1 Proofs of theorems of Section 3

Algorithm 1  
Riemannian coordinate minimization on $O_d$

Input: Differentiable objective function $f$, initial matrix $U_0 \in O_d$

t = 0

while not converged

1. Sample uniformly at random a pair $(i(t), j(t))$ such that $1 \leq i(t) < j(t) \leq d$.
2. $U_{t+1} = \text{argmin}_\theta f(U_t \cdot G(i, j, \theta))$.
3. $t = t + 1$.

end while

Definition 1.  
Riemannian gradient

The Riemannian gradient $\nabla f(U)$ of $f$ at point $U \in O_d$ is the matrix $U \Omega$, where $\Omega \in \text{Skew}(d)$, $\Omega_{ji} = -\Omega_{ij} = \nabla_{ij} f(U), 1 \leq i < j \leq d$ is the directional derivative as defined in Eq. 1 of the main text, and $\Omega_{ii} = 0$. The norm of the Riemannian gradient $||\nabla f(U)||_2 = \text{Tr}(\nabla f(U)\nabla f(U)^T) = ||\Omega||^2_{fro}$.

Definition 2.  
A point $U_* \in O_d$ is asymptotically stable with respect to Algorithm 1 if it has neighborhood $V$ such that all sequences generated by Algorithm 1 with starting point $U_0 \in V$ converge to $U_*$.

Theorem 1.  
Convergence to local optimum

(1) The sequence of iterates $U_t$ of Algorithm 1 satisfies: $\lim_{t \to \infty} ||\nabla f(U_t)|| = 0$. This means that the accumulation points of the sequence $\{U_t\}_{t=1}^\infty$ are critical points of $f$.

(2) Assume the critical points of $f$ are isolated. Let $U_*$ be a critical point of $f$. Then $U_*$ is a local minimum of $f$ if and only if it is asymptotically stable with regard to the sequence generated by Algorithm 1.

Proof.  
(1) Algorithm 1 is obtained by taking a step in each iteration $t$ in the direction of the tangent vector $Z_t$, such that for the coordinates $(i(t), j(t))$ we have $(Z_t)_{ij} = -(\nabla f(U_t))_{ij}$, $(Z_t)_{ji} = -(\nabla f(U_t))_{ji}$, and $(Z_t)_{kl} = 0$ for all other coordinates $(k, l)$.

The sequence of tangent vectors $Z_t \in T_{U_t}O_d$ is easily seen to be gradient related: $\limsup_{k \to \infty} \langle \nabla f(U_t), Z_t \rangle < 0$. This follows from $Z_t$ being equal to exactly two coordinates of $\nabla f(U_t)$, with all other coordinates being 0.

For a rigorous proof we need to slightly complicate the sampling procedure in line 1 of Algorithm 1 such that coordinates with 0 gradient are not resampled until a non-zero gradient is sampled. Alternatively we can state that the result holds with probability 1.
Using the optimal step size as we do assures at least as large an increase \( f(U_t) - f(U_{t+1}) \) as using the Armijo step size rule \([1, 2]\). Using the fact that the manifold \( \mathcal{O}_d \) is compact, we obtain by theorem 4.3.1 and corollary 4.3.2 of Absil et al. \([3]\) that \( \lim_{t \to \infty} ||\nabla f(U_t)|| = 0 \)

(2) Since Algorithm\([4]\) produces a monotonically decreasing sequence \( f(U_t) \), and since the manifold \( \mathcal{O}_d \) is compact, we are in the conditions of Theorems 4.4.1 and 4.4.2 of Absil et al. \([3]\). These imply that the only critical points which are local minima are asymptotically stable.

\[ \square \]

We now provide a rate of convergence proof. This proof is a Riemannian version of the proof for the rate of convergence of Euclidean random coordinate descent for non-convex functions given \([4]\).

**Definition 3.** For an iterate \( t \) of Algorithm\([7]\) and a set of indices \((i(t), j(t))\), we define the auxiliary single variable function \( g^i_j \):

\[
g^i_j(\theta) = f(U_t \cdot G(i, j, \theta)),
\]

(1)

Note that \( g^i_j \) are differentiable and periodic with a period of \( 2\pi \). Since \( \mathcal{O}_d \) is compact and \( f \) is differentiable there exists a single Lipschitz constant \( L(f) > 0 \) for all \( g^i_j \).

