Reactive oxygen species (ROS) act as intracellular compartmentalized second messengers, mediating metabolic stress-adaptation. In skeletal muscle fibers, ROS have been suggested to stimulate glucose transporter 4 (GLUT4)-dependent glucose transport during artificially evoked contraction ex vivo, but whether myocellular ROS production is stimulated by in vivo exercise to control metabolism is unclear. Here, we combined exercise in humans and mice with fluorescent dyes, genetically-encoded biosensors, and NADPH oxidase 2 (NOX2) loss-of-function models to demonstrate that NOX2 is the main source of cytosolic ROS during moderate-intensity exercise in skeletal muscle. Furthermore, two NOX2 loss-of-function mouse models lacking either p47phox or Rac1 presented striking phenotypic similarities, including greatly reduced exercise-stimulated glucose uptake and GLUT4 translocation. These findings indicate that NOX2 is a major myocellular ROS source, regulating glucose transport capacity during moderate-intensity exercise.
A single bout of exercise prompts a rapid adaptive increase in energy substrate metabolism in contracting skeletal muscle to meet the increased demand for ATP production. Understanding the molecular signal transduction pathways that orchestrate these metabolic responses in muscle has broad implications, from optimizing athletic performance, to understanding fundamental stress-adaptive responses at the cellular level, to prevention and treatment of aging-related and lifestyle-related diseases in muscle and other tissues.

The production of oxygen-derived free radicals and derivatives thereof, collectively referred to as reactive oxygen species (ROS), increases in skeletal muscle during exercise and has long been considered to mediate adaptive responses to both acute bouts of exercise and chronic exercise training. Although historically viewed as a by-product of oxidative metabolism in mitochondria, it has been suggested that ROS may be produced enzymatically by extra-mitochondrial sources in contracting muscle, including NADPH oxidase (NOX) and xanthine oxidase. However, the primary ROS source in the context of physiological in vivo exercise remains uncertain due to the difficulty in measuring and quantifying exercise-stimulated ROS production.

Research in the past 60 years has established that glucose transport in vivo is controlled by a coordinated increase in glucose delivery, glucose transport into muscle fibers and intracellular metabolism. Among these events, the insulin-independent translocation of glucose transporter protein 4 (GLUT4) from intracellular storage depots to the cell surface to facilitate glucose entry appears to be a key molecular event. Studies in isolated ex vivo incubated skeletal muscles from rodents have shown that glucose transport in response to electrically stimulated contraction and mechanical stress is lowered by antioxidants, suggesting that ROS are required for increased glucose transport.

Interestingly, the small GTPase Rac1 is activated by muscle contraction and passive stretch, and is necessary for both stimuli to increase glucose uptake in isolated mouse muscles. Rac1 is best known to bind and orchestrate regulators of actin remodeling, but the recruitment of GTP-loaded active Rac GTTPase isoforms in conjunction with a complex of other NOX2 regulatory proteins (p67phox, p47phox, and p40phox) is also essential to stimulate superoxide (O2−)-production by the membrane-bound NOX2 complex. However, whether NOX2-induced ROS production regulates muscle glucose uptake in vivo and if the reduced exercise-stimulated glucose uptake observed in Rac1-deficient muscles is due to reduced ROS production, is currently unknown.

In the present study, we took advantage of recent methodological developments in the redox signaling field, including a method for preservation of in vivo ROS modifications and genetically encoded ROS biosensors. This allowed us to measure both general and localized NOX2-specific ROS production in wild-type (WT) mice and mice lacking NOX2 activity due to the absence of either the Rac1 or p47phox regulatory subunits. Using these approaches, we show that NOX2 is activated by moderate-intensity exercise and is the predominant source of ROS production under these conditions. Moreover, a large reduction in exercise-stimulated glucose uptake and GLUT4 translocation was shared features between the two NOX2 loss-of-function models. Collectively, these results imply that NOX2 is a major source of ROS production during moderate-intensity exercise and that Rac1 is required for GLUT4 translocation and glucose uptake due to its essential role in NOX2 activation.

