Eukaryotic cell biology is temporally coordinated to support the energetic demands of protein homeostasis

John S. O’Neill, Nathaniel P. Hoyle, J. Brian Robertson, Rachel S. Edgar, Andrew D. Beale, Sew Y. Peak-Chew, Jason Day, Ana S. H. Costa, Christian Frezza & Helen C. Causton

Yeast physiology is temporally regulated, this becomes apparent under nutrient-limited conditions and results in respiratory oscillations (YROs). YROs share features with circadian rhythms and interact with, but are independent of, the cell division cycle. Here, we show that YROs minimise energy expenditure by restricting protein synthesis until sufficient resources are stored, while maintaining osmotic homeostasis and protein quality control. Although nutrient supply is constant, cells sequester and store metabolic resources via increased transport, autophagy and biomolecular condensation. Replete stores trigger increased \( \text{H}^+ \) export which stimulates TORC1 and liberates proteasomes, ribosomes, chaperones and metabolic enzymes from non-membrane bound compartments. This facilitates translational bursting, liquidation of storage carbohydrates, increased ATP turnover, and the export of osmolytes. We propose that dynamic regulation of ion transport and metabolic plasticity are required to maintain osmotic and protein homeostasis during remodelling of eukaryotic proteomes, and that bioenergetic constraints selected for temporal organisation that promotes oscillatory behaviour.
Saccharomyces cerevisiae undergo oscillations in oxygen consumption and many other cellular processes that synchronise spontaneously when cells are grown at high density in aerobic, nutrient-limited culture at constant pH\textsuperscript{11,13}. These metabolic cycles are thought to occur cell-autonomously, and to synchronise when the extracellular nutrient supply is insufficient to support exponential growth\textsuperscript{4,5}. Under normal conditions, DNA replication does not occur when oxygen consumption is high, whereas respiratory rate does not affect the timing of mitosis (Supplementary Fig. 1). Thus, yeast respiratory oscillations (YROs) are a population-level phenomenon that is distinct from, and with a different frequency to, the cell division cycle but couples with it by imposing metabolic checkpoints on cell cycle progression\textsuperscript{6}. Despite the importance of these oscillations, the mechanism and utility of the YRO is poorly understood\textsuperscript{7}.

As with circadian and ultradian (<24 h) rhythms in mammalian cells, YROs are accompanied by large-scale changes in transcription and metabolism, as well as marked changes in the rate of cell growth\textsuperscript{8–13}. YROs share many other key features with circadian rhythms in mammalian cells, but have shorter periods that are acutely sensitive to nutrient availability\textsuperscript{3,4,7}. For both oscillations, current understanding of the critical causal relationships and rate constants that function over the course of each cycle is inadequate to explain how the period of oscillation is determined\textsuperscript{14}.

Here we show that the YRO is defined by phases of higher and lower protein synthesis that drive differential rates of oxygen consumption and are facilitated by profound changes in metabolism and the intracellular ionic environment. These are independent of the cell cycle. Inhibition of translation, changes in pH, potassium concentration, or the abundance of stored carbohydrate, perturb the oscillation. Our data support a model in which cells accumulate metabolic resources and degrade unwanted protein when translation, oxygen consumption and intracellular pH are lower, then liquidate storage carbohydrates and release proteins from membrane-less compartments to support translational bursting and higher rates of respiration, when the pH is high.

Results

Cell-intrinsic and -extrinsic factors regulate HOC and LOC.

Oxygen consumption rates (OCRs) across the YRO can be interpolated by measuring dissolved oxygen in continuous culture, where phases of higher oxygen consumption (HOC, LOC) increase, DNA replication restricted) are distinguished from lower oxygen consumption (LOC) during the rest of the cycle (Fig. 1a, Supplementary Fig. 1). Nutrient availability was manipulated by changing the rate at which medium flowed through the culture (dilution rate); higher dilution rates increase nutrient availability, medium turnover and removal of cells\textsuperscript{3}. We noticed that while the period of oscillation and LOC duration lengthened as dilution rate decreased, the duration of HOC was invariant (Fig. 1a, b, Supplementary Fig. 1), suggesting that HOC and LOC are regulated by cell-intrinsic and extrinsic factors, respectively. To explain how YROs are generated, their physiological consequence and identify factors that determine oscillatory period, we sought to understand the differential activities occurring during LOC versus HOC, and at the transition between these two states.

Rhythmic ion transport, metabolism and cytosolic granules.

Previous work suggested that YROs might organise through differentially phased gene expression in order to minimize the cost of expressing large genes\textsuperscript{8,9,15}, with the expression of up to 60% of cellular mRNAs changing over the course of each cycle\textsuperscript{8,9,16}. To gain mechanistic insight, we measured protein, ion and metabolite content by mass spectrometry at multiple time points over the respiratory cycle, from four independent biological replicates at three dilution rates. Given the substantial proteomic coverage, we were surprised to find that only 4% of detected proteins varied with biologically significant amplitudes (>33%)\textsuperscript{17} across all three dilution rates. This argues against a central role for dynamic changes in gene expression across the YRO, as does the poor correlation between the rhythmic amplitude, and the stability, abundance, size of each protein or the energetic cost associated with production (Fig. 1c–e and Supplementary Figs. 2 and 3). Of the few proteins whose abundance was rhythmic at the three dilution rates, unbiased k-means analysis suggested two clusters corresponding directly with LOC and HOC (Supplementary Fig. 1a, b), with gene ontology analysis revealing a significant enrichment for terms associated with transmembrane transport of ions and carboxylic acids (Table 1 and Supplementary Fig. 1c, d). For example, the abundance of the
Table 1 Enrichment for proteins whose abundance changes rhythmically across the YRO reveals the importance of membrane transport.

