Abstract

Thoracican barnacles of the Superorder Thoracicalcarea Gale, 2016 are sessile calcifiers which are ubiquitous in the intertidal zone and present from very shallow to the deepest marine environments; they also live as epiplanктon on animals and detritus. The geochemical composition of their shell calcite has been shown to yield information about environmental conditions, but comprehensive analyses of barnacle shell geochemistry are so far lacking.

Here, a dataset is reported for Mg/Ca, Sr/Ca, Mn/Ca, Fe/Ca, as well as carbon and oxygen isotope ratios for 42 species from the Balaniformes, Verruciformes, Scalpelliformes and Lepadiformes. Barnacles predominantly form low-Mg-calcite with very high Sr/Ca ratios averaging 4.2 mmol/mol. The Mn/Ca and Fe/Ca ratios in shell plates are variable and can exceed >4 mmol/mol in barnacles that are attached to manmade structures or live close to (anthropogenic) sources of Mn and Fe. No strong phylogenetic control on the average element/Ca ratios is observed in barnacles. The Balaniformes show a ca. 40% enrichment of Mg in their scuta and terga as compared to other shell plates—a pattern which is not seen in other barnacles. The combination of low to medium Mg/Ca ratios and high Sr/Ca ratios is rare for marine biogenic calcite. Barnacles may thus become important for robustly reconstructing past seawater composition, if this signature is also present in fossil barnacle calcite and can be used alongside other fossil taxa with different Sr incorporation behaviour.

Carbon and oxygen isotope data support the view that the oxygen isotope thermometer for barnacles is robust and that most barnacle species form their calcite near isotopic equilibrium with ambient water. The Lepadiformes, however, show a tendency for strong co-variation of δ13C with δ18O values and depletion in 13C and 18O which is attributed to isotopic disequilibrium during shell secretion.

Strong systematic fluctuations in Mg/Ca ratios over length scales of ca. 5–15 μm are exhibited by the scalpelliform species Capitulum mitella, the only studied species which consistently forms high Mg calcite, and are tentatively linked to tidal control on the shell secretion pattern. Cathodoluminescence images for this species suggest that additionally a seasonal pattern of Mn distribution in its shell plates is recorded, pointing to a potential use for reconstruction of seasonal changes in terrestrial element supply.

**1. INTRODUCTION**

Barnacles have been of long-standing scientific interest with detailed work on taxonomy and fossil forms reaching back to Charles Darwin (e.g., Darwin, 1851, 1854). Thoracican barnacles (subclass Cirripedia) first appeared in the Early Paleozoic (Briggs et al., 2005; Pérez-Losada et al., 2008) and developed shells of phosphatic composition (Gale and Schwegert, 2016). This basal clade is represented by the living genus *Ibla*, which has shell plates composed of a poorly ordered hydrogen-phosphate-like material (Reid et al., 2012). Thoracicans evolved shells of calcite in the Jurassic, and form a monophyletic clade called the Thoracicalcareae Gale (2016), which are abundant in the World’s oceans today. Calcareaous barnacles first appeared in the Bathonian (mid-Jurassic), and by the end of the Jurassic (Tithonian) forms referred to the family Zeugmatolepadidae were abundant and widespread, mostly as epifauna attached to ammonite shells and driftwood (Gale, 2014, in press). In the Lower Cretaceous (Aptian) stalked benthonic cirripedes of the extant families Calanticidae and Scalpellidae appeared, which persist in deeper marine habitats to the present day (Gale, 2015). One group of stalked calcareaous barnacles became epiplanktonic (lepadomorphs). Calcareaous cirripedes first adapted to shallow marine hard substrates in the Late Cretaceous (Gale and Sørensen, 2015) and neobalanomorphs appeared in the Paleogene. These radiated rapidly, and by the Miocene these sessile forms were globally abundant and locally rock-forming in shallow marine habitats. Today they occupy a wide range of habitats from the intertidal zone down to deep sea trenches in the modern oceans (Foster, 1987).

Calcareaous barnacles secrete their shells onto a chitinous cuticle in a succession of very thin layers in synchronicity with the tidal cycle (Bourget, 1987) or endogenous semidiurnal rhythm (Bourget and Crisp, 1975). The thin layers are composed of polycrystalline calcite crystals enveloped in organic macromolecules (Gal et al., 2015) and show hierarchical patterns. These hierarchical patterns relate to seasonal changes in growth rate and decreasing band with throughout ontogeny modulating the thickness of growth bands (Bourget and Crisp, 1975). After an initial planktic life stage, barnacles settle in their final larval stage and become sessile (Shanks, 1986), recording environmental conditions at their growth site during their adult life. Particular interest has been focused on their attachment to various surfaces due to the negative economic impact of barnacle fouling (e.g., Christie and Dalley, 1987; Swain et al., 1998). The shells of barnacles have, however, also found use in ecological and environmental studies: $\delta^{13}$C and $\delta^{18}$O values of turtle and whale barnacles have been employed to trace the movement patterns of their host animals (Killingley, 1980; Killingley and Lutacavage, 1983) and a barnacle oxygen isotope thermometer has been established (Killingley and Newman, 1982). This barnacle thermometer has, for example, been employed in determining habitats of turtle barnacles (Detjen et al., 2015), and deciphering the point of origin of museum specimens (Newman and Killingley, 1985). Additionally, carbon isotope ratios in body tissues of intertidal barnacles have been identified as a potential proxy for habitat elevation with respect to the tidal level (Craven et al., 2008).

Element/Ca ratios of barnacle shells have been studied and proposed as tracers of salinity (Gordon et al., 1970) and shore level (Pilkey and Harris, 1966; Bourget, 1974). Significant inter-specimen differences in shell composition across different localities have additionally been identified as fingerprinting tool to locate harvest points of edible goose barnacles (Albuquerque et al., 2016). Despite such encouraging studies, not much is known about the chemical composition of barnacle shell material, and compilations of barnacle shell chemistry rely on very few samples (Chave, 1954; Dudd, 1967).

From the few available data it has been noted that barnacle shell calcite is dissimilar from most commonly studied biogenic calcite as its very high Sr concentrations mean it plots off a proposed correlation line of Sr versus Mg content (Carpenter and Lohmann, 1992). Whether barnacles carry any species-specific element signatures and whether there are differences in element concentrations in their shell plates has, however, not been comprehensively addressed (but see Iglikowska et al., 2018a).

