**Abstract**

**Background:** Fatty acids (FAs) with a chain length of more than 18 carbon atoms (> C18) are interesting for the production of specialty compounds derived from these FAs. These compounds include free FAs, like erucic acid (C22:1-Δ13), primary fatty alcohols (FOHs), like docosanol (C22:0-FOH), as well as jojoba-like wax esters (WEs) (C38-WE to C44-WE), which are esters of (very) long-chain FAs and (very) long-chain FOHs. In particular, FAs, FOHs and WEs are used in the production of chemicals, pharmaceuticals and cosmetic products. Jojoba seed oil is highly enriched in diunsaturated WEs with over 70 mol% being composed of C18:1–C24:1 monounsaturated FOH and monounsaturated FA moieties. In this study, we aim for the production of jojoba-like WEs in the yeast *Saccharomyces cerevisiae* by increasing the amount of very long-chain, monounsaturated FAs and simultaneously expressing enzymes required for WE synthesis.

**Results:** We show that the combined expression of a plant-derived fatty acid elongase (FAE/KCS) from *Crambe abyssinica* (CaKCS) together with the yeast intrinsic fatty acid desaturase (FAD) Ole1p leads to an increase in C20:1 and C22:1 FAs in *S. cerevisiae*. We also demonstrate that the best enzyme candidate for C24:1 FA production in *S. cerevisiae* is a FAE derived from *Lunaria annua* (LaKCS). The combined overexpression of CaKCS and Ole1p together with a fatty acyl reductase (FAR/FAldhR) from *Marinobacter aquaeolei* VT8 (MaFAldhR) and a wax synthase (WS) from *Simmondsia chinensis* (ScWS) in a *S. cerevisiae* strain, overexpressing a range of other enzymes involved in FA synthesis and elongation, leads to a yeast strain capable of producing high amounts of monounsaturated FOHs (up to C22:1-FOH) as well as diunsaturated WEs (up to C46:2-WE).

**Conclusions:** Changing the FA profile of the yeast *S. cerevisiae* towards very long-chain monounsaturated FAs is possible by combined overexpression of endogenous and heterologous enzymes derived from various sources (e.g. a marine copepod or plants). This strategy was used to produce jojoba-like WEs in *S. cerevisiae* and can potentially be extended towards other commercially interesting products derived from very long-chain FAs.

**Keywords:** *Saccharomyces cerevisiae*, Very long-chain monounsaturated fatty acids, Very long-chain monounsaturated fatty alcohols, Jojoba-like wax esters

Background

Fatty acids (FAs) play a major role during growth and maintenance of all living cells, since they are components of cell membrane lipids, organelle membrane lipids as well as storage lipids. Moreover, they can function as signaling compounds in the form of sphingolipids. The FAs naturally found in the yeast *Saccharomyces cerevisiae* comprise mostly C16 and C18 species. The most abundant one is palmitoleic acid (C16:1-Δ9), followed by oleic acid (C18:1-Δ9), palmitic acid (C16:0) and stearic acid (C18:0) [1]. The composition of FAs in yeast is strictly regulated and dependent, among other factors, on the cultivation temperature [2] as well as the media composition. Culture medium that contains a certain type of FA can change the distribution of FAs inside the yeast cell [3].

The total distribution of FAs is also reflected by the composition of membrane- as well as storage lipids in yeast. In case of phospholipids (PLs), which make up around 70% of the cell membrane, the main FA residues are C14:1-Δ9, C16:1-Δ9 and C18:1-Δ9, which shows the importance of those FA species for the integrity of cell membranes in *S. cerevisiae*. In case of triacylglycerols (TAGs), which function as storage lipids, the most abundant FA residues are C16:0, C16:1-Δ9, C18:0 and C18:1-Δ9 [4]. Besides having a storage function in yeast, TAGs also act as a buffer and sink for excess unsaturated FAs [5] and reflect the composition of added or synthesized FAs [4]. The addition of oleic acid to the growth medium of yeast cells has a strong effect on lipid metabolism and the composition of storage lipids. While cells grown on glucose show approximately a 50/50 accumulation of the storage lipids sterly esters (SEs) and TAGs, cells grown on oleate show a ratio of 1/99. Moreover, the composition of PLs and TAGs changes towards an increased incorporation of oleic acid in medium supplemented with oleate [4]. Yeast cells unable of producing storage lipids, by deletion of genes encoding SE and TAG formation enzymes (Lro1p, Dga1p, Are1p and Are2p), show a defective regulation of lipid synthesis, an extensive proliferation of intracellular membranes and finally cell death under excess of oleate [5].

The de novo FA synthesis in *S. cerevisiae* is located in the cytosol and uses acetyl-coenzyme A (acetyl-CoA) as a building block. The first step of FA synthesis is the carboxylation of acetyl-CoA to malonyl-CoA by an acetyl-CoA carboxylase (Acc1p) [6]. Studies using a deregulated version of Acc1p, in which the serine 1157 was mutated to an alanine residue to lock the Acc1p in a non-phosphorylatable, highly active state, showed that the ratio of C18 to C16 FAs changed. In wildtype cells, the C18/C16 ratio was found to be around 0.5, while the deregulated Acc1p mutant strain showed a ratio of around 2 [7].

This mutation also led to an increase in very long-chain fatty acids (VLCFAs) (C20-C26). In the second step of FA synthesis, a C2 unit derived from malonyl-CoA is attached to acetyl–acyl carrier protein (acyetyl-ACP) and in the further extensions to the acyl-ACP chain, leading to FAs up to C18. These reactions are in the cytosol catalyzed by the fatty acid synthase (FAS) consisting of Fas1p (β-subunit) and Fas2p (α-subunit), which form a hexameric α6β6 complex. When the FAs are released from the FAS enzyme complex, a coenzyme-A unit is attached to them [6]. Besides originating from de novo FA synthesis, external free FAs or free FAs derived from lipid or lipoprotein turnover can be activated to fatty acyl-CoAs (FACoAs) by FACoA synthetases [8–11]. In *S. cerevisiae*, FAs up to C18 can be further elongated up to C26 at the endoplasmic reticulum (ER). These reactions are catalyzed by the β-ketoacyl-CoA synthases (KCSs), also known as fatty acid elongases (FAEs), the β-ketoacyl-CoA reductase (KCR), the β-hydroxyacyl-CoA dehydratase (HCD) and the enoyl-CoA reductase (ECR) which are all integrated in the ER membrane and face the cytosol with their active site [6] (Fig. 1). *S. cerevisiae* possesses three KCS enzymes, Elo1p, Elo2p and Elo3p which all have a discrete substrate range. Elo1p elongates C12–C16 FACoAs to C16–C18 FACoAs. Elo2p is responsible for the biosynthesis of C20–C24 FACoAs and Elo3p specifically elongates C24 FACoAs to C26 FACoAs [12, 13]. In contrast to the KCS enzymes, which are substrate specific, the other elongation enzymes (KCR, HCD and ECR) show a broad specificity, accepting a wide range of substrates [6]. The elongation enzymes at the ER together fulfill the same function as the FAS complex in the cytosol, with the exception that the ER enzymes are distinct proteins in contrast to the FAS complex which contains two subunits with several functional domains.

