) is represented as an angular current, denoted as \( \mathbf{x} \times \mathbf{j}_\mathbf{x}(\mathbf{x}) \) in Fig. 1(a), where \( \mathbf{x} \times \mathbf{j}_\mathbf{x}(\mathbf{x}) = x_1 j_{\mathbf{x},2}(\mathbf{x}) - x_2 j_{\mathbf{x},1}(\mathbf{x}) \). This current can be divided into drift and diffusion parts as seen in Fig. 1(b); hence, we demonstrate that the resulting rotational motion arises from the combined effects of these two angular currents.

One of the features of NESS is a tilted PDF compared to the equilibrium state whose shape is determined by a potential. For example, when our system is in equilibrium \( (T_1 = T_2 = T) \), the inverse of the covariance matrix is given by \( \mathbf{C}^{-1}_{\mathbf{x} \mathbf{x}} = \frac{1}{2} \mathbf{U} \). In this case, the principal axes of the PDF and the aspect ratio of the variances along the principal axes (\( \sigma_1 / \sigma_2 \)) coincide with the values of potential \( U \). However, in NESS, the PDF is tilted to a higher temperature axis (i.e., \( x_1 \)-axis) compared to the equilibrium state, as shown in Fig. 2(a), and thus the PDF cannot fully cover the potential. In other words, the principal axes of \( \mathbf{C}^{-1}_{\mathbf{x} \mathbf{x}} \) do not coincide with the principal axes of \( U \) in NESS.
of specific angular momentum measures of the violation of detailed balance. The mean stochastic area tensor \([44, 47]\) as well as the probability current that rotates around the center. To quantify the inertial model satisfies the Fokker–Planck equation \[\partial_t \rho(x, t) = -\nabla \cdot \mathbf{j}_\rho(x, t) - \nabla \cdot \mathbf{j}_v(x, t)\] in the limit of \(m \to \infty\). The other parameters are fixed as \(k = 3/2, u = 1/2, T_1 = 5, T_2 = 1,\) and \(\gamma = 1\).

The NESS is characterized by a non-zero probability current that rotates around the center. To quantify this rotational motion, we set the specific angular momentum \(j_\theta(x, t) = x(t) \times \mathbf{v}(x, t)\), where the mean local velocity conditioned on \(x\) is \(\mathbf{v}(x, t) \equiv \langle \dot{x}|x, t = j_\theta(x, t)/\rho(x, t)\rangle [14]\). This term, \(j_\theta(x, t)\), is related to the stochastic area tensor \([44, 47]\) as well as the probability angular momentum \([59]\), which have been proposed as measures of the violation of detailed balance. The mean of specific angular momentum \(\langle j_\theta \rangle_{ss}\) can be evaluated as

\[
\langle j_\theta \rangle_{ss} = \langle \mathbf{x} \times \mathbf{v}(x, t) \rangle_{ss} = \frac{u}{k\gamma} (T_2 - T_1),
\]

where \(\langle \cdot \rangle_{ss}\) denotes the ensemble average in the steady state. In Eq. (6), \(\langle j_\theta \rangle_{ss}\) is proportional to \(u(T_2 - T_1)\), which means that the rotational motion is caused by two effects: temperature difference and anisotropy of the potential. Since the rotational motion of a particle reflects that the system is in NESS, we can confirm that two different temperatures and anisotropy of potential are the sources of the nonequilibrium state.

III. INERTIAL MODEL

A. Steady-state PDF: Approaching equilibrium

To investigate the effects of inertia on a particle in NESS, we consider the Brownian gyrator in an underdamped regime, called the inertial model. The Langevin equation of a particle of mass \(m\) is given by

\[
\dot{x}(t) = \mathbf{v}(t),
\]

\[
m \dot{\mathbf{v}}(t) = -\nabla_x U(x(t)) - \gamma \mathbf{v}(t) + \xi(t),
\]

where the velocity \(\mathbf{v} \equiv (v_1, v_2)^T\). The PDF \(p(x, v, t)\) in the inertial model satisfies the Fokker–Planck equation associated with Eq. (7) written as

\[
\frac{\partial p(x, v, t)}{\partial t} = -\nabla_x \cdot \mathbf{j}_x(x, v, t) - \nabla_v \cdot \mathbf{j}_v(x, v, t),
\]

where the probability currents are given as

\[
\mathbf{j}_x(x, v, t) = \mathbf{v} p(x, v, t),
\]

\[
\mathbf{j}_v(x, v, t) = -\left( \frac{1}{m} \mathbf{U} \cdot \mathbf{x} + \frac{1}{m} \Gamma \cdot \mathbf{v} + \mathbf{D} \cdot \nabla \mathbf{v} \right) p(x, v, t).
\]

Here, \(\Gamma \equiv \begin{pmatrix} \gamma & 0 \\ 0 & \gamma \end{pmatrix}\) and \(\mathbf{D} \equiv \frac{\gamma}{m^2} \begin{pmatrix} T_1 & 0 \\ 0 & T_2 \end{pmatrix}\) are \(2 \times 2\) matrices related to the dissipation due to friction and the diffusion, respectively. The steady-state PDF \(p(z)\) is obtained as

\[
p(z) = \frac{1}{2\pi\sqrt{\det \mathbf{C}}} \exp \left(-\frac{1}{2} z^T \cdot \mathbf{C}^{-1} \cdot z\right),
\]

where the state vector \(z \equiv (x_1, x_2, v_1, v_2)^T\) and the covariance matrix \(\mathbf{C} \equiv \langle zz^T \rangle_{ss}\). The complete expression of \(\mathbf{C}\) is given in Appendix A.