Here we present $\delta^{13}$C and $\delta^{18}$O values as well as Mg/Ca, Sr/Ca, Mn/Ca and Fe/Ca ratios of 42 modern barnacle species of the Lepadiformes, Scalpelliformes, Verruciformes and Balaniformes (see Pérez-Losada et al., 2008 for taxonomic scheme), constituting the first large survey of shell geochemistry in cirripedes. These analyses are complemented by XRD analyses of 27 specimens to confirm the calcitic nature of the shell material. We compare the geochemical signatures of the shells with environmental parameters and evaluate taxonomic trends in shell composition. Furthermore, we investigate intra-shell chemical variability to address overall compositional heterogeneity and plate-specific chemical fingerprints.

**2. MATERIALS AND METHODS**

Specimens from 47 sites, comprising 42 cirripede species of the Balaniformes, Lepadiformes, Scalpelliformes and Verruciformes (Fig. 1) from personal and museum collections have been employed to trace the movement patterns of their host animals (Killingley, 1980; Killingley and Lutacavage, 1983) and a barnacle oxygen isotope thermometer has been established (Killingley and Newman, 1982). This barnacle thermometer has, for example, been employed in determining habitats of turtle barnacles (Detjen et al., 2015), and deciphering the point of origin of museum specimens (Newman and Killingley, 1985). Additionally, carbon
collections, were analysed (Table 1, Supplementary Fig. 1). Often only one specimen or part of one specimen was available for analysis, but in 15 cases several or multiple specimens from one locality could be studied (Table 1). Most of the specimens were preserved in alcohol, but specimens of samples 1, 3, 5, 16, 28, 36, 38, 39 and 46 were stored dried. Collection dates range from the 18th century to 2014. No effect of sample storage and specimen age has been observed in isotopic or element data. The samples cover a wide range of latitudes (75°N to 45°S; Fig. 2) and water depths from the intertidal zone to deep marine settings of approx. 2600 m water depth.

All specimens were transferred into separate beakers and reacted with 5% NaClO for at least 24 h to remove organic matter. The specimens were then rinsed multiple times with de-ionized water and residual organic matter was removed with stainless steel scalpels and tweezers. The cleaned shell plates were left to dry at room temperature. Samples for geochemical analyses were taken using a handheld drill with a drill bit of ca. 1 mm diameter or, where shell plates weighed 5 mg or less, by powdering entire shell plates with an agate pestle and mortar. Between 0.4 and 10 mg of powder per sample (usually 1–3 mg) were prepared and split into subsamples for isotope and element analysis. Typically ten δ13C and δ18O analyses per specimen were conducted (473 analyses in total), alongside 10–40 analyses of Mg/Ca, Sr/Ca, Mn/Ca and Fe/Ca ratios (1138 analyses in total; Supplementary Table 1).

2.1. Carbon and oxygen isotope ratio measurements

Isotope analyses were carried out at the Department of Geosciences and Natural Resource Management (IGN), University of Copenhagen. Samples 858–2045 (Supplementary Table 1) were analysed using a Delta V gas source isotope ratio mass spectrometer coupled with a Kiel IV device; and samples 2046–2681 (Supplementary Table 1) using an IsoPrime in continuous flow configuration.

Analyses using the Delta V were undertaken using ca. 50 μg of calcite powder. Batches of 40 vials, 30 samples and 10 standards comprising NBS-18, NBS-19 and an in-house standard (LM: Laaser Marble, Freie Universität Berlin, δ13C = +1.51‰, V-PDB, δ18O = −5.17‰, V-PDB), were measured. The accuracy of the runs was checked by multiple measurements of these standards. No isotopic adjustments of the raw data were made as analytical results of NBS-18 (n = 19), NBS-19 (n = 20) and LM (n = 28) conformed to certified or accepted values within measurement uncertainty. Reproducibility of multiple standard measurements was better than 0.07‰ (2 sd) for carbon isotope ratios for all standards, better than 0.15‰ (2 sd) for oxygen for NBS-19 and LM and 0.20‰ for NBS-18, which is known to be isotopically heterogeneous at the analysed weight scale (Ishimura et al., 2008).

For analyses using the IsoPrime, typically around 500 μg of calcite were measured. Samples were placed in sealed glass vials, flushed with He and reacted with ca. 50 μl of nominally anhydrous H3PO4 (~102%). Weight-dependent mass discrimination was corrected by multiple analyses of the in-house standard LEO (Carrara Marble, δ13C = +1.96‰, V-PDB, δ18O = −1.93‰, V-PDB) covering the entire weight range of samples. The accuracy of the analyses was controlled by periodic analysis of international standards (see Ullmann et al., 2013a). Reproducibility was checked by multiple measurements of LEO in every run (n = 182) and was 0.08‰ (2 sd) for carbon and 0.17‰ (2 sd) for oxygen isotope ratios over the course of the measurements.

2.2. Element/Ca ratio measurements

Element/Ca ratios were measured using a Perkin Elmer Optima 7000 DV ICP OES at IGN, University of Copenhagen. Typically ca. 500 μg of calcite powder were dissolved at a ratio of 1.5 ml of 2% HNO3 per 100 μg of calcite powder to achieve a Ca concentration of ca. 25 μg/g. Batches of 120 samples were run together with 12 interspersed samples of JLS-1 (Imai et al., 1996) for control of accuracy and precision. Signal quantification was done using a four-point calibration with a blank solution, and three synthetic, matrix-matched solutions made up from single-element solutions. Average measured ratios of JLS-1 (2 sd, n = 235) are 14.0 ± 0.4 mmol/mol for Mg/Ca, 0.35 ± 0.01 mmol/mol for Sr/Ca, 0.03 ± 0.01 mmol/mol for Mn/Ca, and 0.07 ± 0.05 mmol/mol for Fe/Ca. Large relative uncertainty of the Mn/Ca and Fe/Ca analyses of JLS-1 is related to low Mn and Fe concentrations in this standard. The concentrations are near the limit of quantification for the method which are 0.01 mmol/mol for Mn and 0.05 mmol/mol for Fe.

2.3. XRD analysis

For XRD analysis at the University of Greenwich, shell plates were ground to powder in a Tema mill (using industrial methylated spirits to minimise structural grinding damage). A few drops of the resulting slurry were allowed to dry on a silicon wafer. The powders were scanned on a Siemens PSD X-ray diffractometer using Ni-filtered Cu (Kβ) radiation with a 0.02° step width, and 0.2 mm slits, from 5 to 70° 29. The data have been quantified using Macdiff 4.26 (http://www.geol-pal.uni-frankfurt.de/Staff/Homepages/Petschick/MacDiff/MacDiffInfoE.html) to deconvolute and measure peak areas.