| GO term Description         | p value | Enrichment | Activity                      |
|-----------------------------|---------|------------|--------------------------------|
| Transmembrane transport     | 2.31E–06| 2.96       | Ena1, Pex25, Hxt6, Vht1, Mgr2, Jen, Mal11, Tim17, Fcy2, Ato3, Thi7, Yra2, Hip1, Ato2, Agp1, Tim8, Itr1, Sul1, Mdh2, Fmp43, Ymr166C, Yor020W-A |
| Monocarboxylic acid transport| 3.71E–05| 11.03      | Fmp43, Jen1, Vht1, Ato2, Ato3 |
| Ion transmembrane transport | 4.98E–05| 3.54       | Ena1, Hxt6, Jen1, Mal11, Ato3, Yra2, Hip1, Ato2, Agp1, Sul1, Fmp43, Ymr166C, Yor020W-A |

The most highly enriched gene ontology processes for consistently rhythmic proteins, proteins within each GO term are coloured by their YRO phase of expression (bold, HOC; italics, LOC). The complete list of proteins that change in abundance across the YRO is available in Supplementary Data 1. Enriched proteins support the conclusion that membrane transport is important for YROs, likely in response to osmotic stress.

Most active transport in yeast occurs through proton-coupled secondary active transport, driven by a difference of 3 pH units across the plasma membrane, that functions similarly to Na⁺ in mammalian cells. This ~1000-fold gradient is generated by the essential ATP-dependent H⁺-pump, Pma1, which constitutes 15–20% of all yeast membrane protein and consumes 20–40% of cellular ATP. The large variation in cellular osmolyte content over the YRO strongly suggested differential rates of H⁺ export. To test this, we derived the H⁺-export rate from the volume of NaOH required to maintain constant extracellular pH, as a proxy for Pma1 activity. Our data revealed a robust rise in cellular H⁺-export during HOC, which increased >2-fold in parallel with osmolyte export was consistently accompanied by a significant rise in intracellular pH (pHi) of >0.5 units (>3-fold drop in [H⁺]), irrespective of dilution rate (Fig. 2c), which rapidly returned to the lower pH at the HOC-to-LOC transition.

In agreement with previous work, >90% of other cellular metabolites we detected showed consistent variation across the YRO at each dilution rate (Supplementary Fig. 5), and unbiased k-means analysis again suggested two clusters, corresponding to HOC and LOC. Metabolites in the major cluster increased during LOC and fell during HOC (Supplementary Fig. 5a, d). Of particular note, amino acids and storage carbohydrates such as trehalose, and indicators of low energy charge such as AMP, all showed similar profiles to cellular osmolytes—increasing by 2–3-fold during LOC and then decreasing in HOC (Fig. 2a), whereas acetate and intermediates of phospholipid synthesis showed opposite profiles (Fig. 2d).

During glucose limitation or osmotic stress, yeast sequester proteins and mRNAs within non-membrane-bound ribonucleoprotein biomolecular condensates (BMCs), including stress granules and p-bodies, whose formation is stimulated by a fall in pHic and glucose starvation, and maintained by high osmotic potential. We predicted that the dramatic decrease in cellular osmolyte content and increase in intracellular pH during HOC would increase the fraction of soluble protein liberated from BMCs. We observed >2-fold variation in soluble cellular protein content, coinciding with HOC, whereas total cellular protein and protein in the media showed no significant variation (Fig. 2a and Supplementary Fig. 6a, b). Gene ontology analysis of soluble proteins with greatest variation between HOC and LOC revealed significant enrichment for protein chaperones, proteasomes, ribosomal subunits and key metabolic enzymes such as enolase (Eno1/2), pyruvate kinase (Cdc19) and deoxyribonuclease (Pdc1).

**Fig. 2 Variation of metabolites, transport, and soluble protein across the YRO.** a There are consistent phase relationships between intracellular free amino acids (AA), soluble (Sol) protein, trehalose (storage carbohydrate), AMP, betaine, K⁺, OCR and H⁺ export under all conditions (n = 4 biologically independent samples, two-way ANOVA, p value shown, mean ± SEM). b Calibration curve for firefly luciferase emission ratiometric reporter of intracellular (cytosolic) pH. c Intracellular pH (pHi) oscillates as a function of YRO phase under all conditions (representative data). d Summary of key events that occur during HOC and LOC. Source data are provided as a Source Data file.
(Supplementary Fig. 6c). These proteins have previously been found in BMCs34–36.