Integrating the PDF of Eq. (10) over \(v\), the change of positional PDF with \(m\) is illustrated in Fig. 2(a). Compared with the overdamped model (leftmost), the PDF with inertia is less tilted, and its elliptical shape becomes more circular as \(m\) increases. To quantify this asymptotic behavior of the PDF, we take two measures: the slope of the minor principal axis of the PDF \((\tan \phi)\) and the aspect ratio of the variances along the principal axes \((\sigma_1/\sigma_2)\). In evaluating \(\tan \phi\), \(\phi\) is the tilt angle between the minor principal axis and the \(x_1\)-axis, as shown in Fig. 2(b). The variances along the principal axes denoted as \(\sigma_1\) and \(\sigma_2\) are obtained by the eigenvalues of the covariance matrix of \(x\). Figure 2(b) plots the analytical results of the \(\tan \phi\) and \(\sigma_1/\sigma_2\) measures as a function of \(m\). They converge to 1 and \((k - u)/(k + u)\) in the limit of \(m \to \infty\), respectively, where the convergent values are equal to the values of potential \(U\). From the fact that the tilted PDF is one piece of evidence for the NESS, these reflect that the system approaches equilibrium from the NESS as the inertia becomes significant. This result is not surprising because the diffusion matrix \(\mathbf{D}\) is inversely proportional to \(m^2\), and hence the diffusion effects caused by the temperature difference are diminished with \(m\).
This relation gives us not only a simpler calculation but also that the particle are not separate but highly related phenomena. Thus, the tilted PDF and the rotational motion of the particle, i.e. how much the positional PDF is tilted.

\[ \langle j_\theta \rangle_{ss} = 0 \]

**(B.) Specific angular momentum and its fluctuation: Non-monotonic behaviors**

In the inertial model, the specific angular momentum is defined as \( j_\theta (x, v, t) \equiv \langle x(t) \times v(t) \rangle \). The mean, \( \langle j_\theta \rangle_{ss} \), can be obtained using the covariance between \( x \) and \( v \) in \( C \), but it is also possible using the relation with a systematic torque \( M \) which the particle exerts on the potential as

\[ \langle j_\theta \rangle_{ss} = -\frac{1}{\gamma} M, \quad (11) \]

where \( M \equiv \langle x \times \nabla_x U(x) \rangle_{ss} \) [40]. This relation has been shown in the overdamped system in Ref. [41], but a proof with inertia has been absent. We derive this relation in the inertial model in Appendix B. Using Eq. (11), \( \langle j_\theta \rangle_{ss} \) in the inertial model is obtained as

\[ \langle j_\theta \rangle_{ss} = -\frac{1}{\gamma} M = \frac{u}{\gamma}(x^2_t - x^2_1)_{ss} = \frac{\gamma u(T_2 - T_1)}{k\gamma^2 + u^2m}. \quad (12) \]

Here, \( \langle j_\theta \rangle_{ss} \) is determined by the difference between the two variances, i.e. how much the positional PDF is tilted. Thus, the tilted PDF and the rotational motion of the particle are not separate but highly related phenomena. This relation gives us not only a simpler calculation but an important feature for measuring \( \langle j_\theta \rangle_{ss} \). In the underdamped regime, measuring the velocity field is necessary for a full description of the Langevin dynamics. Nevertheless, \( \langle j_\theta \rangle_{ss} \) can be estimated by experimentally given quantities and measurements of the variances of displacements from a positional trajectory of a particle without knowledge of the velocity field.

We take into account two parameters, \( m \) and \( u \), to describe how and to what extent the system dynamics are changed with the inertial term since \( u \) is a controllable parameter in experiments and has a crucial role in keeping the NESS in our system. Figure 3(a) represents \( \langle j_\theta \rangle_{ss} \) and \( M \) as functions of \( m \) and shows that they vanish as \( m \) increases, similarly with the tilted PDF. This result can be intuitively understood by considering the ensemble-averaged moment of inertia of the particle, \( I_0 \), which is derived as

\[ I_0 \equiv m\langle x^2_t + x^2_1 \rangle_{ss} = m\frac{k(T_1 + T_2)}{k^2 - u^2}. \quad (13) \]

\( I_0 \) is directly proportional to \( m \) as expected; accordingly, finding the rotational motion is more difficult for large \( m \). The interesting point is that, in this case, the dependence of \( \langle j_\theta \rangle_{ss} \) on \( u \) is qualitatively changed from the overdamped model as follows: \( \langle j_\theta \rangle_{ss} \) in the overdamped model has a monotonic dependence on \( u \), whereas \( \langle j_\theta \rangle_{ss} \) with finite inertia is maximized at a specific value of \( u \) and becomes smaller as \( u \) approaches \( k \), as shown in Fig. 3(b). For \( m = 0 \), how strongly the two different heat baths are coupled only determines the magnitude of the rotational motion, and thus the monotonic dependence on \( u \) is natural. However, when we consider the inertial term, \( I_0 \) is more significant at high \( u \) because of the large radial variance \( \langle x^2_t + x^2_1 \rangle_{ss} \), and this makes the rotational motion difficult to perform. As the combined effects of the two coupled heat baths and \( I_0 \), \( \langle j_\theta \rangle_{ss} \) of the inertial model shows a non-monotonic behavior with \( u \) in contrast to the overdamped model.

As the next step to grasp how inertia affects the stochastic dynamics of rotational motion, we consider the fluctuation of \( j_\theta (t) \), which is defined as

\[ D_\theta \equiv \lim_{t \to \infty} \frac{t}{2} (\langle j_\theta(t)^2 \rangle - \langle j_\theta(t)^2 \rangle). \quad (14) \]

The fluctuation with finite inertia, denoted by \( D_\theta \), can be explicitly derived as

\[ D_\theta = D_\theta^{th} + D_\theta^{neq}, \quad (15) \]

where

\[ D_\theta^{th} = \frac{2\gamma T_1 T_2}{k\gamma^2 + u^2m}, \]
\[ D_\theta^{neq} = \frac{\gamma u^2(\gamma^4 + u^2m^2 + 5k\gamma^2 m)(T_1 - T_2)^2}{2(k\gamma^2 + u^2m)^3}. \quad (16) \]