Results
Moderate-intensity exercise causes a pro-oxidative shift in human muscle. Plasma redox markers are increased during both moderate-intensity and high-intensity exercise in humans. However, whether muscle ROS production increases during moderate-intensity exercise in humans is unknown. To explore this, we estimated total oxidant production in skeletal muscle from healthy young men (Supplementary Table 2) before and after a single 30 min bout of bicycle ergometer exercise at a moderate 65% peak power output exercise intensity using the redox-sensitive dye dichlorodihydrofluorescein diacetate (DCFH). We found that exercise stimulated an 86% increase in DCFH oxidation in human skeletal muscle (Fig. 1a), which was accompanied by an expected increase in the phosphorylation state of known exercise-responsive proteins (Fig. 1b).

The exercise-induced pro-oxidative shift measured by DCFH requires NOX2 activity in mice. To dissect the ROS source during exercise, we used a previously described p47phox-mutated mice (ncf1*) harboring a loss-of-function mutation in the regulatory NOX2 subunit, p47phox. An acute moderate-intensity treadmill exercise bout (65% maximal running speed) for 20 min increased DCFH oxidation (+45%) in WT mice, a response that was completely abolished in p47phox-deficient ncf1* mice (Fig. 1c).

Exercise-stimulated p38 MAPKThr180/Tyr182 phosphorylation is reduced in ncf1* quadriceps muscle. Exercise-induced ROS production has been suggested to activate a number of kinases linked to glucose uptake-regulation in skeletal muscle. Interestingly, p-p38 MAPKThr180/Tyr182 levels were lower in quadriceps muscle of ncf1* mice compared to WT mice after exercise (Fig. 1d), but not in TA (Supplementary Fig. 1C) or soleus muscles (Supplementary Fig. 1D). The phosphorylation of ERKThr202/Tyr204, AMPKThr172, and its substrate ACCSer212 did not differ significantly between genotypes (Fig. 1d and Supplementary Fig. 1C, D). We also measured SERCA, eEF2Thr57, CaMKIIThr287, and TBC1D1Ser231 but found no genotype-difference (data not shown). No genotype-difference was observed for total AMPKa2, p38 MAPK, ERK 1/2, or ACC in any of the studied muscles (Fig. 1e and Supplementary Fig. 2). The variable responsiveness of these kinases supports that the mice performed moderate-intensity exercise and shows that NOX2 is not consistently required for activation of these kinases.

NOX2 is required for increased cytosolic ROS during exercise. Since DCFH oxidation does not provide information about the ROS source, we further investigated the subcellular redox changes in response to exercise in skeletal muscle using a recently described redox histology method (see graphical depiction in Supplementary Fig. 3A). This method enables the preservation and visualization of the redox state of a transfected redox-sensitive GFP 2 (roGFP2)-Orp1, targeted to cytosolic and mitochondrial compartments following in vivo exercise. The Orp1 domain facilitates roGFP2 oxidation in the presence of H2O2 to elicit a ratiometric change, with an increase in 405 nm and a decrease in 470 nm fluorescence. As such, the ratio between the two wavelengths is a measure of H2O2 production in the targeted compartment, here the cytosol and the mitochondria.

Mito-roGFP2-Orp1 was located in the mitochondrial compartment (co-localizing with tetramethylrhodamine, ethyl ester,
Supplementary Fig. 3B, C) and shown to be sensitive to H₂O₂ (Supplementary Fig. 3D). Interestingly, oxidation of Mito-roGFP2-Orp1 probe was lowered similarly in both genotypes by exercise (Fig. 2a). In contrast, cytosolic roGFP2-Orp1 oxidation showed a main effect of genotype (Fig. 2b), driven by an exercise-induced increase in roGFP2 oxidation in WT but not ncf1* mice.