**Theorem 2. Rate of convergence**

Let \( U_t \) be the sequence generated by Algorithm\([7]\) and let \( L \) be a universal Lipschitz constant for \( f \), which always exists by compactness and differentiability of \( f \). For the sequence of Riemannian gradients \( \nabla f(U_t) \in \mathcal{T}_{U_t} \mathcal{O}_d \) we have:

\[
\max_{0 \leq t \leq T} E \left[ ||\nabla f(U_t)||^2 \right] \leq \frac{L \cdot d^2 (f(U_0) - f_{\min})}{T + 1}.
\]

(2)

**Lemma 1.** Let \( g : \mathbb{R} \to \mathbb{R} \) be a periodic differentiable function, with period \( 2\pi \). Then there exists a positive constant \( L > 0 \) such that for all \( \theta \in [-\pi, \pi] \):

\[
g(\theta) \leq g(0) + \theta g'(0) + \frac{L}{2} \theta^2.
\]

**Proof.** Since \( g \) is periodic it is bounded, with bounded derivatives. Let \( L \) be a Lipschitz constant on the derivative \( g' \). We thus have, for all \( \theta \),

\[
g'(\theta) - g'(0) \leq L|\theta|.
\]

We now have:

\[
g(\theta) = g(0) - \theta g'(0) + \int_0^\theta g'(\tau) - g'(0) d\tau \leq g(0) - \int_0^\theta |g'(\tau)| d\tau \leq \frac{L}{2} \theta^2.
\]

\[ \square \]

**Corollary 1.** Let \( g = g_{(i(t+1), j(t+1))} \): Under the conditions of Algorithm\([7]\) we have:

\[
f(U_t) - f(U_{t+1}) \geq \frac{1}{2L} \nabla_{ij} f(U_t)^2 \text{ for the constant } L \text{ defined in } \[7\].
\]

**Proof.** By the definition of \( g \) we have \( f(U_{t+1}) = \min_{\theta} g(\theta) \), and we also have \( g(0) = f(U_t) \). Finally, by Eq. 1 of the main paper we have \( \nabla_{ij} f(U_t) = g'(0) \). From Lemma\([1]\) we have \( g(\theta) - g(0) \leq \theta g'(0) + \frac{L}{2} \theta^2 \). Minimizing the right-hand side with respect to \( \theta \), we see that \( \min_{\theta} \{g(0) - g(\theta)\} \geq \frac{1}{2L} (g'(0))^2 \). Substituting \( f(U_{t+1}) = \min_{\theta} g(\theta), f(U_t) = g(0), \) and \( \frac{1}{2L} \nabla_{ij} f(U_t) = g'(0) \) completes the result.

\[ \square \]

**Proof of Theorem 2** By Corollary\([1]\) we have \( f(U_t) - f(U_{t+1}) \geq \frac{1}{2L} \nabla_{ij} f(U_t)^2 \). By Definition\([1]\) \( \pm \nabla_{ij} f(U_t) \) is the \( (i, j) \) and \( (j, i) \) entry of \( \nabla f(U_t) \). If we take the expectation of both sides with respect to a uniform random choice of indices \( i, j \) such that \( 1 \leq i < j \leq d \), we have:

\[
E [f(U_t) - f(U_{t+1})] \geq \frac{1}{L \cdot d^2} ||\nabla f(U_t)||^2,
\]

(3)

Summing the left-hand side gives a telescopic sum which can be bounded by \( f(U_0) - \min_{U \in \mathcal{O}_d} f(U) = f(U_0) - f_{\min} \). Summing the right-hand side and using this bound, we obtain

\[
\sum_{t=0}^T E \left[ ||\nabla f(U_t)||^2 \right] \leq L \cdot d^2 (f(U_0) - f_{\min})
\]

(4)

This means that \( \min_{0 \leq t \leq T} E \left[ ||\nabla f(U_t)||^2 \right] \leq \frac{L \cdot d^2 (f(U_0) - f_{\min})}{T + 1} \).

\[ \square \]
2 Proofs of theorems of section 5

Definition 4. A tensor $T$ is orthogonally decomposable if there exists an orthonormal set of vectors $v_1, \ldots, v_d \in \mathbb{R}^d$, and positive scalars $\lambda_1, \ldots, \lambda_d > 0$ such that:

$$T = \sum_{i=1}^{d} \lambda_i (v_i \otimes v_i \otimes v_i),$$

(5)

Theorem 3. Let $T \in \mathbb{R}^{d \times d \times d}$ have an orthogonal decomposition as in Definition 4 and consider the optimization problem

$$\max_{U \in \mathcal{O}_d} f(U) = \sum_{i=1}^{d} T(u_i, u_i, u_i),$$

(6)

where $U = [u_1 \, u_2 \, \ldots \, u_d]$. The stable stationary points of the problem are exactly orthogonal matrices $U$ such that $u_i = v_{\pi(i)}$ for a permutation $\pi$ on $[d]$. The maximum value they attain is $\sum_{i=1}^{d} \lambda_i$.