To simplify the expressions, \( D_{\theta,0} \) denotes the fluctuation in the overdamped model, which is given by

\[ D_{\theta,0} = \frac{2T_1 T_2}{k\gamma} + \frac{u^2(T_1 - T_2)^2}{2k\gamma^3}. \quad (17) \]

The detailed method is written in Appendix C. We divided \( D_\theta \) into two terms, \( D_\theta^{th} \) and \( D_\theta^{neq} \). Here, \( D_\theta^{th} \) is strictly positive in any condition, but \( D_\theta^{neq} \) appears only in a nonequilibrium state \( (T_1 \neq T_2 \text{ and } u \neq 0) \).
As can be seen in Fig. 4(a), $D_\theta$ has an obviously different curve from $D_{\theta,0}$ along $u$; while $D_{\theta,0}$ monotonically increases with $u$, $D_\theta$ decreases as $u$ approaches $k$. This difference comes from the fact that $I_0$ becomes large as $u$ approaches $k$ so that the variance of the rotational motion should be small at large $u$. The remarkable point is that $D_\theta$ is maximized at a non-zero $u^*$, which means the stability of rotation is minimized at this specific $u$. Furthermore, in a certain range of $u$, $D_\theta$ exceeds $D_{\theta,0}$ under a specific condition, that is $\chi > \chi_c$, where $\chi \equiv T_2/T_1$ ($> 1$) and the critical temperature ratio is denoted by $\chi_c$. To obtain the analytical expression of $\chi_c$, we expand $D_\theta$ as

$$D_\theta = D_{\theta,0} + D_{\theta,u}u^2 + O(u^4),$$

where

$$D_{\theta,u} = \frac{5(T_1 - T_2)^2 - 4T_1T_2}{2k^2\gamma^3}m.$$  \hspace{1cm} (18)

When $D_{\theta,u}$ is positive, $D_\theta$ increases more rapidly than $D_{\theta,0}$ near $u = 0$. Thus, $\chi_c$ is obtained as

$$\chi_c = \frac{7 + 2\sqrt{6}}{5}. \hspace{1cm} (19)$$

Figure 4(b) plots $D_{\theta,u}$ (top) and $u^*$ (bottom) as a function of $\chi$. Note that the minimum value of $\chi$ for non-zero $u^*$ is denoted by $\chi_c^*$, which is less than $\chi_c$. Actually, $\chi_c$ is the upper bound of $\chi_u^*$, where

$$\chi_u^* = 1 + \frac{2\left(1 + \sqrt{6 + \gamma^2/km}\right)}{5 + \gamma^2/km}.$$ \hspace{1cm} (20)

Here, $\chi_u^*$ has a value in the range $(1, \chi_c)$ according to the value of $\gamma^2/km$. Thus, $D_\theta$ is maximized at the non-zero $u^*$ and exceeds $D_{\theta,0}$ for $\chi > \chi_c$ at the same time. The dashed dotted line in the bottom panel of Fig. 4(b) indicates the limit of $u^*$ given by

$$u^* < \frac{\gamma}{m}\sqrt{\frac{\gamma^4 + 9k\gamma^2m + 21k^2m^2 - 4km - \gamma^2}{2}}. \hspace{1cm} (21)$$

If the limit from Eq. (22) is larger than $k$, $u^* < k$ due to the existence condition for steady state (see Appendix A).

A similar behavior is also observed along $m$, as can be seen in Fig. 4(c). $D_\theta$ is maximized not at $m = 0$ but at an optimal mass $m^*$ under a specific condition, which means the stability of rotation can be minimized at this specific mass. To obtain the condition for the non-zero $m^*$, we expand $D_\theta$ near $m = 0$ as

$$D_\theta = D_{\theta,0} + D_{\theta,m}m + O(m^2), \hspace{1cm} (23)$$

where

$$D_{\theta,m} = \frac{(5k^2 - 3u^2)(T_1 - T_2)^2 - 4k^2T_1T_2}{2k^4\gamma^3}u^2.$$ \hspace{1cm} (24) \hspace{1cm} \text{(24)}

Since $D_{\theta,m}$ should be positive for the non-zero $m^*$, $D_\theta$ can be separated into two regions, as illustrated in Fig. 4(d), where $D_{\theta,m}$ has a negative (positive) value in region I (II) and thus $D_\theta$ decreases (increases) as $m$ increases. Intriguingly, Eq. (23) matches Eq. (18) for $u^2 \ll k^2$, i.e. $D_{\theta,m}m \approx D_{\theta,u}u^2$. This correspondence leads to similar non-monotonic behaviors of $D_\theta$ along $u$ and $m$ as well as reveals the condition $\chi_c$ at the boundary of regions I and II, as indicated in Fig. 4(d).

While we analytically showed that $D_\theta$ has increasing parts with $u$ and $m$ under specific conditions, it is not easy to clarify what induces these behaviors through the expression of $D_\theta$ alone. To explain the origin of the non-monotonic curves, we divide $D_\theta$ into four terms as

$$D_\theta \approx \lim_{t \to \infty} \frac{1}{2} \frac{1}{2} (\text{Cov}(r^4, \omega^2) + \langle \omega \rangle^2 \text{Var}(r^2)) + \langle r^2 \rangle^2 \text{Var}(\omega) + C_\theta,$$ \hspace{1cm} (25)

where the cycling frequency is defined as $\omega \equiv (\mathbf{r} \times \mathbf{v})/r^2$, $\text{Cov}(r^4, \omega^2) \equiv \langle r^4 \omega^2 \rangle_{ss} - \langle r^4 \rangle_{ss} \langle \omega^2 \rangle_{ss}$, and $C_\theta \equiv \langle r^2 \rangle_{ss} \langle \omega \rangle_{ss}^2 - \langle r^2 \rangle_{ss} \langle \omega \rangle_{ss}^2$. Here, we neglect $\text{Var}(r^2) \text{Var}(\omega)$. Because only $C_\theta$ is calculable and determined independent of time, we measure the other terms by Langevin simulations with time step $\Delta t = 10^{-3}$ and total simulation.
time $t = 10^3$. Figure 5 depicts the Langevin simulation results for $\langle \omega \rangle^2_{ss} \text{Var}(r^2)$, $\text{Cov}(r^4, \omega^2)$, $\langle r^2 \rangle^2_{ss} \text{Var}(\omega)$, and $C_\theta$. Although the magnitudes of $\text{Cov}(r^4, \omega^2)$ and $C_\theta$ are much larger than the others, we should consider all terms since the true behavior of $D_\theta$ will not be revealed if we neglect any of the terms.