**A testable model of the YRO.** To explain our observations, we considered that protein synthesis is the most energetically expensive process that cells undertake, requiring high ATP turnover and tRNAs charged with amino acids27. The assembly of macromolecular protein complexes (e.g., ribosomes, proteasomes, electron transport complexes) is particularly challenging since subunits must be expressed stoichiometrically, at the same time, and without exceeding chaperone capacity, otherwise they are wastefully degraded or misfold and aggregate, with associated fitness costs28–30. Protein synthesis, folding and complex assembly are also sensitive to molecular crowding and osmolyte concentration24,30. Indeed, hyperosmotic challenge leads to degradation or sequestration of macromolecular solutes and export of osmolytes to maintain osmotic potential31,32. Since macromolecular complexes account for ~40% of all cellular protein33,34, efficient complex assembly is particularly challenging for yeast under nutrient-poor conditions, when cells carry out autophagy to generate free amino acids that serve as metabolic substrates for ATP production and accumulate carbohydrate stores of glycogen and trehalose. These stores are rapidly mobilised to fuel anabolic metabolism and cell cycle progression upon the return to growth35,36.

Target-of-Rapamycin Complex 1 (TORC1) is the master regulator of protein homeostasis that controls the switch between anabolic protein synthesis and catabolic autophagy37–39. In yeast, TORC1 activity is regulated by glucose via increased pH/Gtr1 signalling, and indirectly by amino acid availability and energy charge via Gcn2 and Snf1/AMPK, respectively21,26,39,40. TORC1 activity is also sensitive to molecular crowding, pH and osmolality30,38,41. Coincidence detection through TORC1 ensures that the high translation rates required for efficient protein complex biogenesis only occur when sufficient energetic and biosynthetic resources are available.

In light of these well-established features of yeast cell biology, our observations suggest a mechanistic basis for understanding YROs, where oscillations ultimately arise from the selective pressure for efficient protein synthesis when nutrients are limiting (Fig. 3a). In this model, LOC is the default sequester and store state, in which low amino acid availability, energy charge and pHnc inactivate TORC1, thus facilitating ATP generation through respiration of acetate and autophagic products while protein synthesis is low21. Low pHnc also promotes progressive sequestration of macromolecules and glycolytic enzymes, such as Cdc19, into BMCs26 and cytosolic removal of these colloidal macromolecular solutes stimulates osmolyte accumulation to maintain osmotic homeostasis. Respiration of acetate, autophagic and residual glycolytic products generate sufficient ATP to fuel basal Pma1-mediated H+ export, but reduced activity of sequestered glycolytic enzymes redirects the bulk of available glucose towards polysaccharide, lipid and nucleotide biosynthesis. The latter two are favoured because more glucose is available for NADPH and ribose production via the pentose phosphate pathway, increasing production of the essential building blocks for cell growth during the G1/2 and S-phase of the cell cycle, respectively.

When carbohydrate stores are replete, surplus glucose and ATP stimulates increased H+ export by Pma1 (ref. 42), thereby raising pHnc. Increased pHnc triggers the checkpoint for entry into HOC by stimulating a feed-forward switch that liberates glycolytic enzymes such as Cdc19 from BMCs to increase glycolysis, increasing energy charge and further elevating pHnc. Increased pHnc also stimulates TORC1 to license increased protein synthesis, which is sustained because high amino acid levels and ATP:ADP/AMP ratio relieve TORC1 inhibition via the Gcn2 and Snf1/AMPK pathways. Increased translation gradually consumes stored vacuolar amino acids, while energetic requirements are met by liquidation of trehalose and glycogen stores that fuel increased glycolysis and respiration. Liberation of chaperones, proteasomes and other quality control factors from BMCs aids efficient protein synthesis, assembly of protein complexes and turnover of damaged or misfolded proteins. To maintain osmotic homeostasis, the large increase in osmotic potential that would result from increased cytosolic macromolecular solutes during HOC is buffered by export of osmolytes (K+, betaine, choline) to maintain the cytosolic activity of water. In this model, rhythms of respiration and metabolism are ultimately driven by the bioenergetic demands of increased TORC1-stimulated protein synthesis, triggered by elevated pHnc. DNA replication and lipid synthesis are restricted during HOC (Supplementary Figs. 1 and 5), because cellular resources are directed towards protein production.

According to our model (Fig. 3a), the end of HOC occurs due to (1) cytosolic acidification due to insufficient ATP (a result of depleted carbohydrate stores and reduced glucose supply), (2) insufficient O2 supply which also reduces ATP production and/or (3) exhaustion of amino acid or osmolyte stores, resulting in Gcn2 activation or osmotic challenge, respectively. The period of oscillation is therefore determined by the amount of time taken to replenish osmolyte, amino acid and carbohydrate stores during LOC, and the (normally) invariant duration of HOC reflects a consistent time taken to spend stored carbohydrates, osmolytes and/or amino acids on protein synthesis. We would therefore expect that exit from HOC will be brought forward by acute hyperosmotic stress, translational or respiratory inhibition.

**YRO model validation.** This model is consistent with available data and makes many testable predictions. For example, we observed significantly higher rates of protein synthesis and TORC1 signalling during HOC, whereas autophagy was more active during LOC (Fig. 3b, c). Autophagic breakdown products such as free amino acids are stored in the cell vacuole43 and we observed significant differences in vacuolar morphology between LOC and HOC corresponding with differential autophagic flux across the YRO (Fig. 3d and Supplementary Fig. 8c). To test our prediction that the energetic demands of increased protein synthesis drive the characteristic increase in oxygen consumption during HOC, we added cycloheximide (CHX) or rapamycin to cells to inhibit translation or TORC1 activity, respectively. Confirming expectation, both drugs immediately curtailed the anticipated increase in oxygen consumption and proton export during HOC (Fig. 3e), and abolished subsequent oscillations, but without similar effect on basal levels of respiration. At lower, non-saturating concentrations, rapamycin addition during HOC shortened the period of YRO oscillations, but critically the first effect of drug treatment was observed during the next HOC rather than the intervening LOC (Supplementary Fig. 7a, b). By our model LOC is expected to be insensitive to acute TORC inhibition but reduced in length after a truncated HOC, since stores will not be fully depleted and so take less time to replenish. These observations strongly support our hypothesis that TORC1 inactivation suppresses protein synthesis during LOC, and that TORC1 activation triggers the increase in translation that drives the demand for greater respiration during HOC.