Besides synthesis and elongation of FAs, also the desaturation of FAs plays an important role in the yeast cell metabolism. *S. cerevisiae* possesses only one fatty acid desaturase (FAD), Ole1p, which can integrate a double bond at the Δ9-position of FACoAs ranging from a carbon chain length of C12–C19 [14] (Fig. 1). Therefore, in contrast to other fungi, *S. cerevisiae* only contains monounsaturated fatty acids (MUFAs) with ~70–80% of its total glycerolipid acyl chains consisting of C14:1-Δ9, C16:1-Δ9 and C18:1-Δ9 [15].

Since the composition of FAs is very important for the integrity of membrane lipid structures, it can be expected that the yeast FA pool can only be changed to a certain extent. Nevertheless, a change of the FA pool can be interesting if certain compounds with a specific chain length (>C18) shall be produced. Those products include free fatty acids (FFAs), fatty alcohols (FOHs), alkanes/alkenes, lipids as well as speciality FAs like eicosapentaenoic
acid and have been produced by metabolic engineering of \textit{S. cerevisiae} and other yeasts [16].

Several commercially interesting products are also derived from very long-chain fatty acids (VLCFAs) and comprise very long-chain fatty alcohols (VLCFOHs) like docosanol (C22:0-FOH) [17] as well as jojoba-like wax esters (WEs), which are mainly composed of C18–C24 monounsaturated fatty alcohol (MUFOH) and mono-unsaturated fatty acid (MUFA) residues [18] (Fig. 1). The application of jojoba oil ranges from cosmetic and personal care products over medical use to lubricants. The current production of jojoba oil is around 4000 tons/year, while the estimated demand is up to 200,000 tons/year [19]. Because of the increased need for jojoba oil, extraction from its natural source will not be enough to meet the demand in the future, even if growing regions for the jojoba plant are expanded extensively. Since \textit{S. cerevisiae} has already been modified for the production of a wide range of chemicals [20], jojoba oil production in modified yeast represents a very promising approach.
In a previous study we could show that jojoba-like WEs can be synthesized in metabolically engineered _S. cerevisiae_ by heterologous expression of a FAR from _Marinobacter aquaeolei_ VT8 and a WS from _Simmondsia chinensis_, but the products were restricted to saturated very long-chain WEs (C40:0-WE and C42:0-WE) [21]. This study made clear that the pool of very long-chain monounsaturated fatty acids (VLCMUFA)s needs to increase in _S. cerevisiae_ to enable the synthesis of jojoba-like diunsaturated wax esters (DUWEs).

To achieve this goal, we have expressed several endogenous and heterologous KCSs and FADs in _S. cerevisiae_ and demonstrate that this can lead to a high increase in C20:1, C22:1 and C24:1 MUFA.s. Moreover, it is shown that the combined expression of a plant KCS, a bacterial FAR, a plant WS and several yeast intrinsic enzymes leads to a final MUFOH and DUWE producing strain.

**Results**

**Increasing the amount of MUFA.s by expression of a heterologous KCS together with Ole1p of _S. cerevisiae_**

Previously, we demonstrated that jojoba-like WEs can be synthesized in metabolically engineered _S. cerevisiae_ strains by combined overexpression of the yeast intrinsic Elo2p together with a FAR from _M. aquaeolei_ and a WS from _S. chinensis_, but the products were restricted to saturated very long-chain WEs (C40:0-WE and C42:0-WE) [21]. Based on this observation we concluded that the pool of VLCMUFA.s is not high enough to enable the synthesis of jojoba-like DUWEs in _S. cerevisiae_.

Therefore, we investigated the effect of overexpressing the endogenous Ole1p either together with the yeast intrinsic Elo2p or together with a heterologous plant-derived FAE/KCS enzyme in _S. cerevisiae_. The heterologous FAE/KCS enzymes tested include those from _Arabidopsis thaliana_ (AtFAE), _Brassica napus_ (BnKCS), _Crambe abyssinica_ (CaKCS), _Lunaria annua_ (LaKCS), _S. chinensis_ (SciFAE) and _Tropaeolum majus_ (TmKCS). Combinations of a KCS and Ole1p were cloned into the episomal plasmid pYX212 via modular pathway engineering [22] (Additional file 1: Figure S1). The plasmids were transferred into the background strain _S. cerevisiae_ CEN.PK 113-5D elo3Δ X-2::pMPC3::ACC1** X-3::IFAS38::PHS1::TSC13::ACB1. This strain contains a constitutively active version of Acc1p to increase the supply of malonyl-CoA, a deletion of the _ELO3_ gene to prevent formation of C26 FA.s and an additional copy of the genes IFA38, PHS1 and TSC13, encoding the yeast intrinsic elongation enzymes KCR, HCD and ECR, respectively. Moreover, it harbors an additional copy of the _ACB1_ gene encoding the acyl-CoA binding protein Acb1p to increase the acyl-CoA pool, which has been shown in a previous study to result in an increased fatty acid ethyl ester production [23].

The analysis of the FA profile of the resulting strains showed that the combined overexpression of a KCS together with the yeast intrinsic Ole1p leads to an increase in the pool of VLCMUFA.s in case of the KCS enzymes Elo2p, CaKCS and LaKCS. The KCS enzymes from _A. thaliana_, _B. napus_ and _T. majus_ were not able to increase the pool of VLCMUFA.s (Fig. 2).

The highest increase in C20:1 and C22:1 FA.s in our study was obtained by combined expression of the KCS from _C. abyssinica_ (CaKCS) together with the intrinsic Ole1p from _S. cerevisiae_. The level of C20:1 FA.s and C22:1 FA.s increased 20.6- and 95.7-fold, respectively, compared to the wildtype. In contrast to that, the highest increase in C24:1 FA.s (25.6-fold compared to Elo2p overexpression strain) was observed by expression of the KCS from _L. annua_ (LaKCS) together with Ole1p (Fig. 2).