Let us firstly discuss $D_\theta$ in terms of $u$. The divergence of $\langle r^2 \rangle_{ss}$ in the limit of $u \to k$ results in large magnitudes of all terms as $u$ approaches $k$, as shown in Fig. 5(a–d). This increase at large $u$ is a common property between the inertial and overdamped models. The main discrepancy between the two models, though, is that there are local optimum points at specific $u$ caused by $\langle \omega \rangle_{ss}$. Since the inertia of the particle shifts the peak of $\langle \omega \rangle_{ss}$ to lower $u$ (see Fig. 7 in Appendix B), we find curved shapes of $\langle \omega \rangle^2_{ss} \text{Var}(r^2)$, $\text{Cov}(r^4, \omega^2)$, and $C_\theta$. We note that $\langle r^2 \rangle_{ss}$ is proportional to $T_1 + T_2$ whereas $\langle \omega \rangle_{ss}$ increases with $|T_1 - T_2|$. Therefore, when $|T_1 - T_2|$ is not sufficiently large, the curved shapes do not appear and the crossover between $\langle r^2 \rangle_{ss}$ and $\langle \omega \rangle_{ss}$ leads to the non-trivial behavior of $D_\theta$ with $u$, as indicated in Fig. 4(a).

It is more complicated to describe the behavior of $D_\theta$ in terms of $m$ since $D_\theta$ is determined by the joint effects of several factors. As $\langle \omega \rangle_{ss}$ and $\text{Var}(\omega)$ become smaller with $m$, $\langle r^2 \rangle^2_{ss} \text{Var}(\omega)$ and $C_\theta$ monotonically decrease with $m$, as shown in Fig. 5(g,h). In the case of $\langle \omega \rangle^2_{ss} \text{Var}(r^2)$, $C_\theta$ has a role to resist changes in rotational motion, and this induces an increase of radial variance $\text{Var}(r^2)$ with $m$ [35]. Thus, $\langle \omega \rangle^2_{ss} \text{Var}(r^2)$ has a curved shape as illustrated in Fig. 5(e). $\text{Cov}(r^4, \omega^2)$ has a negative value due to the elliptical shape of the rotational motion (Figs. 1 and 2), but because the elliptical shape becomes circular and the magnitude of $\langle j_\theta \rangle_{ss}$ decreases with increasing $m$, the magnitude of $\text{Cov}(r^4, \omega^2)$ approaches zero (i.e., increases), as shown in Fig. 5(f). Therefore, we can conclude that the increases of $\text{Var}(r^2)$ and $\text{Cov}(r^4, \omega^2)$ along with the decrease of $\langle \omega \rangle_{ss}$ together produce the non-trivial curves of $D_\theta$ with $m$.

IV. STOCHASTIC ENERGETICS: RELATION TO SPECIFIC ANGULAR MOMENTUM

To this point we have focused on how inertia affects the system dynamics of a Brownian gyrator, i.e., a tilted PDF and a specific angular momentum. In the present section, we analytically calculate energetic quantities and show that the system dynamics is highly related to the system energetics. Using this relation, it is possible to infer the behavior of energetic quantities through accessible variables in an underdamped regime. In models with multiple heat baths, such as a Brownian gyrator, estimations of the energetic quantities using the stochastic area tensor [47] and the cycling frequency [41] have been reported, but they are restricted to the overdamped regime. Therefore, we extend the previous studies to the underdamped regime and additionally calculate the fluctuations of the energetic quantities in this section.

To calculate the mean current of the absorbed heat, let $dQ_i$ denote the absorbed heat from the environment along $x_i$ over time interval $dt$. Then the absorbed heat is written as

$$dQ_i = (-\gamma v_i(t) + \xi_i(t)) \circ dx_i(t), \quad (26)$$

where $dx_i(t)$ is the evolution of $x_i(t)$ over $dt$ and $\circ$ denotes the Stratonovich product [54]. Using the Langevin equation with finite inertia [Eq. (7)], $dQ_i$ can be expressed in different ways such as $dQ_i = (m\dot{v}_i(t) + \nabla_{x_i} U(x)) \circ dx_i(t)$. 

![Figure 5](https://example.com/figure5.png)
The hot bath is equally dissipated to the cold bath. In our observation law; more specifically, the energy absorbed from production, which is defined by the sum of the system baths. This exchanged heat increases the total entropy different heat baths and converts the rotational motion proportional to the exchanged heat between the two heat baths is proportional to \( \gamma u^2(T_2 - T_1)^2 \).

Thus, we obtain the absorbed heat \( dQ_i \) as follows [55]:

\[
dQ_1 = d \left( \frac{1}{2}mv_1^2 + \frac{1}{2}kx_1^2 + \frac{1}{2}ux_1x_2 \right) - \frac{u}{2} (x_1v_2 - x_2v_1) dt,
\]

\[
dQ_2 = d \left( \frac{1}{2}mv_2^2 + \frac{1}{2}kx_2^2 + \frac{1}{2}ux_1x_2 \right) + \frac{u}{2} (x_1v_2 - x_2v_1) dt.
\]