We next sought to assess the extent of differential BMC sequestration and glycogen storage over the YRO. Consistent with expectation, the stress granule marker, Pab1, was significantly more diffuse during HOC, whereas brighter foci were evident
translational bursts and maintain osmostasis. Replete stores increase Hosmolytes during LOC and consume/export them in HOC to sustain Data throughout presented as mean ± SEM where *p ≤ 0.0001, ****p ≤ 0.0001.

Immunoblots for cleaved/full-length Pgk1-GFP reveal increased autophagy during LOC (Fig. 4a). Moreover, the amount of cellular glycogen fell by 40% during HOC (Fig. 4b), with a profile very similar to that of trehalose (Fig. 2a), the other major storage carbohydrate.

Given the pivotal role of Pma1-mediated H+ transport in our model, we tested a prediction that the period of oscillation should be sensitive to increases in pH gradient across the plasma membrane because more ATP turnover will be required to maintain pHic in both HOC and LOC. Concordantly, we found YROs run >2-fold faster with decreasing, but not increasing, extracellular pH (Fig. 4c, d). Our model also predicts increased Pma1 activity will elicit shorter cycles, as this accelerates the HOC to LOC transition. We tested this with mutants of hsp30, a negative regulator of Pma1 (ref. 44), observing shorter, truncated cycles of oxygen consumption and pH (Fig. 4e, f).

From the model (Fig. 3a), dynamic import and export of osmolytes during LOC and HOC, respectively, is critical for buffering cytosolic osmotic potential: permitting cycles of TORC1 activity and reversible macromolecular sequestration in BMCs/stress granules, both of which are critical for HOC translational bursting and associated respiration increase. Consistent with this, an acute osmotic challenge during HOC, which both inhibits TORC1 activity30 and opposes protein liberation from BMCs, resulted in immediate exit from HOC (Supplementary Fig. 7c).

To functionally validate the importance of intracellular osmolyte accumulation to YRO period determination, at the transitions between LOC and HOC, we manipulated the major intracellular osmolyte K+. The model predicts that decreased osmotic buffering will shorten the duration of both HOC and LOC. This is because insufficient K+ accumulation in LOC means that HOC cannot be sustained, resulting in early osmotic challenge, whereas LOC will be shorter because stored carbohydrates/amino acids were not exhausted during the previous HOC. This, in turn, will reduce the time taken to reach the pHic threshold for HOC entry in the next cycle. To test this, the infed was switched to media where K+ was replaced with Na+. As extracellular K+ decreased, we indeed observed a dramatic and reversible shortening of YRO period, whereas depleting Mg2+, another essential metal ion but without significant osmotic function, simply abolished oscillations (Fig. 4g, h and Supplementary Fig. 7d, e). Conversely, pulse addition of K+ increased YRO period, as well as basal OCR, HOC oxygen consumption and duration, because increased K+ availability facilitates greater osmolyte accumulation during LOC allowing HOC to be sustained for longer (Supplementary Fig. 7f, g).

**Physiological consequences.** We next explored the physiological consequences of our YRO model, which predicts that the yeast should be more sensitive to a heat stress during HOC, as increased cytosolic protein concentration, reduced osmotic buffering capacity and lower trehalose abundance should render cells more susceptible to protein denaturation. To test this, cells sampled from different points of the YRO were immediately subjected to an acute heat shock, and survival measured under standard growth conditions. Consistent with prediction, a twofold difference in viability was observed between cells harvested at the minimum and maximum OCR (Fig. 5a). We then tested whether translational bursting during HOC is sensitive to acute perturbation of the transmembrane pH gradient and to osmotic challenge, as would be expected. For this assay, we measured protein synthesis by puromycin incorporation. Cells were removed from the bioreactor during HOC and transferred immediately into media of different pH or osmolality. Consistent with expectations, higher pH acutely increased translation...
Discussion

We provide an experimentally derived, predictive and testable model of the YRO wherein central metabolism, signal transduction, active transport, and macromolecular condensation are temporally organized to accommodate the bioenergetic demands of protein synthesis (Figs. 3a and 5e). This model accounts for the period of oscillation in that HOC duration depends on the amount of time taken to satisfy one or more of the conditions for HOC exit, whereas the duration of LOC depends on the time taken to accumulate carbohydrate.

Eukaryotes have evolved under conditions where nutrients are limiting and environmental conditions vary. Given the high energetic cost of macromolecular complex assembly, and the selective pressure for efficient use of resources, we propose that oscillations in global protein synthesis rate confer a general fitness advantage, realised in many other biological contexts, that is supported by the same save and spend partitioning of metabolic resources we have observed in yeast.