2.4. High-resolution analysis of Capitulum mitella

The carina of the specimen of Capitulum mitella was set in a circular resin block of 25 mm diameter, glued to a glass slide, cut and polished to expose a section perpendicular to the growth increments at the maximum thickness of the plate.

2.4.1. Cathodoluminescence microscopy

The section was studied using a cathodoluminescence (CL) microscope with a Citl Mk-3a electron source at the University of Exeter, Camborne School of Mines. Operation conditions were approximately 350 μA and 18 kV. Photographs were taken using a Nikon digital camera with 4 second exposure time. A CL map of the entire section was
Table 1
Taxonomic and locality information as well as number of analysed specimens for studied barnacles (see also Supplementary Fig. 1). Samples for which XRD data were acquired are marked with a “y”. Latitudes and longitudes are approximated from locality description where possible.

| Number | Species name          | Order               | Locality                              | specimens | XRD | Latitude | Longitude | Water depth | Collection year |

made using a 2.5× magnification objective and a high-resolution trace approximately parallel to the growth direction was photographed using a 10× magnification objective yielding a nominal resolution of 0.32 μm per pixel. For the high-resolution trace, six images of the same frame were taken. The acquired RGB data were reduced to grayscale and all images combined by signal addition into a single file using image editing software to enhance the signal to noise ratio. Single frames were then overlaid and blended into a single image and the grayscale levels adjusted to yield the full spread from black to white without saturation. In the resulting CL mosaic, a series of eight bands of 10 pixel thickness and lengths from 2290 to 11,075 pixels were defined perpendicular to the growth increments of the shell plate. These bands were then cropped from the merged profile and grayscale information extracted using the Profile function of ImageJ software. Grayscale data for single bands were then merged into a single trace using distinct marker bands in overlapping areas. Where necessary, offsets in grayscale values, due to lateral offsets in the band position, were smoothed over a range of 100 μm around the marker band that defined the correlation point for the profiles. The resulting stacked profile corresponds to approximately 14.3 mm and 44,790 points.

2.4.2. Scanning electron microscopy and EDS scans

An electron dispersive X-ray map of relative Mg concentration in a ca. 850 × 850 μm frame with nominal resolution of 0.78 μm per pixel was generated for the same specimen using a FEI Field Emission Gun Scanning Electron Microscope at the University of Exeter, Environment and Sustainability Institute. Data were quantified using a double EDS detector setup for ca. 16 h in continuous scanning mode at 10 kV and a working distance of 12.9 mm. Line scans of ca. 800 μm long segments perpendicular to the growth increments through the entire section quantifying Ca (Kα) and Mg (K) were acquired with a nominal resolution of 1 μm per step. Integration time per pixel reading was set to 32 milliseconds and the line repeatedly scanned until cumulative integration times of 5 s per pixel were reached. Raw count rates were converted into count ratios of Mg/Ca to account for lateral signal variation and resulting traces overlaid and merged into a consecutive trace through the shell plate. Working distance, acceleration voltage and magnification were the same as for the element mapping. Secondary electron images at 400 nm per pixel resolution (850 μm × 850 μm frame size, 4.5–9 min integration time) were acquired for each line scan covering the entire trace to aid the correlation. The stack of 18 segments corresponds to c. 13.6 mm length, and was measured close to, but not exactly coincident with the CL trace.

3. RESULTS

Calcite was the only carbonate polymorph detected during XRD analyses of the barnacle specimens (Supplementary Fig. 2). Geochemical and isotopic effects potentially arising from other carbonate polymorphs, in particular aragonite (Bourget, 1987), are therefore not considered in the following.
3.1. Mg/Ca and Sr/Ca ratios

A wide range of Mg/Ca ratios of 4.0–132 mmol/mol is encountered in the analysed barnacle species (Supplementary Table 1). The vast majority of the samples can be classified as Low Mg Calcite (LMC) with 95% of the measured Mg/Ca ratios below 50 mmol/mol. Only the scalpelliform barnacle *Capitulum mitella* shows Mg/Ca ratios consistently in the field of high Mg calcite (HMC) (Fig. 3; Supplementary Table 1).

Interquartile (25–75%) ranges of Mg/Ca vary between 5% (*Scalpellum stearnsi*) and 72% (*Chelonibia* sp.), but typically 10–30% around the median value. Variability of the Mg/Ca ratios is, on average, larger in balaniform barnacles than in lepadiform, scalpelliform and verruciform barnacles. Median Mg/Ca ratios of four species observed at several localities show considerable intra-species differences of 16–32% (2 rsd). These differences are independent from distances between the localities. At single localities, however, Mg/Ca ratios of three *Lepas anatifera* specimens (UK) and wall plates of two *Semibalanus balanoides* specimens (Greenland) agree within 8% (2 rsd).

Sr/Ca ratios in the barnacle calcite range from 2.6 to 5.9 mmol/mol (Fig. 3), with median values of single species ranging from 2.7 to 5.2 mmol/mol. No clear correlation of Sr with Mg is noted ($r^2 = 0.09$ for median values). Within single barnacle specimens from a given locality, Sr/Ca ratios are comparatively stable, with interquartile ranges varying between 1% (*Scalpellum stearnsi*) and 15% (*Capitulum mitella*), but typically 4–10% around the median value. Median Sr/Ca ratios of four species observed at several localities also show only small relative differences of 1–13% (2 rsd), suggesting that median Sr/Ca ratios are robustly defined for the species presented here.

No clear distinctions of Mg/Ca ratios or Sr/Ca ratios between different barnacle orders are observed (Fig. 3).

3.2. Mn/Ca and Fe/Ca ratios

A wide range of Mn/Ca (detection limit to 4.1 mmol/mol) and Fe/Ca ratios (detection limit to 6.2 mmol/mol) is observed, but most species show low Mn and Fe levels (Fig. 4). Only specimens from two species exhibit median Mn/Ca ratios $> 1$ mmol/mol (*Semibalanus balanoides; Amphibalanus improvisus*) and the median for all specimens is 0.04 mmol/mol. Median Fe/Ca ratios above $1$ mmol/mol are also limited to two species (*Scalpellum stearnsi; Amphibalanus amphitrite*) and the median for all specimens is 0.05 mmol/mol.

Specimens with substantial amounts of Mn and/or Fe in the shell material (Fig. 4) mostly stem from very near shore localities or man-made structures: *S. balanoides* (median Mn/Ca = 2.7 mmol/mol) from a harbour on the Danish island Romo; *A. improvisus* (median Mn/Ca = 1.2 mmol/mol) from Central Copenhagen, Denmark; *A. Amphitrite* (median Fe/Ca = 1.8 mmol/mol) scraped off a vessel in
Banjul, Gambia; *S. stearnsi* (median Fe/Ca = 1.1 mmol/mol) from Cape Nomamisaki, Japan.