To substantiate that NOX2 activity was required for exercise-stimulated ROS production, we electroporated a biosensor designed to measure NOX2 activity, the p47roGFP construct, into muscles from inducible muscle-specific Rac1 knockout mice (Rac1 imKO), which are predicted to lack functional NOX2 complex. Treadmill exercise caused an acute increase in p47roGFP oxidation in WT TA muscle which was completely
absent in Rac1 KO mice, showing that Rac1 is essential for NOX2 activation in skeletal muscle. (Fig. 2c). A similar dependence of NOX2 activation on Rac1 was observed in electrically stimulated FDB fibers in vitro (Supplementary Fig. 3H). The absence of p47roGFP oxidation in Rac1 imKO muscles was not explicable by differences in antioxidant enzyme abundance (Supplementary Fig. 3I). In accordance, exercise-stimulated DCFH oxidation was completely absent in Rac1 imKO compared to WT littermates (Fig. S2G) with no differences under resting conditions (Supplementary Fig. 21).

Collectively, these results show that NOX2 is activated and constitutes a major source of cytosolic ROS production during endurance-type exercise in skeletal muscle. In contrast, mitochondrial ROS production is lowered during acute exercise independently of NOX2.

NOX2 is required for exercise-stimulated glucose uptake. Given that Rac1 imKO mice display a severe reduction in treadmill exercise-stimulated glucose uptake and GLUT4 translocation17, we reasoned that if Rac1 was acting via NOX2 then ncf1* mice should show a similar reduction. We first conducted a general characterization of ncf1* mice. Similar total body weight but reduced fat mass was observed in ncf1* mice compared to age-matched WT mice (Supplementary Fig. 4). Respiratory exchange ratio (RER) was lower in ncf1* mice during the light phase compared to WT mice (Fig. 3a), despite a similar habitual activity observed between genotypes (Fig. 3b). Thus, ncf1* mice, similar to Rac1 imKO mice23, display a shift towards fat oxidation at rest and during fasting.

Next, we determined whether NOX2-dependent ROS generation is required for exercise-stimulated glucose uptake. Each mouse was exercised at a relative work load corresponding to 65% of its maximum running capacity for 20 min Exercise-induced 2-[^3H] deoxyglucose (2DG) uptake was markedly attenuated in ncf1* mice compared to WT (Fig. 3c-e). Importantly, the reduction of exercise-stimulated glucose uptake in ncf1* mice was not due to differences in maximal running capacity (Fig. 3f), blood glucose levels (Fig. 3g), or intramuscular energetic evaluation as NAD+ and NADH levels (Fig. 3h, i). However, plasma lactate levels were increased by exercise in WT but not in ncf1* mice (Fig. 3j), consistent with a reduced reliance on glycolysis for energy production. No differences were observed in muscle fiber size (Fig. 4a-c), fiber-type composition (Fig. 4d, e), mitochondrial complex expression (Fig. 4f, g), quantifications in Supplementary Fig. 5) or capillary density (Fig. 4h). Thus, ncf1* in comparison to WT mice were markedly impaired in their ability to stimulate glucose uptake in vivo across multiple muscles, without indications of altered glucose delivery or oxidation capacity.

Discussion
The source of ROS during exercise and the role of ROS in the acute and chronic adaptations to exercise, in particular in the context of non-damaging moderate-intensity in vivo exercise, has remained undetermined for more than 30 years.24 The current study showed that moderate-intensity endurance exercise acutely caused a pro-oxidative shift in both humans and mice. Strikingly, our results demonstrated that NOX2 was required for this shift and was a major cytosolic ROS source during moderate-intensity exercise. Furthermore, NOX2 activity was necessary for exercise-stimulated GLUT4 translocation and glucose uptake in skeletal muscle, providing a novel molecular explanation of why Rac1 imKO mice have a strong impairment of exercise-stimulated GLUT4 translocation and glucose uptake.