**Increasing the amount of MUFA.s by expression of a heterologous KCS and a heterologous FAD**

After having identified CaKCS and LaKCS as promising enzyme candidates to increase the C20:1, C22:1 and C24:1 FA concentrations in _S. cerevisiae_, we wanted to study the influence of heterologous FADs on the synthesis of VLCMUFA.s. The heterologous FAD enzymes tested include those from _C. hyperboreus_ (ChDes9-1) and _S. chinensis_ (SciFAD-SP) as well as two acyl-CoA desaturase-like (ADS) proteins from _A. thaliana_ (AtADS1.2 and AtADS1.4). Combinations of CaKCS or LaKCS and a heterologous FAD were cloned into the episomal plasmid pYX212 via modular pathway engineering [22] (Additional file 1: Figure S1). The plasmids were transferred into the background strain _S. cerevisiae_ CEN.PK 113-5D elo3Δ X-2::pMPC3::ACC1** X-3::IFAS38::PHS1::TSC13::ACB1.

The highest amount of C20:1 and C22:1 FA.s (1.36 ± 0.20 mg FA/s/g CDW and 2.91 ± 0.44 mg FA/s/g CDW, respectively), accompanied by a decrease in C18:1 FA.s of 23.3% (compared to strain LW04), was observed in a strain expressing CaKCS together with ChDes9-1. This is slightly less compared with the amount of VLCMUFA.s produced in the strain expressing CaKCS together with Ole1p. The production of C24:1 FA.s was highest in a strain expressing LaKCS together with an ADS protein from _A. thaliana_ (AtADS1.2) (Fig. 3).

Therefore, after evaluation of the combined expression of CaKCS or LaKCS with various FADs, the combination of CaKCS or Ole1p was identified as best enzymes for high level production of C20:1 and C22:1 FA.s and chosen to be expressed together with the WE biosynthesis enzymes MaFAldhR and SciWS to further boost WE production.
Fig. 2 Effect of expression of (heterologous) elongases (FAEs/KCSs) together with the yeast intrinsic Ole1p desaturase on the concentration of fatty acids (FAs) (mg/g CDW) in the background strain CEN.PK 113-5D elo3Δ X-2::pMPC3::ACC1** X-3::pFA38::PHS1::TSC13::ACB1 (LW03). The values represent the mean ± standard deviation (SD) of three biological replicates of strains LW04 (pYX212), LW05 (pYX212::ELO2::OLE1), LW06 (pYX212::AtFAE::OLE1), LW07 (pYX212::BnKCS::OLE1), LW08 (pYX212::CaKCS::OLE1), LW09 (pYX212::LaKCS::OLE1), LW10 (pYX212::SciFAE::OLE1) and LW11 (pYX212::TmKCS::OLE1), respectively. The strains were grown for 48 h in minimal medium containing 20 g/L glucose.
Fig. 3 Effect of expression of (heterologous) elongases (FAEs/KCSs) together with heterologous desaturases (FADs) on the concentration of fatty acids (FAs) (mg/g CDW) in the background strain CEN.PK 113-5D elo3Δ X-2::pMPC3::ACC1** X-3::pFA38::PHS1::TSC13::ACB1 (LW03). The values represent the mean ± standard deviation (SD) of three biological replicates of strains LW04 (pYX212), LW12 (pYX212::CaKCS::SciFAD-SP), LW13 (pYX212::CaKCS::ChDes9-1), LW14 (pYX212::CaKCS::AtADS1.2), LW15 (pYX212::CaKCS::AtADS1.4), LW16 (pYX212::LaKCS::SciFAD-SP), LW17 (pYX212::LaKCS::ChDes9-1), LW18 (pYX212::LaKCS::AtADS1.2) and LW19 (pYX212::LaKCS::AtADS1.4), respectively. The strains were grown for 48 h in minimal medium containing 20 g/L glucose.
Integration of pathway genes to construct MUFOH and DUWE production strain

The overexpression cassettes for CaKCS, Elo1p, Faa1p and Ole1p were integrated into the genome of S. cerevisiae. The combined overexpression of CaKCS, Elo1p, Faa1p and Ole1p (strain LW22) led to a growth defect of the strain with a final OD$_{600}$ of 2.62 ± 0.05 after 48 h, compared with the same strain lacking the overexpression of CaKCS and Ole1p (strain LW21) which showed a final OD$_{600}$ of 10.9 ± 0.18 after 48 h. This growth defect was also observed in strain LW24, expressing CaKCS and Ole1p in combination with the WE synthesizing enzymes MaFAldhR and SciWS as well as Elo2p, but not in strain LW23, expressing MaFAldhR, SciWS and Elo2p, but lacking CaKCS and Ole1p (Additional file 1: Figure S3).

The integration-based expression of CaKCS, Elo1p, Faa1p and Ole1p together with the plasmid-based expression of MaFAldhR, Elo2p and SciWS led to appearance of two additional bands on the thin layer chromatography (TLC) plate in strain LW23 (expressing only Elo1p, Elo2p, Faa1p, MaFAldhR and SciWS) as well as in strain LW24 (expressing CaKCS, Elo1p, Elo2p, Faa1p, MaFAldhR, Ole1p and SciWS) (Additional file 1: Figures S4, S5).

The analysis via gas chromatography-flame ionization detector (GC-FID) and gas chromatography-mass spectrometry (GC/MS) showed that those additional bands on the TLC plate corresponded to FOHs and WEs, respectively (Additional file 1: Figures S6, S7). The control strains LW21 and LW22, which do not contain the plasmid pYX212:: MaFAldhR::SciWS::ELO2, did not show peaks corresponding to FOHs or WEs. In contrast to that, strain LW23 produced C16:0-FOH, C18:0-FOH, C18:1-FOH, C20:0-FOH and C22:0-FOH (Additional file 1: Figure S6). These FOH species could also be detected in strain LW24, which additionally produced C16:1-FOH, C20:1-FOH and C22:1-FOH (Additional file 1: Figure S6). The analysis of WEs via GC/MS showed that both LW23 and LW24 strains produced WEs in the chain length range of C30-WE to C44-WE (Additional file 1: Figure S7), but only in case of strain LW24, DUWE synthesis could be detected. The synthesis of C38:2-WE, C40:2-WE, C42:2-WE and C44:2-WE was confirmed by analysis of the mass spectra of the corresponding GC peaks, which showed the appearance of m/z peaks corresponding to the molecular ions of these DUWES (m/z = 561, 589, 617 and 645, respectively) (Additional file 1: Figure S8). Those DUWE specific m/z peaks could not be detected in the strain lacking the expression of CaKCS and Ole1p (strain LW23).