Since the change of internal energy defined as \( dE = dQ_1 + dQ_2 = d \left( mv^2/2 + U(x) \right) \) cannot affect the steady-state average, the mean heat currents in the steady state are given by

\[
\langle Q_2 \rangle_{ss} = \frac{u}{2} \langle x_1v_2 - x_2v_1 \rangle_{ss}
\]

\[
= \frac{u}{2} \langle j_\theta \rangle_{ss} = \frac{\gamma u^2(T_2 - T_1)}{2(k\gamma^2 + u^2m)}.
\]

where \( \langle Q_2 \rangle_{ss} = -\langle Q_1 \rangle_{ss} \), which reflects the energy conservation law; more specifically, the energy absorbed from the hot bath is equally dissipated to the cold bath. In our system, \( \langle Q_1 \rangle_{ss} \) is positive due to \( T_1 > T_2 \). Additionally, the exchanged heat between the two heat baths is proportional to \( \langle j_\theta \rangle_{ss} \) and vanishes at \( u = 0 \). These tendencies imply that an anisotropic potential connects the two different heat baths and converts the rotational motion of the particle to heat that is exchanged between the baths. This exchanged heat increases the total entropy production, which is defined by the sum of the system and medium entropy productions. The total production rate in the steady state \( \langle S \rangle_{ss} \) is obtained by

\[
\langle S \rangle_{ss} = -\frac{\langle Q_1 \rangle_{ss}}{T_1} - \frac{\langle Q_2 \rangle_{ss}}{T_2}
\]

\[
= \left( \frac{1}{T_1} - \frac{1}{T_2} \right) \frac{u}{2} \langle j_\theta \rangle_{ss} = \frac{\gamma u^2(T_2 - T_1)^2}{2T_1T_2(k\gamma^2 + u^2m)}.
\]

Because the system entropy production rate vanishes in steady state, \( \langle S \rangle_{ss} \) coincides with the medium entropy production rate, \( \langle S_m \rangle_{ss} \). Total entropy production can be used to quantify the violation of detailed balance and has a positive value in a NESS. Here, \( \langle S \rangle_{ss} \geq 0 \) and the equality is satisfied when \( u = 0 \) or \( T_1 = T_2 \), that is the condition for the NESS of our system. As shown in Eqs. (28) and (29), \( \langle Q_1 \rangle_{ss} \) and \( \langle S \rangle_{ss} \) are proportional to \( \langle j_\theta \rangle_{ss} \). Note that we only need the variances of the positional trajectories of the particle to measure \( \langle j_\theta \rangle_{ss} \). Therefore, the system energetics can be easily obtained from only the positional trajectories without observing the velocity fields.

Next, let us evaluate the fluctuations of the energetic quantities, which is necessary to understand the stochastic properties of the energetics or to design a reliable heat engine. Fluctuation of absorbed heat \( D_Q \) is defined as

\[
D_Q = Q_1 = Q_2 = \lim_{t \to \infty} \frac{t}{2} \left( \langle Q_1(2) \rangle(t) - \langle Q_1(2) \rangle(t) \right)^2.
\]

As indicated in the equation, \( D_Q \) and \( D_{Q_2} \) are the same since the absorbed heats are symmetrically coupled by \( u \). The relation between \( D_Q \) and \( D_\theta \) can be obtained as

\[
D_Q = \frac{u^2}{4} D_\theta.
\]

The detailed calculation is written in Appendix C. In the same way, fluctuation of the medium entropy production \( D_{S_m} \) is given by

\[
D_{S_m} = \left( \frac{1}{T_1} - \frac{1}{T_2} \right)^2 \frac{u^2}{4} D_\theta.
\]

Thus, \( D_Q \) and \( D_{S_m} \) are also proportional to \( D_\theta \), similar to the result with the mean currents. According to Eqs. (28), (29), (30), and (32), we know that the mean current and the fluctuations of heat and medium entropy production have the same curves as \( \langle j_\theta \rangle_{ss} \) and \( D_\theta \) as a function of \( m \): \( \langle Q_1 \rangle_{ss} \) and \( \langle S \rangle_{ss} \) become smaller with increasing \( m \), and \( D_Q \) and \( D_{S_m} \) are maximized at \( m^* \) and exceed the overdamped ones in region II as depicted in Fig. 4(d). Despite these similarities to the system not only with \( m \) but also other parameters, only the dependence on \( u \) differs, as shown in Fig. 6(a) and (b). \( \langle Q_1 \rangle_{ss} \) and \( D_Q \) are not typically maximized at moderate \( u \), while their magnitudes increase with \( u \) in contrast to \( D_\theta \). Nonetheless, some important features still remain. First, \( |\langle Q_1 \rangle_{ss}| \) is sufficiently smaller than the value from
Thus, investigating the work current ˙\(W\) of Brownian dynamics. In the inertial model, the mean of the measure \(j\) shows similar behavior. The mean of specific an\(\frac{\text{t}}{\text{c}}\) increases and vanish with increasing mass, starting from the case of the overdamped model. The mean of \(j\) selected as the measure of the rotational motion and proportional to the systematic torque, \(j\), in contrast to its description with Brownian dynamics. Several NESS features of the Brownian gyrator (such as a tilted PDF, rotational motion, and entropy production by the heat current between the two heat baths) distinguish the inertial model from the overdamped model, i.e., Langevin dynamics from Brownian dynamics.

From the analytic solution of the Fokker–Planck equation and the simulation of each model, we have shown that the inertia plays an important role in resisting the breakdown of the detailed balance and reducing the nonequilibrium effects. For instance, in the inertial model, the distortion and tilt of the positional PDF decrease and vanish with increasing mass, starting from the case of the overdamped model. The mean of specific angular momentum \(j_\theta\), selected as the measure of the rotational motion and proportional to the systematic torque, also shows similar behavior.

The most salient feature of our Langevin dynamics description is the non-monotonic behavior of the measure for the rotational motion, which cannot be found through Brownian dynamics. In the inertial model, the mean of \(j_\theta\) has a non-monotonic behavior along \(u\). This is because the anisotropy \(u\) initiates the rotational motion while the averaged moment of inertia, increasing with \(u\), has a contrary role in resisting the rotational motion. Next, the fluctuation of \(j_\theta\) has non-monotonic behaviors along \(u\) and \(m\). Intriguingly, we have found that the fluctuation of \(j_\theta\) with inertia is larger than the value of the overdamped model in some specific conditions. These non-monotonic behaviors of the rotation-related quantity appear only in the inertial model. It will be interesting work, therefore, to check whether other nonequilibrium systems have similar non-monotonic features or not.