A species control on Mn or Fe concentrations in shell calcite is not apparent as Mn and Fe concentrations across multiple specimens of the same species typically differ by an order of magnitude. Multiple specimens of the same species at a given locality, however, show closely matching Mn/Ca and Fe/Ca ratios as observed in three specimens of *Lepas anatifera* from Dorset, UK (Supplementary Table 1).

### 3.3. High resolution element distribution in *Capitulum mitella*

The consistently Mg-enriched nature of the calcite of *Capitulum mitella* means it is possible to study the high-resolution distribution of this element in its plates using electron beam techniques. Using Cathodoluminescence (CL) microscopy the Mg distribution pattern can furthermore be compared to qualitative Mn concentration maps at high spatial resolution.

SEM mapping and line scans of Mg distribution in *C. mitella* visualize prominent differences in Mg content visible already using backscatter electron imaging (Figs. 5 and 6). These strong fluctuations of Mg/Ca ratios from 0.13 to 0.45 cps/cps for large parts of the measured transect show clear peaks and troughs at a spacing of c. 5–15 μm (Supplementary Table 2). A rough conversion of raw Mg/Ca count rates from energy dispersive spectrometers into Mg/Ca ratios was attempted using the median Mg/Ca ratio from
ICP-OES measurements and assuming a similar mean value for the line scans as well as a linear detector response (Fig. 6). If this approximation is reasonably accurate, C. mitella secretes calcite with Mg/Ca ratio changes of 20–70 mmol/mol across a distance of a few micrometres, oscillating from nearly LMC to HMC.

CL mapping reveals a hierarchical banding structure in C. mitella (Fig. 5; Supplementary Table 3). This comprises a set of c. ten zones, starting with more luminescent bands separated by narrower, commonly quite prominent, zones of weak luminescence (Fig. 5). A multitude of thin luminescent bands occurs within the broad zones. The distance between the small-scale luminescent bands is the same as the distance between Mg/Ca peaks; detailed matching of CL and Mg signals in the area for which the Mg map was generated indicates that Mg-rich bands correspond to luminescent bands, even though peak intensities are dissimilar in detail (Fig. 6A). In order to quantify the peak match, both signals were de-trended and normalized and peaks of the CL profile matched against the Mg/Ca profile. Mg/Ca peaks were assigned if the signal showed a spike of at least 1 standard deviation amplitude in the normalized curve. A robust match was assigned for a CL peak if a spike with at least 1 standard deviation amplitude peaking within 1 μm was found. A tentative match was assigned where the CL signal peaked within 2 μm of the Mg peak, or the amplitude of the peak was 0.5 to 1 standard deviations. Of the 69 peaks observed in the Mg/Ca profile, 42 (61%) could be robustly matched and another 20 (29%) tentatively matched, leading to only 7 (10%) Mg peaks without CL match.

3.4. δ¹³C and δ¹⁸O values

δ¹³C values of the barnacle data set span a large range from −6.8 to +2.6‰ (Fig. 7). Typical interquartile ranges of δ¹³C values for the localities are 0.4‰, but at a few localities (Lepas anserifera, one specimen; Solidobalanus fallax, two specimens) a considerably larger interquartile spread of 1.5 and 3.0‰, respectively, is observed. Species with the lightest median δ¹³C values (Amphibalanus improvisus, −5.8‰; Dosima fascicularis, −4.3‰) are from very near-shore settings in central Copenhagen and Skagen, Denmark. Amongst the barnacle orders, the Lepadiformes have a tendency to lighter δ¹³C values (median = −1.7‰; 5 species) than scalpelliform barnacles (median = −0.5‰; 10 species) and balaniform barnacles (median = +0.4‰; 25 species).

δ¹⁸O values of the entire data set range from −5.0 to +5.0‰ (Fig. 7). Typically, interquartile ranges of oxygen isotope ratios for single localities are smaller (0.2‰) than for carbon isotopes and exceed 1‰ only in a specimen of Striatobalanus amaryllis from the Persian Gulf. Species with
the lightest δ¹⁸O values (Amphibalanus improvisus, 2 localities, −4.6 and −3.6‰) come from reduced salinity environments in the Baltic Sea. Other specimens with median values < −2‰ (n = 4) were collected in tropical localities (Singapore, −2.8‰; Singapore, −2.6‰; Gambia, −2.5‰; Hong Kong, −2.1‰). Conversely, specimens with the heaviest median values either come from high latitudes (Balanus balanus, +4.4‰, 24°78′N; Semibalanus balanoides, +2.1‰, ~65°N) or deep water settings (Metaverruca recta, +3.7‰, Rodrigues Ridge, 2600 m; Eochionelasmus ohtai, +3.2‰, North Fiji Basin, 1990 m; Neoscalpellum sp., +3.1‰, Porcupine Seabight, 484 m).

No clear relation of δ¹³C with δ¹⁸O is apparent for the entire dataset (r² = 0.06), where only A. improvisus from central Copenhagen shows median values substantially lower than −2‰ in both isotopic systems. Strong correlations (r² > 0.6), however, are observed at several localities. Specimens of three of five lepadid species (D. exoleta, one specimen; D. fascicularis, one specimen; and L. pectinata, two specimens) show strong covariation of carbon and oxygen isotope ratios (r² = 0.60, 0.64, 0.71) with positive slopes of δ¹⁸O = 0.3–0.4 * δ¹³C (Fig. 8). Strong covariation of these proxies are also noted in both studied representatives of Megabalanus (r² = 0.62, 0.75) and in one of two specimens of Striatobalanus amaryllis (r² = 0.46, 0.72). For both genera the slopes of these co-variations are opposite between the two specimens, however. Correlations of element proxies with isotope ratios for the entire data set are generally very weak (r² < 0.15).

4. DISCUSSION
4.1. Sr vs Mg in biogenic calcite

Since early assessments of Sr and Mg contents of biogenic aragonite and calcite (Odum, 1951; Dodd, 1967), work on mapping the chemical composition of marine calcifying species has been mostly undertaken on single species. Such studies were predominantly concerned with developing new palaeoenvironmental proxies or gaining a better understanding of the biomineralisation process (e.g., Dodd, 1965; Bourget, 1974; Freitas et al., 2006).
The general view is that biogenic calcite shows a broad positive correlation between Sr and Mg, and is enriched in Sr with respect to abiogenic calcite precipitates with a comparable Mg/Ca ratio (Carpenter and Lohmann, 1992). This assessment holds for the comparatively well-studied brachiopods, which cover a wide range of Mg/Ca ratios and reach maximum Sr/Ca ratios of ~3 mmol/mol in the high Mg calcite of craniid brachiopods (Fig. 9; Supplementary Table 4; see data in Brand et al., 2003).