The quantification of FOHs and WEs showed that the expression of CaKCS and Ole1p in strain LW24 leads to the production of 1.27 ± 0.46 mg MUFOHs/g CDW, with a significant increase (p < 0.05) in the MUFOHs C18:1-FOH, C20:1-FOH and C22:1-FOH and a significant decrease (p < 0.05) in the saturated FOHs C16:0-FOH, C18:0-FOH and C20:0-FOH compared to strain LW23. In total, strain LW24 produced 2.46 ± 0.71 mg FOHs/g CDW. In contrast to that, the strain lacking the expression of CaKCS and Ole1p (strain LW23) produced 2.51 ± 0.29 mg FOHs/g CDW, of which 0.014 mg ± 0.005/g CDW were MUFOHs. This corresponds to an increase in MUFOHs by 89.5-fold in strain LW24 compared to strain LW23 (Fig. 4). The overall titer of FOHs was 6.92 ± 0.85 mg/L in strain LW23 and 2.10 ± 0.55 mg/L in strain LW24, which corresponds to a yield of 0.346 mg/g glucose and 0.105 mg/g glucose, respectively.

This increase in MUFOHs was accompanied by the formation of DUWES in strain LW24. The quantification of WEs in strains LW23 and LW24 showed that in total 13.13 ± 5.08 mg WES/g CDW and 14.38 ± 1.76 mg WES/g CDW, respectively, were produced. Strain LW24 showed a significant decrease (p < 0.05) in C34-WE species and a significant increase (p < 0.05) in C42-WE species (Fig. 5). The overall titer of WES was 36.5 ± 16.71 mg/L in strain LW23 and 11.92 ± 1.47 mg/L in strain LW24, which corresponds to a yield of 1.83 mg/g glucose and 0.60 mg/g glucose, respectively. The C40-WE to C44-WE made up 36.6% in strain LW23, while in strain LW24, 76.4% of the WEs were C40-WE to C44-WE. The analysis of the molecular composition of WES in strains LW23 and LW24 led to an overall identification of 73 WE species (Fig. 6). The most abundant WE species in strain LW23 were C18:0–C16:0 (25.30 ± 1.07 mol%), followed by C22:0–C18:1 (17.25 ± 1.24 mol%) and C18:0–C16:1 (10.92 ± 0.82 mol%). In contrast to that, strain LW24 produced WEs that contain longer and more unsaturated FOH and FA moieties, with the most abundant WE species being C22:0–C20:1 (12.52 ± 0.90 mol%), C22:1–C20:1 (10.67 ± 2.48 mol%) and C22:0–C18:1 (7.16 ± 1.38 mol%). Additionally, low amounts of C46-WE could be identified in strain LW24 (Additional file 1: Table S3). This represents the first study in which the production of DUWES of a chain length of C38-WE to C46-WE was achieved in the yeast S. cerevisiae.

Discussion

In this study we aimed for the increased production of VLCMUFAs in the yeast S. cerevisiae as precursors for the synthesis of jojoba-like DUWES. For this purpose, we have screened a range of endogenous and heterologous FAEs/KCSs and FADs. It could be shown that the KCSs derived from the plants C. abyssinica (CaKCS) and L. annua (LaKCS), as well as the yeast intrinsic FAOlo1p, are able to increase the pool of VLCMUFAs when expressed together with the yeast intrinsic FAD Ole1p. In contrast
to that, the KCS enzymes from *A. thaliana*, *B. napus*, *S. chinensis* as well as *T. majus* failed to increase the concentration of FAs (Fig. 2). *A. thaliana* and *B. napus* enzymes have been expressed previously in *S. cerevisiae* and were shown to be able to increase the pool of VLCFAs [24, 25]. However, in those studies no codon optimized sequences were used, and the enzymes were expressed in a different *S. cerevisiae* background strain (INVSc1), which might explain the different results observed in our study.

The first isolation and functional characterization of CaKCS has been performed by Mietkiewska et al. [26]. They heterologously expressed CaKCS in *S. cerevisiae* strain INVSc1 and showed that the strain produces the non-native to yeast FAs C20:1-Δ11, C20:1-Δ13, C22:1-Δ13, C22:1-Δ15, C26:1-Δ17 and 26:1-Δ19. Enzyme assays demonstrated that the preferred substrate of the enzyme is C20:1-CoA, and erucic acid (C22:1-Δ13) was synthesized as main product [26]. The heterologous expression of LaKCS in the *S. cerevisiae* strain INVSc1 led to the synthesis of C20:1-Δ11, C22:0, C22:1-Δ13, C24:0, C24:1-Δ15 and C26:1-Δ17 FAs [27].

A recent study in the oleaginous yeast *Rhodospirillum toruloides*, in which the influence of the expression of several plant derived KCS enzymes on the VLCFA pool was investigated, also showed that the highest amount of C22:1 FAs (24% of total fatty acids (TFAs)) was observed under expression of the KCS derived from *C. abyssinica*. This increase in C22:1 FAs was accompanied by a 50% decrease in C18:1 FAs. In our *S. cerevisiae* strain, the expression of CaKCS led to an erucic acid (C22:1-Δ13) content of 6% of TFAs and a 35.4% decrease in C18:1 FAs. In contrast to our study which identified the KCS from *L. annua* as best candidate for nervonic acid production, expression of LaKCS in *R. toruloides* did not lead to a high increase in nervonic acid, but a high increase in eicosenoic acid (21.4% of TFAs). In *R. toruloides*, the highest production of nervonic acid (10% of TFAs) was obtained by expression of the KCS from *Cardamine graeca* [28]. This comparison shows that the expression of plant derived KCS enzymes can lead to different results, depending on the yeast species.
The heterologous FADs we tested to increase the amount of MUFAs in *S. cerevisiae* included those from *C. hyperboreus* (*Ch*Des9-1) and *S. chinensis* (*Sci*FAD-SP) as well as two ADS proteins from *A. thaliana* (*At*ADS1.2 and *At*ADS1.4). Our results indicate that the combined expression of *Ca*KCS and *Ch*Des9-1 can increase the amount of C20:1 and C22:1 FAs, but not as strong as the combined expression of *Ca*KCS and *Ole*1p. The production of C24:1 FAs was highest in a strain expressing *La*KCS together with *At*ADS1.2 (Fig. 3).

*Ch*Des9-1 was identified previously as a new type of Δ9-desaturase, which introduces a Δ9-double bond into VLCFAs ranging from C20:0 to C26:0 in its natural host, the marine copepod *C. hyperboreus*. When *Ch*Des9-1 was expressed in the *S. cerevisiae* strain INVSc1, the yeast mainly produced two new FAs, C20:1-Δ9 and C26:1-Δ9. Upon supplementation of the medium with C18:0, also C22:1-Δ9, C22:1-Δ11, C24:1-Δ9, C24:1-Δ11 and C24:1-Δ13 could be detected, besides the production of C20:1-Δ9 and C26:1-Δ9. The highest conversion efficiency was observed for C20:0 [29].