Considering this intrinsic difference between the two descriptions, i.e., inertial and overdamped models, even in a long time limit, it is necessary to choose Langevin dynamics rather than Brownian dynamics except under the special condition of negligible mass compared to friction. Brownian dynamics may be inadequate to study the Brownian gyrator in experiment, where the particle is not so tiny that it is controllable and observable.

Finally, we have clarified how the system energetics is associated with the system dynamics in the underdamped regime. We have shown that the mean current and fluctuation of heat currents and entropy production could be inferred using the dynamic characteristics of the system. For example, by observing the tilted angle of the positional PDF or the rotational motion of the particle, it is possible to infer how much energy is exchanged or how much total entropy production increases.

We expect our results to be helpful in studying the dynamic properties of various systems with motion influenced by inertia, such as insects, microflyers, and other mesoscale organisms [29]. Moreover, our results will provide practical ways to investigate various biological systems from an energetic perspective or to quantify the violation of detailed balance. In many experimental cases, detailed information is frequently unknown, and it is difficult to estimate the energetics directly. The dynamic characteristics can be adequate measures in such systems for estimating the energetics or inferring their behaviors, as also claimed in Refs. [41, 47]. Particularly, \(j_\theta\) will be a useful tool for measuring the energetics of tractable nonequilibrium systems because \(j_\theta\) is directly associated with them and can be evaluated using experimentally accessible quantities and positional trajectories.

As future work, various models in NESS such as the \(N\) bead-spring model or self-propelled particles can be considered to study the inertial effects and the relation between the dynamics and the energetics of the system.

V. CONCLUSIONS

In our work, we have examined how Langevin dynamics describes the rotating particle of the Brownian gyrator by explicitly considering the inertia of the particle, in contrast to its description with Brownian dynamics. Considering this intrinsic difference between the two descriptions, i.e., inertial and overdamped models, even in a long time limit, it is necessary to choose Langevin dynamics rather than Brownian dynamics except under the special condition of negligible mass compared to friction. Brownian dynamics may be inadequate to study the Brownian gyrator in experiment, where the particle is not so tiny that it is controllable and observable.

Finally, we have clarified how the system energetics is associated with the system dynamics in the underdamped regime. We have shown that the mean current and fluctuation of heat currents and entropy production could be inferred using the dynamic characteristics of the system. For example, by observing the tilted angle of the positional PDF or the rotational motion of the particle, it is possible to infer how much energy is exchanged or how much total entropy production increases.

We expect our results to be helpful in studying the dynamic properties of various systems with motion influenced by inertia, such as insects, microflyers, and other mesoscale organisms [29]. Moreover, our results will provide practical ways to investigate various biological systems from an energetic perspective or to quantify the violation of detailed balance. In many experimental cases, detailed information is frequently unknown, and it is difficult to estimate the energetics directly. The dynamic characteristics can be adequate measures in such systems for estimating the energetics or inferring their behaviors, as also claimed in Refs. [41, 47]. Particularly, \(j_\theta\) will be a useful tool for measuring the energetics of tractable nonequilibrium systems because \(j_\theta\) is directly associated with them and can be evaluated using experimentally accessible quantities and positional trajectories.

As future work, various models in NESS such as the \(N\) bead-spring model or self-propelled particles can be considered to study the inertial effects and the relation between the dynamics and the energetics of the system.

Appendix A: Steady-state probability density

To obtain the steady-state PDF \(p(x, v)\), let \(z \equiv (x_1, x_2, v_1, v_2)^T\) be a state vector. Then we can rewrite Eq. (7) as

\[
\dot{z}(t) = -F \cdot z(t) + \eta(t),
\]

where \(F = \left(\begin{smallmatrix} 0 & \gamma \\ -\gamma/m & m \end{smallmatrix}\right)\), \(0\) (I) is a 2 x 2 null (identity) matrix, and \(A\) and \(\Gamma\) are drift and friction matrices, respectively. \(\eta\) is a Gaussian white noise satisfying \(\langle \eta_\alpha(t) \rangle = 0 \) and \(\langle \eta_\alpha(t) \eta_\beta(t') \rangle = 2D_\alpha\delta_{\alpha\beta}\delta(t-t')\). Where \(D_\alpha = \left(\begin{smallmatrix} 0 & 0 \\ 0 & 0 \end{smallmatrix}\right)\) and \(\Gamma = \left(\begin{smallmatrix} \gamma & 0 \\ 0 & \gamma \end{smallmatrix}\right)\) and \(D \equiv \frac{1}{2m^2} \left(\begin{smallmatrix} \gamma & 0 \\ 0 & \gamma \end{smallmatrix}\right)\) as mentioned in Sec. III.
Since our system assumes an Ornstein–Uhlenbeck process, the steady-state PDF takes a Gaussian form as \( p(z) \propto \exp \left[ -(1/2)z^T \cdot C^{-1} \cdot z \right] \) where \( C \) is the covariance matrix of the state vector \( z \) in the steady state defined as \( \langle zz^T \rangle_{ss} \). The covariance matrix \( C \) is given by

\[
C = F^{-1}(D_z + Q), \quad (A2)
\]

where \( Q \) is an antisymmetric 4 x 4 matrix that can be uniquely determined by

\[
FQ + QF^T = FD_z - D_z F^T. \quad (A3)
\]

Here, \( Q \) is non-zero in the NESS, which implies the violation of the detailed balance \([57, 58]\). Solving Eq. (A3) and inserting the result into Eq. (A2), we obtain

\[
C = \begin{pmatrix}
\frac{2k^2 \gamma \nu x}{\gamma - \nu x} & \frac{2k \gamma \nu}{\gamma - \nu} & 0 & 0 \\
\frac{2k \gamma \nu}{\gamma - \nu} & \frac{2k^2 \gamma \nu}{\gamma - \nu} & 0 & 0 \\
0 & 0 & 0 & 2k \gamma \nu \\
0 & 0 & 2k \gamma \nu & \frac{2k^2 \gamma \nu}{\gamma - \nu}
\end{pmatrix}. \quad (A4)
\]

For the existence of a steady state, \( F \) should be positive-definite. This condition provides the existence condition for steady state \( u^2 < k^2 \). Otherwise, the particle diverges from the potential.