The myocellular ROS source(s) during exercise conditions has long been debated, with both cytosolic and mitochondrial sources having been proposed based on pharmacological in vitro/ex vivo studies.23-28 Presently, we observed an increase in oxidants measured by DCFH oxidation in exercising mouse and human muscle. Remarkably, despite the non-specific nature of DCF fluorescence, we found that the increase in exercise-stimulated DCFH oxidation was virtually abolished in mice lacking either Rac1 or p47phox components of NOX2. It should be noted, though, that there might be a potential species-difference in DCFH staining pattern, with the human staining for unknown reasons seeming less homogeneous than the mouse staining. To further investigate the contribution of different intramyocellular ROS sources during exercise in mice, we used genetically encoded redox probes targeted to different myocellular compartments to study the ROS sources during in vivo exercise. Exercise promoted an oxidation of cytosol-targeted roGFP2-Orp1 biosensor in WT but not in NOX2-deficient mice. On the other hand, mitochondria-targeted roGFP2-Orp1 probe oxidation was reduced by exercise independently of NOX2. The NOX2 complex-targeted p47roGFP biosensor oxidation was increased by exercise in WT muscles but not in Rac1-deficient mice. Overall, this demonstrates that a functional NOX2 complex, but not mitochondria, is required for cytosolic ROS production
induced by exercise in concordance with previous in vitro studies. We and others have shown that the small rho family GTPase Rac1 is necessary for insulin, contraction and passive stretch-induced skeletal muscle glucose uptake. We have previously found this Rac1-dependency of glucose uptake and GLUT4 translocation to be more pronounced during in vivo treadmill exercise compared to in vitro contractions.

**Fig. 2** NOX2 is a major ROS source during exercise in skeletal muscle. Subcellularly targeted redox-sensitive GFP2 (roGFP2) were electroporated in ncf1* and p47roGFP in inducible muscle-specific Rac1 mice. Representative image and quantification of a Mito-roGFP2-orp1 (WT, n = 4 and ncf1* = 3), b cyto-roGFP2-Orp1 in Flexor Digitorum Brevis fibers (WT, n = 3–4 and ncf1* = 3) and c p47roGFP oxidation in tibialis anterior muscle in WT and Rac1 imKO mice (WT, n = 4/8 for rest/exercise, Rac1 imKO, n = 3/8 for rest/exercise groups). Two-way ANOVA was performed to test for effects of exercise (Exer) genotype (Geno), and interaction (Int), followed by Tukey’s post hoc test with correction for multiple comparisons. * Denotes $p < 0.05$ for main effects/interaction. #, ### Denotes $p < 0.05$ and $p < 0.001$ compared to the WT group. Individual values and mean ± SEM are shown. Scale Bar = 10 µm (a and b) / 30 µm (c). For a–c, source data and $p$ values are provided in the Source Data file.
GLUT4 trafficking field has mostly focused on Rac1 as an orchestrator of the dynamic reorganization of the cortical actin cytoskeleton consisting of the cytoplasmic β and γ actin-isoforms\(^\text{15}\). This actin-reorganization was shown to be crucial for insulin-stimulated GLUT4 translocation in muscle cells\(^\text{32}\). However, the cytoplasmic β and γ actin-isoforms are both downregulated during muscle differentiation and whether dynamic reorganization occurs in adult skeletal muscle fibers similarly to in cells is presently unclear\(^\text{33}\). Our present data suggest that NOX2 is a vital downstream mediator of the effect of Rac1 on exercise-induced glucose uptake and GLUT4 translocation, since the Rac1 imKO phenotype is shared by mice lacking...
another essential regulatory subunit of NOX2, p47phox. In addition, our in vivo glucose uptake data provide a likely physiological mechanism explaining why exogenous antioxidants inhibit ex vivo contraction-stimulated and stretch-stimulated glucose uptake. The relative dependence on actin and NOX2, and whether NOX2 and actin interact in muscle to regulate glucose uptake, as suggested in other cell types, should be clarified in future studies.