*At*ADS1.2 was characterized recently in an attempt to determine the biological function of seven members of the ADS gene family in *A. thaliana*, which in total contains nine genes encoding FAD-like proteins. The enzymes were expressed in the yeast strain *fat1Δ* (BY4741 MATa his3D1 leu2D0 met15D0 ura3D0 YBR041w::kanMX4) from Invitrogen. Yeast cells expressing *At*ADS1.2 showed the synthesis of C22:1-Δ9, C24:1-Δ9 and C26:1-Δ9 FAs [30].

In contrast to the VLCMUFAs produced by *Ch*Des9-1 and *At*ADS1.2, which mostly contain the double bond in the Δ9-position, jojoba oil consists of C20:1-Δ11, C22:1-Δ13 and C24:1-Δ15 FAs, which result from the elongation of C18:1-Δ9 [31, 32]. This means that the VLCMUFAs produced in a yeast strain heterologously expressing *Ch*Des9-1 or *At*ADS1.2 probably do not represent the FA spectrum in jojoba oil. However, *Ole*1p introduces a double bond at the Δ9-position of FAs with a chain length up to C19 [14], indicating that a combined expression of a heterologous plant FAE/KCS together with the yeast intrinsic *Ole*1p can lead to the formation of VLCMUFAs.
Fig. 6 Molecular composition of wax ester (WE) species (mol%). The values represent the mean ± standard deviation (SD) of three biological replicates of strains LW23 (expressing only Elo1p, Elo2p, Faa1p, MalFAldhR and SciWS) and LW24 (expressing CaKCS, Elo1p, Elo2p, Faa1p, MalFAldhR, Ole1p and SciWS), respectively. The strains were grown for 48 h in minimal medium containing 20 g/L glucose.
of jojoba-like VLCMUFAs in yeast by elongation of C18:1-Δ9 produced by Ole1p.

Therefore, the combination of CaKCS and Ole1p was identified as best enzymes for high level production of C20:1 and C22:1 FAs in *S. cerevisiae* and chosen to be expressed together with the WE biosynthesis enzymes MaFAldhR and SciWS to further boost WE production. The *S. cerevisiae* strain expressing CaKCS, Elo1p, Faa1p and Ole1p (strain LW22) showed a growth defect which was not detected in the same strain lacking the overexpression of CaKCS and Ole1p (strain LW21). This growth defect was also observed in strain LW24, expressing CaKCS and Ole1p in combination with the WE synthesizing enzymes MaFAldhR and SciWS as well as Elo2p, but not in strain LW23, expressing MaFAldhR, SciWS and Elo2p, but lacking CaKCS and Ole1p (Additional file 1: Figure S3). This observation indicates that the growth defect is due to an increased synthesis of VLCMUFAs in strains LW22 and LW24 which seem to be toxic to the cells as has been shown before for C16:1-Δ9 and C18:1-Δ9 FAs [5].

The synthesis of VLCMUFAs in a strain expressing a FAR from *M. aquaeolei* (MaFAldhR) and a WS from *S. chinensis* (SciWS) (strain LW24) triggered the synthesis of MUFOHs (C16:1-FOH, C18:1-FOH, C20:1-FOH and C22:1-FOH) and DUWEs (up to C44:2-WE) (Figs. 4, 5, Additional file 1: Figures S6, S7, S8). The analysis of the molecular composition of the WEs led to the identification of 73 WE species (Fig. 6). Whereas strain LW23 mostly showed the production of saturated C34-WE (25.30 ± 1.07 mol%), strain LW24 showed a clear trend towards longer and more unsaturated WEs with the most abundant one being C42:2-WE (18.26 ± 4.18 mol%), followed by C42:1-WE (17.43 ± 0.63 mol%), C40:1-WE (14.01 ± 1.55 mol%) and C40:2-WE (10.29 ± 0.41 mol%) (Additional file 1: Table S3). This composition of WEs is similar to the one of jojoba oil, which consists mostly of C42:2-WE (46.8 mol%), followed by C40:2-WE (20.7 mol%), C44:2-WE (6.0 mol%) and C38:2-WE (4.3 mol%), with the exception that jojoba oil only contains DUWEs [18]. These results clearly demonstrate that the production of jojoba-like WEs is possible in *S. cerevisiae* under supply of appropriate precursors and that MaFAldhR and SciWS are enzymes with a broad substrate specificity.

**Conclusions**

Our study shows that it is possible to drastically increase the amount of VLCMUFAs in *S. cerevisiae* by heterologous expression of a plant derived KCS together with a yeast intrinsic FAD. Moreover, we were able to show that the increase of VLCMUFAs can also trigger the synthesis of MUFOHs and DUWEs in a strain expressing a FAR and a WS. The general amount of jojoba-like WEs with a chain length of C40-WE to C44-WE was increased 2.3-fold by expression of a plant derived KCS together with a yeast intrinsic FAD compared to the same strain lacking the overexpression of those enzymes.

**Methods**

**Strains and reagents**

In this study, the strain *S. cerevisiae* CEN.PK 113-5D (*MATa MAL2-8c SUC2 ura3-52*), kindly provided by P. Kötter (University of Frankfurt, Germany), was used as the parental strain. Yeast strains constructed based on this strain are listed in Table 1. For construction and maintenance of plasmids, *Escherichia coli* DH5α was used.

**Cultivation of strains**

Saccharomyces cerevisiae CEN.PK 113-5D derived strains were grown in yeast extract-peptone-dextrose (YPD) medium containing 10 g/L yeast extract (Merck Millipore), 20 g/L peptone (Difco) and 20 g/L glucose (Merck Millipore) at 30 °C and 200 RPM. Yeast strains carrying a plasmid- or integration-based *URA3* marker were selected on synthetic dextrose medium lacking uracil (SD-URA) plates, containing 6.9 g/L yeast nitrogen base (YNB) without amino acids (Formedium), 0.77 g/L complete supplement mixture (CSM) without uracil (Formedium), 20 g/L glucose and 20 g/L agar (Merck Millipore) with the pH adjusted to 5.5–6.0. To counter-select for the *URA3* marker, strains were cultivated on plates with 5-fluoorotic acid (5-FOA), containing 6.9 g/L YNB without amino acids, 0.77 g/L CSM without uracil, 0.05 g/L uracil, 20 g/L glucose, 20 g/L agar and 1.0 g/L 5-FOA (Sigma). Strains containing the *kanMX* marker were selected on YPD plates containing 200 mg/L G418 disulfate salt (Sigma Aldrich). To select for the *natMX* marker, yeast strains were grown on YPD plates containing 100 mg/L nourseothricin (Nordic Biotise).