Biogenic LMC with Sr/Ca ratios of 1 to 2 mmol/mol is ubiquitous (Fig. 9), in good agreement with precipitation-rate dependent Sr distribution coefficients of 0.07–0.24 in abiogenic calcite at typical marine pH (Tang et al., 2008; DePaolo, 2011). From these distribution coefficients Sr/Ca ratios of 0.6–2.1 mmol/mol for calcite are predicted to precipitate from modern seawater. A considerably wider range of compositions is allowed if changes in pH are permitted (Tesoriero and Pankow, 1996; DePaolo, 2011), helping to explain the partly very low Sr concentrations observed in abiogenic marine calcite (Carpenter and Lohmann, 1992). Sr/Ca ratios consistently greater than 2 mmol/mol in modern biogenic calcite are seldom observed, and a miscibility gap between SrCO$_3$ and CaCO$_3$ limits the amount of Sr that can be accommodated in the calcite crystal lattice. Even though experimental results on this miscibility gap below 350°C and ambient pressure are missing (Carlson, 1980), the upper limit of Sr uptake has been proposed to be near Sr/Ca ratios of ca. 5 mmol/mol (Tesoriero and Pankow, 1996). Crystal lattice distortions in biogenic calcite induced by the incorporation of organic macromolecules (Pokroy et al., 2006) may allow for even higher Sr/Ca ratios in shell calcite and explain the otherwise surprisingly high Sr/Ca ratios in arthropod calcite (Fig. 9).

The Sr/Ca and Mg/Ca pattern of barnacle calcite stands in strong contrast to other biogenic, marine calcite. When incorporated into a comprehensive dataset of marine shell calcite the observed signatures of arthropod Sr/Ca are distinctly higher than other biogenic calcite at comparable Mg/Ca ratios (see also Carpenter and Lohmann, 1992). Despite the nearly exclusive secretion of LMC, barnacle calcite shows very high Sr concentrations indicating Sr distribution coefficients of 0.3–0.7. High Sr/Ca ratios are not uncommon for arthropods (e.g., decapods, Gibbs and Bryan, 1972), but barnacles differ from decapods by almost exclusively forming LMC.
rather than HMC. Sr and Mg signatures similar to cirripedes are observed for marine ostracodes (Fig. 9; Dwyer et al., 2002). Very few species of marine ostracodes have, to date, been studied for their shell geochemistry, so the potential range of composition in this group is not yet well constrained. It has been hypothesized that the calcite secreted by crustaceans is particularly Sr-rich because of very high shell secretion rates in this group of animals (Carpenter and Lohmann, 1992). The result would be an arthropod-specific covariation of Sr and Mg concentrations at elevated Sr concentrations. However, organisms which secrete shell calcite much faster than barnacles have comparatively low Sr/Ca ratios. Oyster specimens studied by Ullmann et al. (2013b) for example reached heights of 17–19 cm in four years but only have average Sr/Ca ratios of 0.81 mmol/mol. Bivalves in general, which on average exhibit much faster metabolic rates than brachiopods (Payne et al., 2014) and secrete shell calcite more rapidly, do not show any tendency to higher Sr/Ca ratios than brachiopods (Fig. 9). Furthermore, it has been shown experimentally (Gabitov et al., 2014) and observed in biogenic calcite (Ullmann and Pogge von Strandmann, 2017) that secretion rate-related effects on element uptake in biogenic calcite should lead to a negative correlation of Sr/Ca with Mg/Ca ratios. This negative correlation, however, is not observed as an overarching control on crustacean calcite composition (Fig. 9). These factors taken together rather suggest that shell secretion rate is not the primary driver for the Sr enrichment in cirripedes.

Even though the causes, utility, and mechanisms of Sr enrichment in biogenic calcite remain poorly understood, the empirically constrained species-specific elemental fingerprints of biogenic calcite can nevertheless be utilized. In particular, the various specific combinations of Sr/Ca and Mg/Ca ratios in biogenic calcite may be highly beneficial to trace the chemical composition of seawater through time. Previously, a constant Sr distribution coefficient of 0.41 equating to a barnacle Sr/Ca ratio of 3.8 mmol/mol was proposed for intertidal barnacles on the basis of data from four species (Bourget, 1974; Smith et al., 1988). The more comprehensive dataset assembled here for four cirripede orders suggests an average of 4.2 ± 0.2 mmol/mol (2 se, n = 47) which nearly coincides with the earlier estimate. When applied to single species, such an assumption of constant Sr/Ca is clearly an oversimplification (Fig. 9) and some minor, but significant differences in Sr/Ca and Mg/Ca have been identified between scalpelliform barnacles from various localities (Pollicipes pollicipes, Albuquerque et al., 2016). Using taxonomy-identified barnacle calcite, however, could still be valuable for seawater Sr/Ca reconstruction. Nevertheless, clear concerns for robust seawater element/Ca reconstruction include: complicated response of biomineral element/Ca to seawater element/Ca ratios (Segev and Erez, 2006), temperature (Dodd, 1965; Cléroux et al., 2008), growth rate (Gillikin et al., 2005; Ullmann and Pogge von Strandmann, 2017), and diageneis (Brand and Veizer, 1980; Al-Aasm and Veizer, 1986). If a variety of marine calcites shows consistent offsets and trends through time (e.g., Ullmann et al., 2013c), confidence in the reconstruction of seawater composition, however, can be substantially improved. To this end, barnacles can become a useful additional archive because of the Sr-enriched LMC of their shell material.
4.2. Mg/Ca heterogeneity in shell plates of barnacles