We observed no genotype difference in other possible determinants of muscle glucose uptake in vivo, including capillary density, muscle fiber-type, or protein expression of glucose metabolic proteins. Consistent with our previous reports in ncf1 mice and Rac1 imKO mice, Rac1 regulates glucose uptake. However, the reduction in exercise-stimulated kinase signaling is less consistent than the reduction in glucose uptake in the different muscles analyzed in the ncf1 mice. Moreover, Rac1 imKO mice share the same glucose uptake phenotype without showing reductions in stretch-stimulated signaling, including p38 MAPK. Instead, we speculate that the shared reduction in exercise-stimulated glucose uptake in ncf1 mice and Rac1 imKO mice might relate to a shared and yet undetermined redox-sensitive signaling mechanism. Worth noting, we believe NOX2 signal independently of the AMPK-TBC1D1 signaling axis, based on the previous work by us and others. In conclusion, with the current study, strongly suggesting that Rac1 regulates glucose uptake via NOX2, we propose that NOX2 also signals independently of AMPK to regulate glucose uptake during moderate-intensity exercise. Future studies should work to identify the shared cell signaling traits between different NOX2-deficient mouse models using, e.g. redox proteomics.

In conclusion, this study showed for the first time that NOX2 is activated during moderate-intensity exercise in human and mouse skeletal muscle and is the primary source of ROS under such conditions. Furthermore, our comparison of two mouse models lacking regulatory NOX2 subunits showed that lack of ROS generation during exercise strongly impaired muscle glucose uptake and GLUT4 translocation during exercise. This indicates that NOX2 is a major source of ROS generation during exercise and that NOX2-dependent ROS production is an important signal for increasing muscle glucose uptake during exercise.

Materials and methods

Animals. Male B10.Q WT and B10.Q p47phox mutant (ncf1) mice contain a point mutation in exon 8 generated in a previous study.46,47. Age-matched WT and ncf1 mice between 12 and 16 weeks of age were used for experiments. Inducible muscle-specific male Rac1 mice (imKO) and littermate control mice were generated by crossing breeders Rac1 imKO mice with mice expressing Cre recombinase from the tetracycline-controlled transactivator coupled to the human skeletal actin promoter. Control Rac1 WT mice were littermates carrying the Cre recombinase or the corresponding wild-type allele. Rac1 mKO mice were homozygous for the floxed Rac1 gene and either homozygous or heterozygous for the Cre recombinase. Rac1 mKO mice were induced at 10–14 weeks of age by adding doxycycline in the drinking water (1 g/L; Sigma-Aldrich) for 3 weeks followed by a washout period of 3–5 weeks. Control wild type (WT) mice were littermates and also received doxycycline.

All mice were group-housed maintained on a 12:12-h light–dark cycle, at 21 °C, and received standard rodent chow diet (Altromin no. 1324; Chr. Pedersen, Denmark) and water ad libitum. All experiments were approved by the Danish Animal Experimental Inspectorate and complied with the “European Convention for the Protection of Vertebrate Animals Used for Experiments and Other Scientific Purposes.”

Human experiments. Three young, healthy men (age 29 ± 3.56 years, subjects’ characteristics are shown in Supplementary Table 2) gave their written, informed consent to participate in the study approved. The volunteers visited the laboratory on two separate days. The first day, the subjects completed an incremental test on a Monark Ergomedic 839E cycle ergometer (Monark, Sweden) to determine peak power output (PPO). On the second day, each subject performed a 30-min exercise trial at the intensity corresponding to ~65% of their individual peak power output in fasted state. Muscle biopsies were obtained from the vastus lateralis under local anesthesia (~3 ml xylolacine [20 mg ml⁻¹ lidocaine], Astra, Stockholm, Sweden) before and after exercise using a 5 mm Bergstrom needle with suction. The muscle biopsies were embedded in optimal cutting temperature compound (tissue-tek) and frozen in liquid nitrogen-cooled isopentane and stored at ~80 °C for further analysis.

Ethical regulations. All experiments were approved by the Danish Animal Experimental Inspectorate (2015-15-0201-00477). Human experiments were approved by the Regional Ethics Committee for Copenhagen (H-16040740) and complied with the ethical guidelines of the Declaration of Helsinki II.