Aspects of our model that involve H\(^+\) gradients and vacuoles are unlikely to apply to eukaryotic cell types that lack cell walls or use Na\(^+\) instead of H\(^+\) gradients. However, we speculate that dynamic transport of cellular osmolytes to buffer osmotic homeostasis against changes in macromolecular condensation, and dynamic rerouting of metabolic flux to increase ATP production during TORC1-dependent translational bursting, are essential for the temporal organization of proteome remodelling, and therefore common to most eukaryotic cells. Cell-autonomous rhythms of TORC activity, protein synthesis, potassium transport and cellular respiration have been all been observed in mammalian cells over the course of the circadian cycle.\(^{45-54}\)

We therefore speculate that the central utility of biological oscillations such as the YRO, and circadian rhythms throughout the eukaryotic lineage, is to facilitate the efficient utilisation of metabolic resources in order to minimize the cost of protein homeostasis.

Methods

Biorreactor continuous measurement and discrete sampling. Respiratory oscillations were initiated and maintained in a DASip bioreactor\(^7,9\). For generation of samples for high-throughput analysis (metabolomics, proteomics, ionomics and flow cytometry) the bioreactor was operated with four replicates in parallel at 220 sL h\(^{-1}\) at 30 °C; pH 3.4 was maintained by addition of 2 M NaOH in media containing 1 g L\(^{-1}\) of antifoam A, 0.5 mL L\(^{-1}\) of 1% ammonium sulfate, 0.5 g L\(^{-1}\) magnesium sulfate heptahydrate, 20 g L\(^{-1}\) of 75% sulfuric acid). To initiate YROs bioreactor vessels were each inoculated with 100 OD\((_{600})\) units L\(^{-1}\) cells in the stationary phase. The culture was allowed to grow, return to the stationary phase and maintained without addition of new media for 6 h. Oscillations were initiated by refeeding the culture at the dilution rates above and allowed to stabilise for 1–2 days before data collection or harvesting of samples. The dissolved oxygen (DO\(_T\)) traces are shown in Supplementary Fig. 1a. pH was monitored using a calibrated pH electrode and the pH maintained by automated addition of 2 N NaOH. In 1.5 L media, 0.5 mL L\(^{-1}\) 2 N NaOH neutralises H\(^+\) production equivalent to 0.37 µM s\(^{-1}\).

Dissolved O\(_2\) was monitored with an O\(_2\) electrode. To establish the relationship between relative DO\(_2\) and oxygen consumption, the O\(_2\) electrode was calibrated by allowing anaerobic media to equilibrate with atmospheric O\(_2\) under the conditions...
Glycogen breakdown (\(\text{gly} \)) is necessary for proteostasis. Representative silver-stained gel (two-sided black arrows represent predicted metabolic enzymes, red arrows represent ATP production/stimulation of ATP production, via nucleotide and lipid synthesis, predicted relative metabolic flux (high/low)) is derived for any steady-state concentration of O\(_2\) (Supplementary Fig. 1d) where O\(_2\) is removed from the system. To allow quantitative comparison between experiments, we defined HOC as a sustained increase in OCR such that the 10 min moving average of the first derivative of OCR (dOCR/dt) is >0 for \(\geq\)10 min and increases by \(\geq\)10% overall within each bout. The phase of LOC occurs between bouts of HOC.

At stated time points, 1.5 mL samples were removed from the bioreactor and harvested by centrifugation (2840g, 4 °C, 3 min). The supernatant and pellet were flash frozen separately in liquid nitrogen and stored at \(-80^\circ \text{C}\). Cell pellets (60 µL volumes) were then thawed on ice, and washed twice in 1 mL ice cold, isosmotic buffer X (25 mM Na\(_2\)SO\(_4\), 25 mM NaF, 25 mM NaN\(_3\), made up to 150 mMosm with 1 M sorbitol) to remove extracellular ions, proteins and metabolites and inactivate cellular enzymes. Pellets were resuspended in 1 mL buffer X, split into three aliquots, centrifuged, supernatant removed, and stored at \(-80^\circ \text{C}\) for analysis by mass spectrometry.

Unless stated, all other bioreactor experiments took place under identical conditions except that 175 L h\(^{-1}\) aeration and 1.0 L media per vessel were used, with appropriate O\(_2\)/pH calibrations and calculations also being performed. Drugs were dissolved in DMSO (Sigma D26560) and added by pulse addition of drug or vehicle to the bioreactor vessel and infused media. Rapamycin (Sigma R0395) 15 or 200 nM final concentration, CHX 25 µg mL\(^{-1}\) (Sigma C7698) was used for the experiments.

**Proteomics.** Samples were prepared using 20 µL pellets of yeast, which were lysed in 100 µL lysis buffer (6 M urea, 2 M thiourea, 20 mM HEPES pH 8, with protease and phosphatase inhibitors) with 50 µL of 0.5 mm glass beads by agitation using a BeadRuptor Genie (Scientific Industries) at 4 °C (3 × 60 s with 5 min on ice between runs). Lysates were clarified by centrifugation at 21,000g for 5 min and total protein concentrations determined using the Pierce BCA assay (Thermo). The concentration of each sample was normalised to 200 µg at 1 mg mL\(^{-1}\). For each dilution rate, 100 µL of supernatant from four biological replicates was pooled to generate samples representing nine time points. A pooled cell extract reference sample was made by mixing 25 µL from each of the nine samples.