To monitor FA, FOH and WE synthesis, growth experiments with *S. cerevisiae* strains were performed in modified minimal medium [33], containing 7.5 g/L (NH₄)₂SO₄, 14.4 g/L KH₂PO₄, 20 g/L glucose and with the pH adjusted to 6.5 with 5 M NaOH. In case of strains not carrying a *URA3* marker, 60 mg/L uracil (Alfa Aesar) were added to the medium. Single colonies were used to inoculate 5 mL of precultures, which were incubated for 2 days at 30 °C and 200 RPM before they were used to inoculate main cultures of 20–100 mL minimal medium in 100–500 mL shake flasks with an initial OD₆₀₀ of 0.1. The growth rate of the strains was monitored by measuring the optical density of the cultures at 600 nm in a GENESYS™ 20 spectrophotometer (Thermo Fisher Scientific). The cells were harvested after 48 h of incubation.

by centrifugation at 1000×g for 5 min. After washing the cells with 5 mL phosphate buffer (10 mM KH₂PO₄, pH 7.5), the supernatant was removed, the pellet was frozen in liquid nitrogen and freeze-dried (Christ Alpha 2–4 LSC, Martin Christ Gefriertrocknungsanlagen GmbH) for 48 h.

Cultivations of E. coli were performed at 37 °C and 200 RPM in lysogeny broth (LB), containing 10 g/L tryptone (Merck Millipore), 5 g/L yeast extract (Merck Millipore), 10 g/L NaCl (Merck Millipore) or on plates containing additionally 20 g/L agar. E. coli strains carrying an AmpR marker were selected on LB plates containing 100 mg/L ampicillin (AppliChem).

### Construction of plasmids and strains

In this study, we investigated genes coding for KCSs from A. thaliana (AtFAE) (NCBI accession no. AT4G34520), B. napus (BnKCS) (NCBI accession no. AF490459), C. abyssinica (CaKCS) (NCBI accession no. AY793549), L. annua (LaKCS) (NCBI accession no. EU871787), S. cerevisiae (ScElo2p) (NCBI accession no. YCR034 W), S. chinensis (SciFAE) (NCBI accession no. AAC49186) and T. majus (TmKCS) (NCBI accession no. AAC49186) as well as genes coding for FADs from Calanus hyperboreus (ChDes9-1) (NCBI accession no. AHL21604), S. cerevisiae (ScOle1p) (NCBI accession no. YGL055W) and S. chinensis (SciFAD-SP) (NCBI accession no. AAA33932).

In case of SciFAD, a truncated version of the protein (SciFAD-SP), which did not include the 31 amino acids plast localization signal at the N-terminus, was used. We also studied two acyl-coenzyme A (CoA) desaturase-like (ADS) proteins from A. thaliana (AtADS1.2/AtADS1.4) (NCBI accession no. AAC49186/AAC49186). Other genes investigated in this study include one coding for a FAR from M. aquaeolei VT8 (MaFAldhR = Maq2-2200) (NCBI accession no. YP_959486) as well as one coding for a WS from S. chinensis (SciWS) (NCBI accession no. AF149919) and the yeast intrinsic genes ACB1, ELO1, FAA1, IFA38, PHS1, TSC13.

The heterologous genes, which were codon optimized and synthesized by Genscript, are listed in Additional file 1: Table S1. The yeast intrinsic genes ACB1, ELO1, FAA1, IFA38, PHS1 and TSC13 (NCBI accession no. NP_010269.1/NP_014962.3/NP_009717.1/NP_011460.3/NP_012438.1/NP_010269.1) were amplified based on genomic DNA of S. cerevisiae CEN.PK 113-5D. Genes coding for a KCS/FAE as well as for Ole1p were integrated into the region 839226–840357 of chromosome XII (XII-5). Genes coding for Faa1p and Elo1p were integrated into the region 236336–237310 of chromosome X (X-4).

Oligonucleotides used for amplification of genes included specific overhangs to promoter and terminator sequences for fusion of promoter-gene-terminator parts, using PrimeStar DNA polymerase (TaKaRa Bio). They were custom synthesized by Eurofins and are listed in Additional file 1: Table S2. Episomal plasmids containing combinations of a KCS and a FAD were constructed via modular pathway engineering based on the background plasmid pYX212 [22] (Additional file 1: Figure S1). All episomal plasmids were first assembled in S. cerevisiae CEN.PK 113-5D and then extracted by using the Zymoprep Yeast Plasmid Miniprep II kit (Zymo Research Corp). The plasmids were re-transformed into E. coli.
DH5α competent cells based on the method by Inoue et al. [34]. After purification of the plasmids, they were verified by restriction analysis and sequencing. Finally, the plasmids were transformed into the desired yeast strain. Integrative plasmids were constructed based on the EasyClone(-Marker Free) vector toolkit [35–37] (Additional file 1: Figure S2). Yeast competent cells were prepared and transformed with 1 µg of plasmid DNA according to the lithium acetate/single-stranded carrier DNA/polyethylene glycol method [38]. Restriction enzymes, DNA gel purification and plasmid extraction kits were purchased from Thermo Fisher Scientific.

**Construction of the background strain S. cerevisiae**

The background strain S. cerevisiae CEN.PK 113-5D elo3Δ was constructed in a previous study [21] as well as the plasmid containing the double mutated ACC1** gene under control of the S. cerevisiae MPC3 promoter and CYC1 terminator [39]. The plasmid contains a kanMX marker, flanked by loxP sites, for selection, and homologous sequences guiding the integration of the fragment into the region 194944–195980 of chromosome X (X-2) [37]. The genes ABC1, IFA38, PHS1 and TSC13 were integrated into the region 223616–224744 of chromosome XI (XI-5). The fragment contains a K. lactis URA3 marker, which is flanked by direct repeats. The URA3 marker was removed in the final strains as described above.

**TLC**

For preparative TLC, 20–50 mg of freeze-dried cells were weighed and mixed with 10 µg lauryl laurate as well as 10 µg heptadecanol as internal standards. The extraction of lipids was performed as described previously [40] with the exception that the sample was redissolved in 50 µL chloroform/methanol (2:1, v/v). The sample was loaded onto a TLC silica gel 60 F254 plate (Merck Millipore). The mobile phase used was composed of heptane, 2-propanol and acetic acid with a ratio of 95:5:1 (v/v/v). A standard composed of 100 µg each of cholesterol, oleic acid, triolein, methyl oleate and cholesteryl oleate as well as a separate WE standard composed of 50 µg lauryl laurate were loaded onto the plate for identification of sterols, FFAs, TAGs, fatty acid methyl esters (FAMEs), SEs and WEs. The analytical standards were purchased from Nu-Chek Prep, Inc with an exact weight amount. After drying of the plate, the visualization of spots was performed by spraying the plate with 0.05% 2,7-dichlorofluorescein in ethanol and exposing it to ultraviolet radiation. The spots of the TLC plate corresponding to FOHs and WEs, respectively, were scraped off with a razor blade and extracted with a mix of 3 mL hexane, 2 mL methanol and 2 mL milliQ water. The tube was vigorously vortexed, and after centrifugation at 3000 RPM for 5 min, the upper layer was transferred to a clean tube. This solution, containing the FOHs and WEs, respectively, was dried by vacuum evaporation using a miVac concentrator (Genevac) before the samples were finally dissolved in 200 µL of hexane in case of WEs and 200 µL of ethyl acetate in case of FOHs.