In vivo gene transfer in adult skeletal muscle. For the in vivo transfection experiments, mice were anesthetized with 2–3% isoflurane. Hyaluronidase (Sigma-Aldrich) dissolved in sterile saline solution (0.36 mg/ml) was injected subcutaneously on the plantar side of the foot near but not into the FDB and intramuscularly in TA muscle, followed by 20 and 40 µl plasmid injections 1 h later, respectively. FDB muscle electroporation was performed by delivering 10 electrical pulses at an intensity of 75 V/cm, 10-ms pulse duration, 200-ms pulse interval using acupuncture needles (0.20 × 25 mm, Tai Chi, Lhasa OMS) connected to an ECM 830 BTX electroporator (BTX Harvard Apparatus). TA electroporation was performed following the same protocol but raising the intensity to 100 V/cm (#45-0101 Caliper Electrode, BTX Caliper Electrodes, USA). The p7-roGFP2 construct used to determine NOX2 activity was a kind gift from Professor George G. Rodenbeck. The Mito-roGFP2-Orp1 (Addgene #64991) and Mito-roGFP2-Orp1 (Addgene #64992) plasmids were gifts from Professor Tobias Dick. The GLUT4-myc-GFP construct was a gift from Professor Jonathan Bogan (Addgene #52872). After electroporation, mice were allocated to their cages for 10 days before performing the experiments.

Metabolic chambers. O2 uptake (VO2) and CO2 production (VCO2) were measured using a CaloSys apparatus (TSE Systems, Bad Homburg, Germany). The data presented is the average for light and dark periods measured over 2 consecutive days in WT and ncf1 mice. The RER was calculated as VCO2 production/VO2 uptake.
Fig. 4 Ncf1* mice show similar muscle size, fiber-type composition, mitochondrial content and capillary density compared to WT group. a Fiber size-related parameters in WT and ncf1* mice were determined using wheat germ agglutinin (WGA) staining. b Myofiber cross-sectional area, and c minimum (min.) Ferret diameter. d Quantification and e representative merged image of fiber-type staining where Type I fibers (blue), Type IIa (green), Type IIb (red), Type IIx (non-stained) in WT (n = 6), and ncf1* (n = 5) TA muscles. Subunits of mitochondrial oxidative phosphorylation complexes were determined in f quadriceps and g soleus muscle lysates (n = 14 per group). h Capillary density was estimated by PECAM immunostaining in tibialis anterior sections. Two-way ANOVAs was performed to test for effects of exercise (Exer), genotype (Geno), and interaction (Int), followed by Tukey’s post hoc test with correction for multiple comparisons. Individual values and mean ± SEM are shown. Scale Bar = 100 µm. For b, c, d, and h, source data and p values are provided in the Source Data file. For f and g, uncropped blots are provided in the Source Data file.
Exercise-stimulated GLUT4 translocation requires NOX2 activity. a the GLUT4-myc-GFP construct was electroporated into tibialis anterior muscles of both WT and ncf1* mice. Non-permeabilized muscle fibers from exercised (20 min, 65% maximal running speed) or resting mice were stained with anti-myc antibody and imaged by confocal microscopy (n = 4 mice, a minimum of 10 fibers/muscle). Total endogenous GLUT4 and HK II were determined by western blot in the following muscles b quadriceps, c soleus, and d TA muscles in WT and ncf1* mice (n = 14). Unpaired t-test (b–d) and two-way ANOVA were performed to test for effects of exercise (Exer), genotype (Geno), and interaction (Int), followed by a Tukey’s post hoc test with correction for multiple comparisons. * Denotes p < 0.05 for main effect. # Denotes p < 0.05 compared to the WT group. Individual values and mean ± SEM are shown. Scale bar = 20 μm. For a, source data and p values are provided in the Source Data file. For b–d, uncropped blots are provided in the Source Data file

**Maximal running tests.** Mice were acclimated to the treadmill three times (15 min at 0.16 m/s) (Treadmill TSE Systems) a week prior to the maximal running tests. The maximal running test started at 0.16 m/s for 300 s with 10% incline, followed by a continuing increase (0.2 m/s) in running speed every 60 s until exhaustion. Exhaustion was defined as the point at which instead of running on the treadmill, the mice fall back on the grid three times within a 30 s period. Maximal running speed was determined as the last completed stage during the incremental test.