**Appendix B: Relation between the systematic torque and the specific angular momentum**

Here we derive the relation between the systematic torque and \( j_\theta(t) \) in Eq. (11) in the underdamped regime. The systematic torque \( \mathbf{M} \) that the particle exerts on the potential \( U(x) \) can be expressed as

\[
\mathbf{M} = -\gamma \int dx \times \mathbf{C} \cdot \mathbf{C}^{-1} \cdot \mathbf{x} \cdot \mathbf{p}(\mathbf{x})
\]

\[
+ m \int dx \times \mathbf{C} \cdot \mathbf{v} \cdot \mathbf{C}^{-1} \cdot \mathbf{x} \cdot \mathbf{p}(\mathbf{x}). \quad (B7)
\]

The first term on the right-hand side can be rearranged into a function of \( \langle j_\theta \rangle_{ss} \) as follows:

\[
-\gamma \int dx \times \mathbf{C} \cdot \mathbf{C}^{-1} \cdot \mathbf{x} \cdot \mathbf{p}(\mathbf{x})
\]

\[
= -\gamma \int dx \times (\mathbf{v} \times \mathbf{x}) \cdot \mathbf{p}(\mathbf{x}) = -\gamma \langle j_\theta \rangle_{ss}. \quad (B8)
\]

In the second row of Eq. (B8), we use the local averaged velocity \( \langle \mathbf{v} \times \mathbf{x} \rangle = \mathbf{C} \cdot \mathbf{C}^{-1} \cdot \mathbf{x} \) \([59]\). To evaluate the second term on the right-hand side of Eq. (B7), let us consider a linear transformation \( \mathbf{z}' = \mathbf{B} \cdot \mathbf{z} \) where \( \mathbf{B} \) is a non-singular matrix. Then, the covariance matrix in the transformed coordinates \( \mathbf{C}' \) can be given by \( \mathbf{C}' = \mathbf{B} \cdot \mathbf{C} \cdot \mathbf{B}^T \) \([60]\). If we consider the specific coordinates that satisfy \( \mathbf{C} = \mathbf{I} \), the second term on the right-hand side of Eq. (B7) vanishes:

\[
\int dx \times \mathbf{C} \cdot \mathbf{v} \cdot \mathbf{C}^{-1} \cdot \mathbf{x} \cdot \mathbf{p}(\mathbf{x})
\]

\[
= \int dx \times (-\mathbf{x}_2 \times \mathbf{x}_1) \cdot \mathbf{C} \cdot \mathbf{v} \cdot \mathbf{C}^{-1} \left( \begin{array}{c}
\mathbf{x}_1 \\
\mathbf{x}_2
\end{array} \right) \cdot \mathbf{p}(\mathbf{x})
\]

\[
= \frac{1}{\det \mathbf{B}} \int d\mathbf{x}' \cdot (-\mathbf{x}_2' \times \mathbf{x}_1') \cdot \mathbf{C} \cdot \mathbf{v} \cdot \mathbf{C}^{-1} \left( \begin{array}{c}
\mathbf{x}_1' \\
\mathbf{x}_2'
\end{array} \right) \cdot \mathbf{p}(\mathbf{x}') = 0,
\]

since \( \mathbf{C}' \) is a symmetric matrix. Consequently, we obtain the relation as

\[
\mathbf{M} = -\gamma \langle j_\theta \rangle_{ss}. \quad (B10)
\]

It is also possible to calculate the cycling frequency by using the relation in the same way as in Ref. \([41, 42]\). We can express the conditional average \( \langle \mathbf{v} \times \mathbf{x} \rangle \) in another way
as $\langle \mathbf{v}|\mathbf{x}\rangle = \Omega \cdot \mathbf{x}$, where $\Omega$ is a matrix of frequencies defined as $\Omega \equiv \mathcal{C}_{\alpha}^{-1} \mathcal{C}_{\alpha}^{-1}$ \[60\]. In the transformed coordinates, the matrix of frequencies is given by

$$\Omega' = \begin{pmatrix} 0 & -\alpha \\ \alpha & 0 \end{pmatrix},$$

(B11)

so $\Omega'$ is skew-symmetric. Thus, the eigenvalues of $\Omega$ can be obtained by $\lambda = \pm i \alpha$ where $\alpha$ is a real number. Then, $\langle j_\theta \rangle_{ss}$ can be calculated as

$$\langle j_\theta \rangle_{ss} = \int dx \ x \times \Omega \cdot \mathbf{x} p(x)$$

$$= \frac{1}{\det \mathcal{B}} \int d\mathbf{x}' \ \mathbf{x}' \times \Omega' \cdot \mathbf{x}' p(x)$$

(B12)

$$= \frac{\alpha}{\det \mathcal{B}} \langle x^2 \rangle_{ss} = \frac{\alpha}{2} \frac{\alpha}{\det \mathcal{B}}.$$

Using the fact that $\alpha$ is equal to the cycling frequency $\langle \omega \rangle_{ss}$ defined as $\omega(t) = (x(t) \times \mathbf{u}(t))/\tau(t)^2$ \[42\], the cycling frequency can be calculated as

$$\langle \omega \rangle_{ss} = \frac{\langle j_\theta \rangle_{ss}}{2 \sqrt{\det \mathcal{C}_{\alpha \alpha}}}$$

$$= \frac{\gamma u(T_2 - T_1) \sqrt{k^2 - u^2}}{\sqrt{(u^2 m + k \gamma)^2 (T_1 + T_2)^2 - \gamma^2 (k^2 - u^2)(T_1 - T_2)^2}}.$$

(B13)

Here, we used $\det \mathcal{B} = \sqrt{\det \mathcal{C}_{xx} / \det \mathcal{C}_{xx}}$ to derive Eq. (B13). As illustrated in Fig. 7, the magnitude of $\langle \omega \rangle_{ss}$ decreases with $m$ and the peak of $\langle \omega \rangle_{ss}$ shifts to lower $u$ as $m$ increases because $I_\theta$ becomes larger as $m$ and $u$ increase.