4.2.1. Mg/Ca variability in single specimens

For 12 species (15 sites; Supplementary Table 5) of balaniform cirripedes for which scuta, terga, and wall plates were available for analysis, a significant enrichment of Mg in scuta and terga over Mg/Ca in the wall plates is observed (Fig. 10). On average, Mg/Ca ratios of the scuta are 32 ± 6% and Mg/Ca ratios of terga 41 ± 8% (2 se) higher than Mg/Ca ratios in the wall plates and most species show slightly higher Mg/Ca ratios in terga than in scuta. A ca 60% enrichment of Mg in scuta and terga with respect to the wall plates has also been observed for the sessile barnacle *Balanus balanus* (Iglikowska et al., 2018a). In nine species of scalpelliform barnacles, no such enrichment of Mg is observed (Fig. 10, Supplementary Table 5). Here, scuta have 97 ± 6% and terga 98 ± 8% (2 se) of the Mg content of other plates. Also in two species of *Lepas* (Lepadiformes) for which various plates could be measured, Mg/Ca ratios of scuta and terga coincide with those of other plates within uncertainty. For the two verruciform species studied here, neither scuta nor terga were available, so that their Mg incorporation behaviour could not be addressed. The strong Mg enrichment

---

**Fig. 9.** Average Mg/Ca and Sr/Ca ratios for barnacle species analysed here as well as Sr/Ca and Mg/Ca ratio averages for other calcite secreting species taken from the literature (Pilkey & Hower, 1960; Schopf & Manheim, 1967; Gibbs & Bryan, 1972; Delaney et al., 1985; Carpenter & Lohmann, 1992; Cronin et al., 1996; Klein et al., 1996; Rathburn and De Dekker, 1997; Almeida et al., 1998; De Dekker et al., 1999; Brand et al., 2003; Vann et al., 2004; Freitas et al., 2005, 2006; Hermans et al., 2010; Iglikowska et al., 2018b; Supplementary Table 4). Brachiopods marked with “t” belong to the Thecideida and the species marked with “c” is a craniid brachiopod. Tentative trends of biotic and abiotic calcite from Carpenter and Lohmann (1992) are also shown.
in the scuta and terga of Balaniformes does explain the observation of higher Mg variability in their shell material as compared to other barnacle orders (Section 3.1).

Mg-enriched parts of biogenic shells controlled by functional morphology are not restricted to the Balaniformes but are known from echinoderms (Davies et al., 1972; Busenberg and Plummer, 1989; Ries, 2011; Iglíkowska et al., 2018b), brachiopods (Pérez-Huerta et al., 2008; Ullmann et al., 2017) and bivalves (Freitas et al., 2009). The consistency of the observed Mg enrichment in the scuta and terga of balaniform barnacles, however, is striking. The homology of shell plates in the Thoracica (encompassing all sessile and stalked barnacles) has been proposed (Pérez-Losada et al., 2008). It is intriguing in this context that a shared phylogenetic blueprint of the various shell plates does not seem to be mirrored in similar element concentration patterns across all barnacle species. A particular form of bioengineered calcite geochemistry for movable shell plates as opposed to the fixed wall plates in Balaniformes is an intriguing observation which warrants further study.

4.2.2. Mg/Ca as a temperature proxy in barnacles?

A direct relationship between temperature and Mg concentration in barnacle calcite has been proposed on the basis of a small set of specimens with mostly unknown taxonomic designation (Chave, 1954). A monospecific dataset of *Tetraclita serrata* from South Africa broadly confirmed such a relationship but pointed to a large uncertainty of any temperature calibration of barnacle Mg/Ca (Smith et al., 1988). Additionally, a strong Mg gradient within single shell plates was observed using electron probe microanalysis which was tentatively related to dissolution-precipitation reactions in the intertidal zone (Smith et al., 1988). A possible temperature effect on Mg uptake in barnacle calcite was also suggested for barnacles from the coast of Wales and Irish Sea (Bourget, 1974), but growth rate was deemed to be the dominant forcing on shell element/Ca ratios in that study.

In the present dataset covering a wide range of species the lowest Mg/Ca ratios from 4–12 mmol/mol occur in whae barnacles (*Coronula diadema*) collected in Greenland and the highest ratios of 65–105 mmol/mol in *C. mitella* from Hong Kong. These data are compatible with a temperature control on Mg/Ca. Phylogeny, however, seemingly exerts the prevalent control on skeletal Mg/Ca ratios: comparatively high Mg/Ca ratios are also observed in the cold water specimen of *Metaverruca recta* from ca. 2.6 km depth (31–65 mmol/mol) and lower ratios of 18 to 44 mmol/mol in *Amphibalanus variegatus* from the warm waters of Singapore.

Nevertheless, the derivation of species-specific Mg/Ca thermometers might be possible: Specimens of *Semibalanus balanoides* from Greenland, Iceland and Denmark exhibit different Mg/Ca ratios across a gradient of annual average temperatures from ca. 2 °C (Greenland) to 10 °C (Denmark) (WOD13, Boyer et al., 2013). The Danish specimens experienced the highest ambient temperatures and, as expected, show the highest Mg/Ca ratios in wall plates, scuta and terga (Fig. 11). The Mg/Ca ratios of the Greenland specimen that secreted its shell in the coldest water, however, are not consistently the lowest. The tight correlation of Mg/Ca data with temperature in the terga of *S. bal-

---

![Fig. 10. Enrichment factors of Mg in scuta and terga of the investigated barnacle species (see also Supplementary Table 5). Small symbols represent individual species and larger symbols the averages for Balaniformes and Scalpelliformes. Mg in scuta and terga of balaniform barnacles is significantly enriched with respect to Mg in wall plates. For individual species, error bars are 2 se (standard error) of the analytical results. For the pooled data for Balaniformes and Scalpelliformes, error bars indicate 2 se of the species averages. No data for verruciform barnacles is available.](image-url)
S. balanoides is likely caused by a sampling effect. The terga of this species are relatively small, so that material extracted from them are more likely to constitute representative samples than material taken from the larger scuta and wall plates.

An increase of Mg/Ca can also be read from data for Striatabalanus amaryllis from the Persian Gulf (ca. 25 °C) and Singapore (ca. 29 °C) (WOD13, Boyer et al., 2013), where S. amaryllis from Singapore shows on average 5 mmol/mol higher Mg/Ca ratios. These data suggest that a control of Mg/Ca in barnacles linked to changes in temperature may exist and could lead to the development of species-specific Mg/Ca thermometers (see also Bojar et al., 2018). The barnacle calcite, however, generally exhibits large heterogeneity in Mg/Ca ratios even in environments where seasonal temperature variability is much reduced. This heterogeneity implies that such a thermometer would only be useful in environments with reduced and variable salinity, where the oxygen isotope thermometer could not be employed or would be less precise (see also Smith et al., 1988).