Proof. For a tensor $T'$ denote $\text{vec}(T') \in \mathbb{R}^d$ the vectorization of $T'$ using some fixed order of indices. Set $\hat{T}(U) = \sum_{i=1}^{d} (u_i \otimes u_i \otimes u_i)$, with $\hat{T}(U)_{abc} = \sum_{i=1}^{d} u_{ia}u_{ib}u_{ic}$. The sum of trilinear forms in Eq. (5) is equivalent to the inner product in $\mathbb{R}^d$ between $\hat{T}(U)$ and $T$: $\sum_{i=1}^{d} T(u_i, u_i, u_i) = \sum_{i=1}^{d} \sum_{abc} T_{abc}u_{ia}u_{ib}u_{ic} = \sum_{abc} T_{abc} \sum_{i=1}^{d} (u_{ia}u_{ib}u_{ic}) = \sum_{abc} T_{abc} \hat{T}(U)_{abc} = \text{vec}(T) \cdot \text{vec}(\hat{T}(U))$. Consider the following two facts:

1. $\hat{T}(U)_{abc} \leq 1$ for all $a, b, c = 1, \ldots, d$: since the vectors $u_i$ are orthogonal, all their components $u_{ia} \leq 1$. Thus $\hat{T}(U)_{abc} = \sum_{i=1}^{d} u_{ia}u_{ib}u_{ic} \leq \sum_{i=1}^{d} u_{ia}u_{ib} = \leq 1$, where the last inequality is because the sum is the inner product of two rows of an orthogonal matrix.

2. $||\text{vec}(\hat{T}(U))||_2^2 = d$. This is easily checked by forming out the sum of squares explicitly, using the orthonormality of the rows and columns of the matrix $U$.

Assume without loss of generality that $V = I_d$. This is because we may replace the terms $T(u_i, u_i, u_i)$ in the objective with $T(V^T u_i, V^T u_i, V^T u_i)$, and because the manifold $V^T \mathcal{O}_d$ is identical to $\mathcal{O}_d$. Thus we have that $T$ is a diagonal tensor, with $T_{aaa} = \lambda_a > 0$, $a = 1, \ldots, d$. Considering facts (1) and (2) above, we have the following inequality:

$$\max_{U \in \mathcal{O}_d} \sum_{i=1}^{d} T(u_i, u_i, u_i) = \max_{U \in \mathcal{O}_d} \text{vec}(\hat{T}(U)) \cdot T \leq \max_{\hat{T}} \text{vec}(\hat{T}) \cdot T \quad \text{s.t.} \quad ||\text{vec}(\hat{T})||_{\infty} \leq 1 \land ||\text{vec}(\hat{T})||_2^2 = d.$$

(7)

(8)

$T$ is diagonal by assumption, with exactly $d$ non-zero entries. Thus the maximum of (6) is attained if and only if $\hat{T}_{aaa} = 1, a = 1, \ldots, d$, and all other entries of $\hat{T}$ are 0. The value at the maximum is then $\sum_{i=1}^{d} \lambda_i$.

The diagonal ones tensor $\hat{T}$ can be decomposed into $\sum_{i=1}^{d} \epsilon_i \otimes \epsilon_i \otimes \epsilon_i$. Interestingly, in the tensor case, unlike in the matrix case, the decomposition of orthogonal tensors is unique up to permutation of the factors $\epsilon_i$. Thus, the only solutions which attain the maximum of (7) are those where $u_i = e_{\pi(i)}$, $i = 1, \ldots, d$. \hfill \square

3 Algorithm for streaming sparse PCA

Following are the details for the streaming sparse PCA version of our algorithm used in the experiments of section 4. The algorithm starts with running the original coordinate minimization procedure on the first $m$ samples. It then chooses the column with the least $l_2$ and replaces it with a new data sample, and then re-optimizes on the new set of samples. There is no need for it to converge in the inner iterations, and in practice we found that order $m$ steps after each new sample are enough for good results.
Algorithm 2 Riemannian coordinate minimization for streaming sparse PCA

**Input:** Data stream $a_j \in \mathbb{R}^d$, number of sparse principal components $m$, initial matrix $U_0 \in O_m$, sparsity parameter $\gamma \geq 0$, number of inner iterations $L$.

$AU = [a_1 a_2 \ldots a_m] \cdot U_0$. // $AU$ is of size $d \times m$

while not stopped do
  for $t = 1 \ldots L$ do
    1. Sample uniformly at random a pair $(i(t), j(t))$ such that $1 \leq i(t) < j(t) \leq m$.
    2. $\theta_{t+1} = \arg\max_\theta \sum_{k=1}^d (|\cos(\theta)(AU)_{ki(t)} + \sin(\theta)(AU)_{kj(t)}| - \gamma)_+^2$
       $+$ $| - \sin(\theta)(AU)_{ki(t)} + \cos(\theta)(AU)_{kj(t)}| - \gamma)_+^2$.
    3. $AU = AU \cdot G(i(t), j(t), \theta_{t+1})$.
  end for
  4. $i_{\min} = \arg\min_{i=1 \ldots m} ||(AU)_{.,i}||_2$.
  5. Sample new data point $a_{new}$.
  6. $(AU)_{.,i_{\min}} = a_{new}$.
end while

$Z = \text{solveForZ}(AU, \gamma)$ // Algorithm 6 of Journée et al. [7].

**Output:** $Z \in \mathbb{R}^{d \times m}$