**Appendix C: Mean and fluctuation of energetic quantities**

In this section, we present how to calculate the fluctuations of $j_\theta$, absorbed heat, and medium entropy production using the scaled cumulant generating function (SCGF). We follow the same procedure as in Refs. [18, 19, 61]. Because the work current $W(t)$ is proportional to $j_\theta(t)$, we calculate the mean current and fluctuation of work instead of calculating the values of $j_\theta(t)$ directly.

When we apply an external force defined by $\mathbf{F}_{ext}(x(t)) = K(x_2 - x_1)^T$, the extracted work, absorbed heat, and medium entropy production over time $\tau$ are given by

$$W(\tau) = \int_0^\tau W \cdot \mathbf{z}(t) \circ dt(t),$$

(C1)

$$Q_{1(2)}(\tau) = \int_0^\tau Q_{1(2)} \cdot \mathbf{z}(t) \circ dt(t),$$

and

$$S_m(\tau) = -\int_0^\tau \left( \frac{Q_1}{T_1} + \frac{Q_2}{T_2} \right) \cdot \mathbf{z}(t) \circ dt(t)$$

(C2)

where the matrices $W$ and $Q_{1(2)}$ are defined as

$$W = \begin{pmatrix} 0 & K & 0 & 0 \\ -K & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix},$$

(C3)

$$Q_1 = \begin{pmatrix} k & u - K & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & m & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix},$$

(C4)

and

$$Q_2 = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ u + K & 0 & 0 & 0 \\ 0 & 0 & 0 & m \end{pmatrix}.$$ 

(C5)

They are dynamical observables due to the dependence on the trajectory over time $\tau$. Thus, the SCGF of work is written as

$$\lambda(h) = \lim_{\tau \to \infty} \frac{1}{\tau} \ln \langle \exp(hW(\tau)) \rangle$$

(C6)

$$= \langle W \rangle_{ss} h + DW h^2 + O(h^3),$$

with a real valued $h$. Here, the mean current and fluctuation of work are denoted as $\langle W \rangle_{ss}$ and $DW$, respectively. It is known that $\lambda(h)$ is the largest eigenvalue of the tilted operator given by

$$\mathcal{L}^\dagger = -\mathbf{z}^T \cdot F^T \cdot \left( \nabla_{\mathbf{z}} + hW \cdot \mathbf{z} \right)$$

$$+ \left( \nabla_{\mathbf{z}} + hW \cdot \mathbf{z} \right)^T \cdot D \cdot \left( \nabla_{\mathbf{z}} + hW \cdot \mathbf{z} \right),$$

(C7)

with $\nabla_{\mathbf{z}} \equiv \partial / \partial \mathbf{z}$. Equation (C6) can be derived from the fact that the quantity $\langle \exp(hW(t)) \rangle$ has a semi-group property and is governed by tilted operator [Eq. (C7)]. This is the so-called Feynman–Kac formula \[61\]. Assuming that the left eigenfunction $g(z, h)$ of $\lambda(h)$ is Gaussian as $g(z, h) = \exp(-\frac{1}{2} z^T \cdot G(h) \cdot z)$ with a symmetric matrix $G(h)$, the SCGF can be expressed as

$$\lambda(h) = \langle \mathcal{L}^\dagger(h) g(z, h) \rangle / g(z, h)$$

(C8)

$$= \text{tr} \{ D[hW - G] \} + z^T \cdot F^T (G - hW) \cdot z$$

$$+ z^T \cdot (hW - G)^T D(hW - G) \cdot z.$$
Comparing the coefficients, we can obtain
\[ \lambda(h) = \text{tr} \{ D[hW - G(h)] \}, \quad (C9) \]
and
\[ F^T(hW - G) + (hW - G)^T F = 2(hW - G)^T D(hW - G). \quad (C10) \]
To solve Eq. (C10), we expand \( G(h) \) near \( h = 0 \) as

\[ G(h) = G_1 h + G_2 h^2 + \mathcal{O}(h^3). \quad (C11) \]

Here, the constant term of \( G(h) \) is zero since \( \lambda(h) = 0 \) with \( g(z, h) = 1 \) [61]. Inserting Eq. (C11) into Eq. (C10) and comparing the coefficients of \( h \) and \( h^2 \), the mean current and fluctuation of work are obtained by

\[ \langle W \rangle_{ss} = \text{tr} \{ D(W - G_1) \} = \text{tr} \{ FCW_a \}, \quad (C12) \]
and

\[ D_W = -\text{tr} \{ DG_2 \} = \text{tr} \{ FCW_a C(W^T - G_1) \}, \quad (C13) \]

where \( W_a = (W - W^T)/2 \) is a skew-symmetric matrix. We used the Lyapunov equation \( FC + CF^T = 2D_2 \) to derive Eqs. (C12) and (C13).

Since the work done by the external force \( F_{ext} \) is proportional to \( j_\theta(t) \), we can calculate the mean and fluctuation of \( j_\theta(t) \) as

\[ (j_\theta)_{ss} = \lim_{K \to 0} \frac{-\langle W \rangle_{ss}}{K}, \quad D_\theta = \lim_{K \to 0} \frac{D_W}{K^2}. \quad (C14) \]

In the same way, the mean current and fluctuation of the absorbed heat and medium entropy production can also be obtained by using the matrix defined in Eqs. (C4) and (C5).