4.3. Mn/Ca and Fe/Ca in barnacle calcite

Mn/Ca and Fe/Ca ratios in biogenic calcite are most commonly taken to address the preservation state of fossil materials. Both, Mn and Fe concentrations are typically very low in marine environments (Milne et al., 2010; Biller and Bruland, 2012), such that substantial enrichments in these elements in fossil shell materials are good indicators of diagenetic overprint (see Ullmann and Korte, 2015 for a review). In proximal shelf areas, however, Mn can be made available for biomineralisation through biogeochemical pathways (Vander Putten et al., 2000) and seasonal temperature and sediment redox variation (Morris, 1974; Freitas et al., 2006) or be a sign of disease (Almeida et al., 1998).

In barnacles, dominant controls on shell Mn/Ca ratios, however, appear to be ambient water Mn concentrations (Gordon et al., 1970, see also Hockett et al., 1997) and possibly salinity (Pilkey and Harriss, 1966). Continental or anthropogenic Mn sources as in the case of Chesapeake Bay (Gordon et al., 1970) may thus leave a strong imprint on barnacle calcite, particularly in species living close to such sources in intertidal environments. Also, barnacles appear to have a much stronger affinity for incorporation of Mn into their shells than other sessile calcifiers like oysters (Pilkey and Harriss, 1966), possibly related to growth rate or organic matter associated with shell calcite (Bourget, 1974). Similar controls can be envisioned for the incorporation of Fe into barnacle calcite.

The absolute levels of Mn and Fe in barnacle shell material may thus be first and foremost an indication of habitat and even Mn/Ca and Fe/Ca ratios > 4 mmol/mol (Supplementary Table 1; Fig. 4; Pilkey and Harriss, 1966) can be reached in primary calcite. When employing Mn and Fe as preservation markers for fossil barnacles, it is therefore of importance to check for other known elemental and isotopic co-variations produced by diagenesis, as well as assessing the spatial distribution of Mn and Fe.

4.4. Tidal control on element distribution in Capitulum mitella?

Growth functions of C. mitella (Nakamura and Tanaka, 1995) and decreasing thicknesses of the ten broader zones delineated by CL in the investigated carina of this species (Figs. 5 and 6; Table 2) suggest that these are the expression of annual cycles of shell secretion. The exact sample locality and data for the specimen of C. mitella is unknown – it was sampled in the intertidal zone in Hong Kong in the early 20th century (Table 1). This lack of exact provenance data and the complicated tidal regime in the Pearl River estuary (Mao et al., 2004) make exact reconstructions of

![Fig. 11. Mg/Ca ratios in Semibalanus balanoides and Striatabalanus amaryllis from various localities. A broadly positive correlation of Mg/Ca ratios with temperature is observed for both species. Large symbols designate average value for shell plate type for each sample location.](image-url)
environmental parameters at the life time of the barnacle impossible. Increased discharge of Mn in the Pearl River in the spring, however, could explain the more prominent luminescent bands at the beginning of an annual zone which are then followed by bands that are overall less luminescent. Alternatively, Mn enrichments could be associated with increased amounts of intracrystalline organic matter (Bourget, 1974), which may occur as part of the animal's seasonal growth cycle.

Durations of 1.3–1.8 days have been proposed for the formation of growth ridges on plates of *Balanus amphitrite* (Clare et al., 1994), features which are controlled by the molting cycle (Chave, 1984). For internal banding, however, a strong control on immersion time and the tidal cycle have been observed in *Semibalanus balanoides* (Bourget and Crisp, 1975) and *Elminius modestus* (Crisp and Richardson, 1975). The average thickness of the thin luminescent bands in *C. mitella* is similar to these examples and suggests that the bands may be related to the tidal cycle.

Distances between intensity peaks are usually 5–15 μm in the juvenile and early adult part in *C. mitella*, where the broader, possibly annual zones are 2–3 mm thick (Fig. 5; Table 2; Supplementary Tables 2 and 3). Regions with indistinct bands, complicated peak shapes and high-frequency oscillations preclude an exact assessment of the number of bands within a single zone. The average distance between CL peaks, however, makes it possible that the number of bundles of luminescent and non-luminescent calcite within a zone is controlled by daily or tidal cycles. Considering the intertidal habitat of *C. mitella* it is probable that the tidal cycle exerts a prominent control on the barnacle metabolism, even though this hypothesis requires further testing. If tides are indeed the main drivers of growth bands in *C. mitella*, the less luminescent bands may be formed during immersion at high tides, whereas more Mn-enriched calcite is formed when restricted tidal pools develop at low tides and barnacles close their shell plates until immersion re-occurs (Craven et al., 2008).

The extraordinary control on both Mn and Mg incorporation, the comparative ease with which both these parameters can be measured in *C. mitella*, as well as the comparative longevity of *C. mitella* could make this species a very important archive for reconstructing continental runoff and tidal dynamics in recent and fossil settings. Collection and study of modern *C. mitella* from well-constrained sites will be important to verify these hypotheses.

### 4.5. C and O isotopes in barnacle calcite

#### 4.5.1. Oxygen isotope thermometry

**4.5.1.1. Δ18O enrichment in barnacles.** A precise, barnacle-specific oxygen isotope thermometer is available over a wide range of temperatures (c. −2 to +26 °C, Killingley and Newman, 1982). This thermometer is based on oxygen isotope ratios in the calcite shells of a variety of barnacle species and predicts considerably higher temperatures for a given shell Δ18O value than other common oxygen isotope thermometers. For example, the offset from the Epstein et al. (1953) equation is between 2.7 °C at the low end and 5.7 °C at the high end of the calibrated temperature range, suggesting that barnacles secrete their shells with increased oxygen isotope fractionation factor, i.e. preferentially incorporating the heavy oxygen isotopes. A series of studies on barnacle calcite have indirectly or directly commented on this surprising finding, which has been related to poorly understood disequilibrium incorporation of oxygen isotopes into shell calcite (McConnaughey, 1989a).

At one extreme, 18O enrichment even beyond the Killingley and Newman (1982) barnacle thermometer has been proposed for the green sea turtle barnacle *Platylepas* by comparison of predicted and observed 18O/16O values in barnacle shells on turtles in the Palmyra Atoll National Wildlife Refuge (Detjen et al., 2015). At the other extreme, the Killingley and Newman (1982) thermometer has been rejected for the cold-water barnacle *Bathyasmasa corollifome* from the McMurdo Ice Shelf, Antarctica (Burgess et al., 2010). Burgess et al. (2010) found the same δ18O values as Killingley and Newman (1982) who studied the same species at a site within a few kilometres and the same oceanographic conditions. However, in the absence of seawater oxygen isotope data at the time, Killingley and Newman (1982) argued that a +1.0‰ offset of *B. corolliforme* from the gastropod *Lima tul* at the same locality confirmed their thermometer. Conversely, Burgess et al. (2010), relying on measurements of Ross Sea water and a proposed general model of water circulation at the Ice Shelf (Jacobs et al., 1985), argued for isotopically comparatively heavy sub-ice seawater. These seawater isotope ratios in turn led to estimated barnacle oxygen isotope fractionation factors in close agreement with mollusc, foraminifer and abiogenic calcite (Burgess et al., 2010).