**FDB fiber isolation.** Muscle fibers were obtained by enzyme digestion of the whole muscle with collagenase type II (1.5 mg/ml) (Worthington, Lakewood, NJ) for 90 min at 37 °C followed by mechanical dissociation with fire-polished Pasteur pipettes. Isolated fibers were seeded in ECM Gel-coated (Sigma-Aldrich) cell culture dishes in DMEM supplemented with 10% fetal bovine serum. After 16 h of seeding, the fibers were used for experimentation.

**Live imaging.** FDB fibers were imaged in phenol red-free growth medium (5% horse serum) while kept at 95% O2, and 5% CO2 and 37 °C using a Pecon Lab-Tek S1 heat stage. Electrical stimulation protocol (10 V, 1 Hz, 0.1 ms duration) was delivered to isolated FDBs for 15 min via field electric field stimulation device (RC-37FS, Warner instruments, USA). Fibers were loaded with 20 nM tetrathymethylrhodamine, ethyl ester (TMRE®, Life Technologies) for 30 min before imaging.

**Exercise-stimulated GLUT4 translocation.** GLUT4 translocation was measured as recently described41. Briefly, rapidly dissected TA muscles were fixed by immersion in ice-cold 4% paraformaldehyde in PBS for 4 h. TA muscles were transferred to a Syngard dish and isolated into smaller bundles using fine forceps. The bundles were transferred to a storage solution containing PBS and glycerol (1:1) and kept at 4 °C overnight. Individual fibers were teased from fixed muscle with fine forceps under a dissection microscope. Non-permeabilized isolated muscle fibers were incubated in blocking buffer (1% BSA, 5% goat serum (16210-064, Gibco), 0.1% Na Azide (247-852, Merck) for 1 h and then incubated with an anti-myc antibody overnight (Supplementary Table I). The next day, fibers were then washed 3 × 10 min in PBS containing 0.04% saponin and incubated with Alexa 568 antibody (Supplementary Table I) in blocking buffer containing 0.04% saponin for 120 min. Individual muscle fibers were transferred to mounting media (H-1000; Vector Laboratories) on a glass slide and covered by a coverslip. A minimum of 10 transfected fibers were blindly imaged from each muscle (a total of 60 fibers) using a x63 1.4 NA Plan-Apochromat objective on a Zeiss 780 microscope driven by Zeiss Zen Black 2012. Image analysis is described in the image analysis sections and as previously described41.

**Redox histology.** TA muscles were dissected and embedded in optimum cutting temperature (OCT) medium from Tissue-Tek, frozen in melting isopentane and kept at −80 °C until processing. An independent set of TA muscles were used for western blotting. Total oxidant levels were estimated as previously described42. Briefly, 10 μm thickness muscle cryosections were incubated with 5 μM of 2′,7′-DCFH (Molecular Probes, Eugene) and allowed to dry overnight at room temperature in dark. Muscle membranes were visualized using Texas red-labeled wheat germ agglutinin (WGA; Molecular Probes). The redox histology was performed as previously described43,44 and in Supplementary Fig. 3A. Whole FDB muscles were immediately immersed in PBS containing freshly dissolved NEM (100 mM) in ice and then fixed in 4% PFA in PBS (pH 7.4) plus 100 mM NEM for 2 h at 4 °C.
p70S6K-GFP–transfected TA cryosections were incubated with PBS containing 50 mM N-ethylmaleimide (NEM) for 10 min at 4 °C, followed by phosphorylation levels of relevant proteins were determined by standard immunoblotting techniques, loading equal amounts of protein.