Samples in 200 µL lysis buffer were reduced with 5 mM DTT at 56 °C, 30 min and alkylated with 10 mM iodoacetamide in the dark at room temperature, 30 min. Samples were then digested with Lys-C (mass spectrometry grade, Promega), 133:1 (protein: Lys-C ratio, w/w) for 4.5 h, 25 °C and then diluted from 8 M to 1.8 M urea with 20 mM HEPES (pH 8.5) and digested with trypsin (Promega) 100:1 (protein: trypsin ratio, w/w) overnight, 25 °C. Digestion was stopped by the addition of trifluoroacetic acid (TFA) to 1% final concentration. Precipitates were removed by centrifugation (9300g, 5 min). The supernatants were desalted using home-made C18 stage tips (100 µM Empore) containing 4 mg porous R3 (Applied Biosystems) resin. Bound peptides were eluted with 30–80% acetonitrile (MeCN) in 0.1% TFA and lyophilized.

Tandem mass tag (TMT) labelling was carried out by resuspending peptide mixtures in 75 µL 3% MeCN and MeCN and concentrations determined using the Pierce Quantitative Colorimetric Peptide assay (Thermo Scientific) according to the manufacturer’s instructions, except the absorbance was measured using NanoDrop Spectrophotometers (Thermo Scientific) at 480 nm. TMT 10plex reagent (Thermo Fisher Scientific) of 0.8 mg each was re-constituted in 41 mL anhydrous MeCN. In all, 61.5 µL (1.5 × 0.8 mg) of the reagent was used for each sample. The labelling reaction was performed in 150 µM triethylammonium bicarbonate, 1 h at room temperature and terminated by 15 min incubation with 9 µL 5% hydroxyamine. Labelled peptides were combined into a single sample and partially dried to remove acetonitrile in a SpeedVac. The labelled mixture was desalted using C18 stage tips, with 6.6 µg of R3.

Off-line high pH reverse-phase peptide fractionation was carried out using approximately 100 µg of the labelled peptides. These were separated on an off-line, high-pressure liquid chromatography (HPLC). The experiment was carried out using XBridge BEH130 C18, 5 µm, 2.1 × 150 mm (Waters) column with XBridge BEH C18 5 µm VanGuard cartridge, connected to an Ultimate 3000 Nano/ Capillary LC System (Dionex). Peptides were separated over a 100–90% B (A: 5% MeCN/10 mM ammonium bicarbonate, pH 8 [5:95]; B: 90% MeCN/10 mM ammonium bicarbonate, pH 8, [9:1]) in 60 min at a flow rate of 250 µL min\(^{-1}\). Sixty fractions were collected, combined into 20 fractions and partially dried in a SpeedVac to about 50 µL.

Liquid chromatography-tandem mass spectrometry (LC-MSMS) was performed on an Ultimate 3000 RSLC nano System (Thermo Scientific) fitted with a 100 µm × 2 cm PepMap100 C18 nano trap column and a 75 µm × 25 cm reverse-phase C18 nano-column (Aclam PepMap, Thermo Scientific). Samples were separated using a binary gradient consisting of buffer A (2% MeCN, 0.1% formic acid) and buffer B (80% MeCN, 0.1% formic acid). Peptides were eluted with a step gradient of 5–50% B in 87–105 min, 50–90% B in 6–10 min, with a flow rate of 300 nL min\(^{-1}\). The HPLC system was coupled to a Q-Exactive Plus mass spectrometer (Thermo Scientific) with a nanospray ion source. The mass spectrometer was operated in standard data dependent mode, performed MS full-scan at 350–2000 m/z range, resolution 140,000. This was followed by MS2 acquisitions of the 15 most intense ions with a resolution of 35,000, and NCE of 32%. MS target values of 3e5 and MS2 target values of 1e5 were used. Isolation window of

**Fig. 5 The YRO regulates resistance to heat stress and protein homeostasis.** a) Viability of cells removed from the bioreactor after heat treatment (55 °C, 2 min) is greatest at the end of LOC, when the abundance of trehalose and osmotolysis are greatest. Percentage of heat-tolerant cells, corrected for viability of non-heat-tolerant cells harvested at the same time (OWA, \(n=3\) biological replicates). b) Sensitivity of protein HOC synthesis rate to pH and hyperosmotic stress assayed by puromycin incorporation (gly, 10% glycero; srb, 1 M sorbitol, \(n=4\) biological replicates). c) Strains deficient in glycogen synthesis (\(\text{gly}2\)) or glycogen breakdown (\(\text{gph}1\)) do not initiate YROs and, d, \(\text{gph}1\) strains accumulate aggregated protein, showing that glycogen breakdown is necessary for proteostasis. Representative silver-stained gel (two-sided unpaired t-test, \(n=4\)). e A detailed, testable and experimentally derived model for the YRO. Green arrows/lines represent activation/repression, red arrows represent ATP production/stimulation of ATP production, black arrows represent predicted metabolic flux, see key for further details. Data are shown as mean ± SEM. Source data are provided as a Source Data file.
precursor was set at 1.2 Da and dynamic exclusion of sequenced peptides enabled for 40 s.