**Gas chromatography-mass spectrometry (GC/MS) analysis of FAMEs and WEs/**

**GC-flame ionization detector (GC-FID) analysis of FOHs**

After separation of WEs from other lipids via TLC, the WE containing fraction was isolated, purified and analyzed by GC/MS (Focus GC ISQ™ single quadrupole GC; Thermo Fisher Scientific), using a ZB-50 column (L = 30 m, ID = 0.32 mm, df = 0.5 μm) (Phenomenex). The inlet temperature was set to 375 °C, the helium (carrier) gas flow to 1 mL/min splitless. The initial oven temperature was set to 150 °C and held for 10 min. Then the temperature was ramped to 350 °C by 7.5 °C/min and held for 10 min. The mass transfer line temperature was set to 250 °C, the ion source temperature was set to 250 °C and a full scan for m/z of 50 to 650 was performed. WEs were identified by comparison to analytical WE
standards which were purchased from Nu-Check Prep, Inc. with an exact weight amount. They were dissolved in hexane and analyzed using the same protocol and column as for the samples. WEs are designated according to the nomenclature CX:Y-WE, with X indicating the total number of carbon atoms and Y indicating the total number of double bonds in the WE, e.g. C30:1, palmitoyl myristoleate. FOHs which were isolated and purified from TLC were analyzed via GC-FID as described previously [17]. FOH standards were purchased from Nu-Check Prep, Inc. with an exact weight amount. They were dissolved in ethyl acetate and analyzed using the same protocol and column as for the samples. FOHs are designated according to the nomenclature CX:Y-FOH, with X indicating the number of carbons and Y indicating the number of double bonds, e.g. C16:0, palmitoyl alcohol (hexadecanol); C16:1, palmitoleoyl alcohol (hexadecenol). FAMEs were prepared and analyzed as described previously [41]. FAME standards were purchased from Sigma Aldrich. FAs are designated according to the nomenclature CX:Y, with X indicating the number of carbons and Y indicating the number of double bonds (e.g. C16:0, palmitic acid (hexadecanoic acid); C16:1-Δ9, palmitoleic acid (hexadecenoic acid)). If the position of the double bond is indicated, it is counted from the carboxyl group (A) and unless otherwise noted, the Z (cis) species (e.g. C16:1-Δ9, cis-Δ9 hexadecenoic acid).

**Determination of molecular composition of WEs**

Yeast cell lysis and lipid extraction were carried out at 4 °C as previously described [42]. In short, yeast cells (~10 ODu) were resuspended in 1 mL 155 mM ammonium formate and lysed with 400 μL of acid-washed glass beads using a cell disruptor.

Lipids were extracted from 0.4 ODu of yeast lystate in a total of 200 μL 155 mM ammonium formate by adding 990 μL chloroform/methanol (2:1 v/v) and mixing (1400 RPM, 2 h, 4 °C) using a ThermoMixer (Eppendorf). The lower organic phase was collected after centrifugation (1000 × g, 2 min, 4 °C). Lipid extracts were dried and kept at −20 °C until analyzed. Lipid extracts were analyzed by positive ion mode MS\textsuperscript{ALL} analysis, as previously described [43], using an Orbitrap Fusion Tribrid (Thermo Fisher Scientific) equipped with a robotic nanoflow ion source, TriVersa NanoMate (Advion Biosciences). In short, lipid extracts were dissolved in 100 μL chloroform/methanol (1:2 v/v). For MS\textsuperscript{ALL} analysis, 10 μL lipid extract was mixed with 12.9 μL 13.3 mM ammonium formate acetate in 2-propanol and infused using a back pressure of 1.25 psi and ionization voltage of +0.96 kV. Survey Fourier Transform MS (FTMS) data were recorded using a target resolution setting of 500,000, a max injection time of 100 ms, automated gain control of 1e5, and three macroscans. Sequential FTMS\textsuperscript{2} data were recorded in 1.0008 amu steps across the precursor m/z range 320.3–920.8 using a quadrupole ion isolation with a width of 1.0 amu, HCD fragmentation with collision energy at 22%, max injection time of 100 ms, automated gain control of 5e4, three microscans, and a target resolution of 30,000. All FTMS data were acquired in profile mode and using an ion transfer tube temperature of 275 °C. WE molecules detected by MS\textsuperscript{ALL} analysis were identified and quantified using ALEX\textsuperscript{123} software and SAS 9.3 [43–45]. Searches of FTMS and FTMS\textsuperscript{2} data were done with mass tolerances of 0.0025 and 0.0050 amu, respectively, and using an in silico-generated database of ammoniated, even- chained WE molecules having a total of 28 to 56 C-atoms and 0 to 2 double bonds in their FOH and FA chains. WE molecular species detected by FTMS and FTMS\textsuperscript{2} analysis in all samples were annotated by molecular composition nomenclature denoting the number of C-atoms and double bonds in both the FOH and the FA chain, following the general pattern CX\textsubscript{1}Y\textsubscript{1}-CX\textsubscript{2}Y\textsubscript{2}, with the first part of the abbreviation referring to the FOH moiety and the second part referring to the FA moiety of the WE (e.g. C16:1-C14:0, palmityl myristoleate). The “X” in the formula indicates the number of carbon atoms in the alcohol and acid moiety, respectively, and the “Y” indicates the number of double bonds in each moiety. Data are presented as mean ± standard deviation of three biological replicates, expressed as mol% per all monitored WE molecules (calculated by normalizing the intensity of individual WE molecules to the total intensity of all identified WE molecules).