Most commonly, however, it is stated that barnacle calcite is comparatively rich in 18O (Newman and Killingley, 1985; Smith et al., 1988; Craven et al., 2008), particularly when compared against mollusc carbonate from the same sites (Killingley and Newman, 1982; Brand et al., 1987). It thus appears that barnacles have a tendency to secrete comparatively 18O-rich shell calcite.

Somewhat uncertain provenance, water composition and annual temperature ranges at the sites of collection for the present dataset preclude a meaningful discussion of minor deviations of calcite-water oxygen isotope fractionation factors. No bias towards heavy oxygen isotope ratios, however, is required to explain observed values in

| Subdivision no | Position (mm) | Thickness (mm) |
|----------------|---------------|----------------|
| 1              | 2.69          | >2.69          |

| Edge           | 14.33         | 0.32           |

Table 2 Positions of boundaries between zones delineated by cathodoluminescence in carina of *Capitulum mitella*.
deep marine barnacle for which strong fresh water input as a potential bias of shell δ18O can be excluded: Using a deep sea water δ18O estimate of +0.1‰ SMOW (Bigg and Rohling, 2000) and the Killingley and Newman (1982) isotope thermometer for Metacutucora recta, a δ18O value of +4.9‰ would be expected from temperatures of +2°C at the approximate sample position (WOD13, Boyer et al., 2013). A much less positive range of values of +3.3 to +3.8‰ is observed, however, which is much more compatible with commonly employed thermometers of Epstein et al. (1953) as well as Anderson and Arthur (1983). The same conclusions can be drawn for Eochionelasmus ohtai from the North Fiji Trench, for which an expected δ18O value of +4.9‰ stands in contrast to observed values between +3.1 to +3.5‰.

Despite the uncertain absolute oxygen isotope fractionation factor for barnacles, a strong temperature dependence on δ18O in their calcite is evident (e.g., Killingley and Newman, 1982). Reconstructions of relative temperature changes from barnacle shells are therefore possible where other complicating factors such as variable δ18O of ambient water are negligible.

4.5.1.2. Mg-effect on oxygen isotope fractionation factor. A systematic increase of oxygen isotope fractionation factors in calcite with increasing Mg substitution of the Ca site has been found (Tarutani et al., 1969; Jiménez-López et al., 2004). Proposed magnitudes of these effects are +0.06‰ per mol% MgCO3 (Tarutani et al., 1969) or +0.17 ± 0.02‰ (Jiménez-López et al., 2004). The latter was adopted for an empirical calibration of brachiopod data (Brand et al., 2013). The median Mg/Ca ratio of 25 mmol/mol (interquartile range of 19–31 mmol/mol) for the entire barnacle dataset equates to approximately 2.5 (~1.9–3.1) mol% MgCO3 (discounting a small offset due to the presence of other impurities such as SrCO3 etc.). Adopting the recent estimate of the Mg effect on oxygen isotope fractionation, barnacle calcites may thus be enriched in 18O by 0.43 (0.32–0.53) ‰ with respect to pure calcite. Calcite oxygen isotope thermometers are usually calibrated on materials with low Mg/Ca ratios such as pure calcite. 18O depleted calcites with the typically observed stronger depletion of the heavy carbon isotopes (Wefer and Berger, 1991; Carpenter and Lohmann, 1995). D. fascicularis specimens which showed the strongest depletion of 13C amongst the lepadids were sampled as part of a barnacle mass occurrence that left numerous individuals stranded on beaches in Northern Jutland (Denmark). Kinetic isotope fractionation induced by accelerated growth rate leading to a depletion of the heavy isotopes in these specimens would thus not be surprising.

5. CONCLUSIONS

The present dataset constitutes the first large survey of barnacle shell geochemistry, confirming and refining known patterns of element/Ca as well as C and O isotope ratios in barnacle calcite and pointing to their potential use as proxies for palaeoenvironmental conditions.

Barnacles generally secrete low-Mg-calcite with very high Sr/Ca ratios, but also some cases of high-Mg-calcite, in particular Capitulum mitella, are observed where Sr/Ca ratios are equally high. The Mg-enriched nature of C. mitella, intertidal habitat, and clear banding pattern in the shell make it a potential archive for reconstructing the tides, seasonality and terrestrial element fluxes into shallow marine environments from fossil representatives of this species.

A possible temperature control on Mg/Ca ratios in barnacles is confirmed, but heterogeneity of shell material and species-specific Mg distribution coefficients complicate the derivation of robust Mg thermometers for barnacles. Barnacle Mg thermometry may nevertheless be useful in estuarine and near-shore environments, where δ18O values of ambient water may be highly variable.

Barnacles from very near-shore localities and those attached to manmade structures can incorporate very high amounts of Mn and Fe into their shell calcite (Mn/Ca and Fe/Ca > 4 mmol/mol) which has to be considered when studying fossil barnacles.

Balaniform barnacles exhibit a strong Mg enrichment in their scuta and terga over other shell plates (32 ± 6 and
41 ± 8%), a geochemical pattern which is not observed in other barnacle orders.

No clear indication for strong disequilibrium isotope incorporation has been detected in balaniform, verruciform and scalpelliform barnacles permitting their use for reconstructions of palaeotemperatures, or at least relative temperature changes. The majority of lepadiform barnacles, however, appear to preferentially incorporate the light carbon and oxygen isotopes into their shell calcite.

ACKNOWLEDGEMENTS

The authors thank three anonymous reviewers for their insightful and constructive comments that helped to substantially improve the clarity and quality of the manuscript. The authors acknowledge the Natural History Museum of Denmark (Zoological Museum) for permitting destructive sampling of archived specimens (numbers 2, 4, 17-27, 29, 30, 32, 33, 37, 41, 45) and Jens Hoeg for help during work in the archives of the Zoological Museum. CVU acknowledges funding from the Natural Environment Research Council (NERC) (grant no. NE/N018508/1). Many thanks are due to Joe Pickles for help with FEG-SEM analyses and to Steve Pendray (both University of Exeter) for barnacle thin section preparation and Bo Petersen (University of Copenhagen) for assistance with C and O isotope analysis.

APPENDIX A. SUPPLEMENTARY DATA