The MSMS raw files were processed using Proteome Discoverer (v2.1, Thermo Scientific). MSMS spectra were searched against the reviewed Saccharomyces cerevisiae, UniProt Fasta database (July 2017), using Mascot (version 2.4, Matrix Science) search engine. Carbamidomethylation of cysteines was set as fixed modification, while methionine oxidation, N-terminal acetylation (protein), phosphorylation (STY) and TMTplex (peptide N-term/lysine) as variable modifications. Other parameters were precursor mass tolerance, 10 ppm and fragment mass tolerance, 0.03 Da. Only peptides with FDR of 1% based on a target decoy approach (high confidence peptides) were included in the results. The output file from Protein Discoverer, however, proteins table was filtered for proteins with FDR of 1% and exported as Excel files.

Sample pooled ratio (SPS) was calculated for each time point and normalised so that the median SPS = 1. Sampling times were calculated from dissolved oxygen (DO2) measurements and converted into radians where 2 radians is equal to the offset time where the correlation coefficient of a linear autocorrelation was at its maximum. Linear interpolation was used on each dataset to calculate the mean SPS across all dilution rates every 0.9 radians. The fold-change between the maximum and minimum SPS detected in the time course for each protein identified in all dilution rates was calculated (FC). FC versus relative protein abundance and protein cost (relative abundance x length in residues) was also calculated. Protein SPS profiles where FC > 1.33 were clustered (k means, Hartigan Wong algorithm, R version 3.3.3). The between-cluster sum of squares/total within cluster sum of squares was calculated for 1 kmeans (Hartigan Wong algorithm, R version 3.3.3). The between-cluster sum of squares occurred. GO analysis was performed on each cluster independently, and, when combined, using SGD GO Term Finder version 0.86 involving the process ontology with p < 0.05 and default settings.

Ionomics. Twenty microlitres cell pellets were dissolved in 550 µL 65% HNO3, supplemented with 100 p.p.b. cerium, at 90 °C for 1 h, then centrifuged at 18,000 g for 20 min to remove debris. The supernatant was dialysed 1:12 in HPLC-grade water to remove the cerium contamination. Cellular elemental composition was determined by inductively-coupled plasma mass spectrometry (ICP-MS) on a PerkinElmer Elan DRC II ICP-MS instrument in helium collision mode. Cerium was used to correct for dilution errors introduced during handling, and then normalised to sodium in buffer X. The operator was blinded to the samples, which were randomly diluted on a vortex mixer and incubated for further 2 min. A cell dilution of 10x SPS-SW2 standard (LGC), which was injected nine times during the run. The calibration was checked for accuracy with a second multielement standard purchased from SCP Science (Canada).

Metabolomics. Cells were collected by centrifugation, the discarded medium and the samples extracted with 200 µL 80 °C hot ethanol. Residual medium resulted in a final ethanol concentration of approximately 80%. The extract was heated for 2 min at 80 °C. The solution was dried under vacuum for further 2 min. The extract was re-dissolved in 200 µL of 80% ethanol. The dried pellet was resuspended in 200 µL of 8 M urea, 2 M thiourea, 4% CHAPS, 10 mM TCEP and incubated at 37 °C with shaking at 400 r.p.m. for 2 h to dissolve soluble protein, then clarified by centrifugation at 21,000 g for 10 min. Soluble and total protein concentration was measured by tryptophan fluorescence (excitation 280/295 nm, emission 340/355 nm) on a Spark 10M (Tecan), using bovine serum albumin (BSA) to generate a standard curve. Variation in protein content was confirmed qualitatively by SDS-PAGE (Supplementary Fig. 6). Four bands containing soluble protein were excised from denaturing gels, reduced, alkylated and digested with trypsin, using the Janus liquid handling system (PerkinElmer, UK). The digests were subsequently analysed on an LC-MS/MS Q-Exactive plus orbitrap mass spectrometer (Thermo Scientific, San Jose, USA). LC-MS/MS data were searched against a protein database (UniProt KB) using the Mascot search engine programme52,53 (Matrix Science, UK). Proteins of the appropriate molecular weight and at least two peptides were identified. GO annotation and enrichment was carried out using the Saccharomyces Genome Database (SGD).

Glycogen content. Cells were harvested by centrifugation, washed with ice-cold phosphate-buffered saline (PBS) and lysed by incubation in 0.25 M sodium carbonate at 98 °C for 4 h. One molar acetic acid and 0.2 M sodium acetate were added to bring the solution to pH 5.2. Glycogen was digested overnight using amyloglucosidase (10115, Sigma-Aldrich) and the glucose released measured using a glucose (GOD) Assay Kit (GA3020, Sigma-Aldrich). Glucose (mg mL−1) was determined from a standard curve and corrected for the starting material.

Puromycin incorporation. Samples from the bioreactor were immediately incubated with puromycin (AGC Scientific, P-1033) at 8 mg mL−1 final concentration, 30 min, 30°C in the dark with agitation, before harvesting by centrifugation at 1150g for 5 min at 4 °C. For testing the effect of an osmotic challenge, or change in pH, samples were first diluted into an equal volume of media containing 1% glucose plus glycerol or sorbitol at pH 3.4, or into media of different pH, before addition of puromycin, 8 mg mL−1 final, and incubation for 20 min at 30 °C.