**Additional file**

**Additional file 1: Table S1.** Codon optimized sequences of genes used in this study. Table S2. Sequences of oligonucleotides used in this study. Table S3. Distribution of wax ester species (mol%) in strains LW23 and LW24. The values represent the mean ± SD of three biological replicates of strains LW23 and LW24, respectively. **Figure S1.** DNA pathway assembly constructs. Genes coding for a heterologous fatty acyl reductase (FAR), a wax synthase (WS), a fatty acid elongase (FAE) or a fatty acid desaturase (FAD) were synthesized with a codon optimization for S. cerevisiae. The ELO2 gene and the OLE1 gene were amplified based on g-DNA from S. cerevisiae CEN.PK 113-5D. The promoter p\textsuperscript{PTP1} and the terminator p\textsuperscript{YX212} are homologous to the respective promoter and terminator on the p\textsuperscript{YX212} plasmid. All plasmids were constructed using the modular pathway engineering strategy [22]. **Figure S2.** Integration constructs. The gene coding for Ca\textsuperscript{KCS} was synthesized with a codon optimization for S. cerevisiae. The FA\textsuperscript{38}, PHS\textsuperscript{1}, TSC\textsuperscript{13}, ACB\textsuperscript{1}, FAA\textsuperscript{1}, ELO\textsuperscript{1} and OLE\textsuperscript{1} genes were amplified based on g-DNA from S. cerevisiae CEN.PK 113-5D. The ACC\textsuperscript{**} linear fragment, carrying a kan\textsuperscript{MK} marker under the Ashbya gossypii TEF\textsuperscript{**} promoter/terminator and flanked by loxp sites, was integrated at position X-2. The TSC\textsuperscript{13}/PHS\textsuperscript{1}/FA\textsuperscript{38}/ACB\textsuperscript{1} linear fragment, carrying a Kluyveromyces lactis URA3 marker flanked by direct repeats, was integrated at position X-3. The FAA\textsuperscript{1}/ELO\textsuperscript{1} linear fragment was integrated at position X-4. The Ca\textsuperscript{9} linear fragment was integrated at position XI-5 and the Ca\textsuperscript{KCS}/OLE\textsuperscript{1} linear fragment at position XII-5 in the genome. Integrative plasmids
were constructed based on the EasyClone(-Marker Free) vector toolkit [35–37]. Figure S3. Growth behavior of strains LW21, LW22, LW23 and LW24 in minimal medium containing 20 g/L glucose. Figure S4. Thin layer chromatography. 1, TLC standard = 100 µg cholesterol, 100 µg oleic acid, 100 µg triolein, 100 µg methyl oleate, 100 µg cholesterol oleate; 2, wax ester standard = 50 µg lauryl laurate (C24:0); 3, strain LW21 clone1; 4, strain LW21 clone 2; 5, strain LW21 clone 3; 6, strain LW21 clone 1; 7, strain LW23 clone 1; 2, strain LW23 clone 3. The TLC was performed as described in Materials and Methods.

Figure S5. Thin layer chromatography. 1, TLC standard = 100 µg cholesterol, 100 µg oleic acid, 100 µg triolein, 100 µg methyl oleate, 100 µg cholesterol oleate; 2, wax ester standard = 50 µg lauryl laurate (C24:0); 3, strain LW22 clone 1; 4, strain LW22 clone 2; 5, strain LW22 clone 3; 6, strain LW24 clone 1; 7, strain LW24 clone 2; 8, strain LW24 clone 3. The TLC was performed as described in Materials and Methods.

Figure S6. GC-FID chromatograms of fatty alcohols (FOHs) isolated from strains LW21 (A), LW22 (B), LW23 (C) and LW24 (D). The peak labeled with (I) corresponds to the internal standard used (C17:0-FOH). A mixture of standards (c = 200 µg/mL) containing the saturated FOHs (II), C16:0-FOH; (III), C18:0-FOH; (IV), C20:0-FOH; (V), C22:0-FOH and (VI), C24:0-FOH is shown in (E). A mixture of standards (c = 200 µg/mL) containing the monounsaturated FOHs (II), C16:1-FOH; (III), C18:1-FOH; (IV), C20:1-FOH; (V), C22:1-FOH and (VI), C24:1-FOH is shown in (F). The chromatogram in (G) shows a combination of the standards (E), (c = 50 µg/mL); (F), (c = 50 µg/mL) and C17:0-FOH (c = 250 µg/mL). The strains were grown for 48 h in minimal medium containing 20 g/L glucose. Figure S7. GC/MS chromatograms of wax esters (WEs) isolated from strains LW21 (A), LW22 (B), LW23 (C) and LW24 (D). The peak labeled with (I) corresponds to the internal standard used (C24:0-WE). A mixture of standards (c = 10 µg/mL) containing the saturated WEs (I), C24:0-WE; (II), C30:0-WE; (III), C32:0-WE; (IV), C34:0-WE; (V), C36:0-WE; (VI), C38:0-WE; (VII), C40:0-WE and (VIII), C42:0-WE is shown in (E). A mixture of standards (c = 10 µg/mL) containing the diunsaturated WEs (III), C32:2-WE; (IV), C34:2-WE; (V), C36:2-WE; (VI), C38:2-WE; (VII), C40:2-WE; (VIII), C42:2-WE and (IX), C44:2-WE is shown in (F). The strains were grown for 48 h in minimal medium containing 20 g/L glucose. Figure S8. Mass spectra of selected peaks of total ion chromatograms of lipids extracted from strain LW24. Mass spectrum of the C38:2-WE (MW = 561 g/mol), eluting after 27.95 min with the specific m/z peak of 561 (A). Mass spectrum of the C40:2-WE (MW = 589 g/mol), eluting after 29.23 min with the specific m/z peak of 589 (B). Mass spectrum of the C42:2-WE (MW = 617 g/mol), eluting after 30.73 min with the specific m/z peak of 617 (C). Mass spectrum of the C44:2-WE (MW = 645 g/mol), eluting after 32.53 min with the specific m/z peak of 645 (D).

(FAE) β-ketoacyl-CoA synthase (fatty acid elongase).

Authors’ contributions
LW designed the study, conducted the experiments (except for the molecular species profile of the WEs), analyzed the results and wrote the manuscript; FD, VS and JN contributed to designing the study and writing the manuscript. RRS and CSE performed the quantitative analysis of molecular WE species. All authors read and approved the final manuscript.

Acknowledgements
Help with the analytics by the Chalmers Mass Spectrometry Infrastructure (CMSI) is much acknowledged.

Competing interests
LW, FD, VS and JN have filed for patent protection of part of the work presented here.

Availability of data and materials
All data generated or analyzed during this study are included in this published article and its additional files.

Consent for publication
Not applicable.

Ethics approval and consent to participate
Not applicable.

Funding
This research project received funding from the People Programme (Marie Curie Actions) of the European Union’s Seventh Framework Programme FP7/2007-2013/under REA Grant Agreement No 606795, project acronym: YEASTCELL, from the Strategic Research Council (SSF) in Sweden, and from the Novo Nordisk Foundation (grant no. NNF10CC1016517). In addition, this project has received funding from the European Union’s Horizon 2020 Framework Programme for Research and Innovation—Grant Agreement No. 720824. We also acknowledge funding from the Knut and Alice Wallenberg Foundation. C.S.E. is supported by the VILLUM Foundation (VKR023439) and the VILLUM Center for Bioanalytical Sciences (VKR023179).