The primary antibodies used p-AMPKThr172 diluted 1:100 in 3% BSA (Cell Signaling Technology (CST), #2535s), p-p38 MAPKThr180/Tyr182 diluted 1:100 in 3% BSA (CST, #9211), Erk1/2Thr202/Tyr204 diluted 1:100 in 3% BSA (CST, #9101), p-AC2 pSer123 diluted 1:100 in 3% BSA (Millipore, 03-030), GLUT4 (TiamoFisher Scientific, PA-7902), Rac1 diluted 1:1000 in 2% skim milk (BD Biosciences, #610650), NOX2 diluted 1:1000 in 2% skim milk (Abcam, #AB92968), Catalase diluted 1:250 in 2% skim milk (SCBT, sc-271803), MnSOD diluted 1:1000 in 2% skim milk (Millipore, 06-984), TRX2 diluted 1:1000 in 2% skim milk (SCBT, sc-50336), actin diluted 3:1000 in 2% skim milk (CST, #49706), p38 MAPK diluted 1:1000 in 2% skim milk (Abcam, #Ab229504), and Hexokinase II diluted 1:1000 in 3% BSA (CST, #2867). ACC protein was detected using horseradish peroxidase-conjugated streptavidin from Dako (P0397), dilution 1:3000 in 3% BSA (Supplementary Table 1). All antibodies were optimized for signal linearity. Membranes were blocked for 1 h at room temperature in TBS-Tween 20 containing either 2% skimmed milk or 2% BSA and incubated overnight at 4 °C with primary antibody. The membranes were incubated in the corresponding horseradish peroxidase-conjugated secondary antibody for 1 h at room temperature and washed in TBS-T before visualization of the proteins (Chemiluminescent Imaging System, Bio Rad). Uncropped blots from the main Figs. are shown in the Source Data file.

Statistical analyses. Results are shown as individual values and mean ± S.E.M. Statistical testing was carried out using t-tests or two-way (repeated measures when appropriate) ANOVA as applicable. Tukey’s post-hoc test was performed for multiple comparisons when ANOVA revealed significant main effects or interactions. Statistical analyses were performed using GraphPad Prism v8. All p values are provided in the Source Data file.

11. Chambers, M. A., Moyaln, J. S., Smith, J. D., Goodyear, L. J. & Reid, M. B. Stretch-stimulated glucose uptake in skeletal muscle is mediated by

Running-stimulated muscle 2-deoxyglucose (DG) uptake.

Muscle-specific 2DG uptake was measured as previously described16. [3H]2DG (PerkinElmer) was injected intraperitoneally (as a bolus in saline, 10 μg/g body weight) containing 0.1 mM/L, 2DG and 50 μCi/mL. [3H]2DG corresponding to ~12 μCi/mouse into fed mice immediately before the exercise bout. Blood glucose was measured before and immediately after 20 min of exercise. Mice were euthanized by cervical dislocation, and muscle tissues and plasma samples quickly frozen in liquid nitrogen and stored at −80 °C for future analysis. Samples were deproteinized using 0.1 mol/L NaOH (3.1), 0.1 mol/L ZnSO4. The total muscle [3H]2DG tracer activity found in 2DG-6-phosphate was divided by the area under the curve of the specific activity at time points 0 and 20 min multiplied with the average blood glucose at time points 0 and 20 min This was related to muscle weight and the time to obtain the tissue-specific 2DG uptake as micromoles per gram per hour.

Western blot analyses.

Tissue was homogenized for 1 min at 30 Hz using a Tissue Lyser in ice-cold lysis buffer (0.05 mol/L Tris Base pH 7.4, 0.15 mol/L NaCl, 1 mmol/L EDTA and EGTA, 0.05 mol/L sodium fluoride, 5 mmol/L sodium pyrophosphate, 2 mmol/L sodium orthovanadate, 1 mmol/L benzamidine, 0.5% protease inhibitor cocktail (P8340, Sigma Aldrich), and 1% NP-40). After rotating end-over-end for 30 min, lysate supernatants were collected by centrifugation (18 327 × g) for 20 min at 4 °C. Lysate protein concentrations were determined using BSA standards and bichinonic acid assay reagents (Pierce). Total protein and
reactive oxygen species and p38 MAP-kinase. J. Physiol. 587, 3363–3373 (2010).