Western blot analysis. Yeast whole-cell extracts were prepared as described59, except that disruption of the cell wall with glass beads was carried out using a Virtis Genie 2 (Scientific Industries, Bohemia, USA) fitted with a TurboMix head and the protein pellet resuspended in 50 µL Buffer A per OD unit of cells, with protease as described in ref. 7. Approximately 10 µg protein was separated by gel electrophoresis in MES buffer on 4–12% bis-tris mid nuPAGE gels (Life Technologies) according to the manufacturer’s instructions. Proteins were transferred to Immobilon-FL (Millipore) in Towbin buffer using a Biorad Transblot Turbo v1.02 blotter set at 25 V, 1.0 A, 30 min, room temperature, stained for total protein using 1% Ponceau Red. Intact cells were removed by centrifugation at 3000 g for 20 min. Membrane proteins were removed by washing twice with 320 µL of lysis buffer and stored at −80 °C.

Primary antibodies: mouse monoclonal anti-puromycin (1:5000, Millipore), mouse monoclonal anti-GFP (1:3000, Roche), polyclonal rabbit anti-Phospho-S6 Ribosomal Protein (Ser235/236), recognises Rps6 in yeast and is a readout for osmotic stress in yeast. Secondary antibodies were visualised as in ref.62: Western blot analysis was performed on a Dionex U3000 UHPLC system coupled to a Q-Exactive mass spectrometer (Thermo Fisher Scientific). The liquid chromatography system was fitted with a SeQuant ZIC-pHILIC column (150 × 2.1 mm, 5 µm) from Merck Millipore. The mobile phase was composed of 20 mM ammonium carbonate and 0.1% formic acid (solvent A) and 80% acetonitrile (solvent B, 17 min 20% B, 17.1 min 80% B and a hold at 80% for 5 min. Samples were randomized to avoid bias due to machine drift, and the operator was blind to the key. The acquired spectra were analysed using the XCalibur Qual Browser and XCalibur Quant Browser software (Thermo Fisher Scientific) by referencing to an internal library of compounds. Each metabolite is normalised to the total sum of metabolites. The 1-D Gel Image analysis software by Quantity One (Bio-Rad Laboratories) was used to analyse bands in gels. For specific bands containing soluble protein were excised from denaturing gels, reduced, alkylated and digested with trypsin, using the Janus liquid handling system (PerkinElmer, UK). The digests were subsequently analysed on an LC-MS/MS Q-Exactive plus orbitrap mass spectrometer (Thermo Scientific, San Jose, USA). LC-MS/MS data were searched against a protein database (UniProt KB) using the Mascot search engine programme52,53 (Matrix Science, UK). Proteins of the appropriate molecular weight and at least two peptides were identified. GO annotation and enrichment was carried out using the Saccharomyces Genome Database (SGD).
using the Silver Quest Kit (Invitrogen) and images captured using a Perfection V600 Photo scanner (Epson). ImageJ was used to obtain the background corrected signal intensity per lane.

Flow cytometry. Propidium iodide labelling: 1.5 mL cells (OD 7 to 8) undergoing oscillations in 1.5 L culture were harvested from the bioreactor (4 biological replicates). Aliquots containing ~10^7 cells were washed in water, resuspended in 500 µL 70% ethanol and stored at 4°C until use. Samples were harvested by centrifugation at 3381g, 4°C for 10 min. Cell pellets were resuspended in 250 µL Tris buffer pH 7.4 (50 mM) containing RNase A (200 µg mL^-1^) and incubated at 37°C for 3 h. RNase-treated cells were harvested by centrifugation at 9931g for 5 min and pellets resuspended in 500 µL sodium citrate (50 mM, pH 7.0) before sonication to break up clumps of cells. The volume of sonicated cells was brought up to 500 µL with sodium citrate (50 mM, pH 7.0) containing propidium iodide (Sigma P4170) to give a final concentration of 12.5 µM mL^-1^ and approximately 10^7 cells mL^-1^. Tubes were put in the dark at 4°C before processing. Flow cytometry was carried out at the CICT Flow Cytometry Core on a FACS Canto II (Becton Dickinson). Analysis was performed using the FCS Express density plot function, with the gates shown in Supplementary Fig. 1.

Ratiometric bioluminescence monitoring of pH_5_ across the YRO. YROs were established in strains with a stably transformed bioluminescent pH reporter plasmid (either pRS306-PTEF1Luc2 or pRS304Nat-PTEF1Luc2), 850 mL culture in a 3 L BioFlo 115 benchtop fermentor (New Brunswick) with pH 3.4, 54 L h^-1_ air, 550 r.p.m., and an initial dilution rate of 0.08 h^-1_ (ref. 36). Luminescence was continuously recorded using two Hamamatsu PMTs (HCC135-012); however, the PMTs were fitted with 550 ± 5 and 610 ± 5-nm band pass filters (66704 and 66709; Edmund Optics).

After monitoring luminescence from the YRO (as above), continuous culture was terminated and luminescence ratio data generated. The pH of the culture was adjusted to 5.8 by addition of 2 M NaOH. Beetle luciferin (Promega), 5 µM concentration, and carbonyl cyanide (CCCP, Promega) 50 µM was added directly to cells in the bioreactor. 

Data availability
Proteomic data that support the findings of this study have been deposited in the ProteomeXchange Consortium via the PRIDE partner repository with the identifier PXD013653. Other data that support the findings of this study are available from the corresponding authors upon reasonable request. Source data are provided with this paper.
