Clinical Outcomes of Anterolateral Ligament Reconstruction or Lateral Extra-articular Tenodesis Combined With Primary ACL Reconstruction

A Systematic Review With Meta-analysis

Investigation performed at the Department of Orthopedic Surgery, Chonnam National University Medical School and Hospital, Chonnam, Republic of Korea

Background: Residual rotational instability after isolated anterior cruciate ligament reconstruction (ACLR) has been a challenge for many years. Anterolateral extra-articular procedures (AEAPs), including anterolateral ligament reconstruction (ALLR) or lateral extra-articular tenodesis (LET), are performed as a surgical option for additional rotational stability, but clear evidence for their usefulness is lacking.

Purpose: To conduct a systematic review and meta-analysis of the literature regarding the efficacy of AEAP in primary ACLR.

Study Design: Systematic review; Level of evidence, 3.

Methods: A literature search, data extraction, and quality assessment were conducted by 2 independent reviewers. MEDLINE, EMBASE, and the Cochrane Library were searched in April 2020, following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. A total of 3444 studies were screened, and 20 studies (11 randomized controlled trials and 9 nonrandomized studies) were evaluated. Functional outcomes, stability, and complications were compared between patients who underwent primary ACLR with AEAP and those who underwent isolated primary ACLR. For subgroup analysis, outcomes were compared according to AEAP technique (ALLR vs LET) and time from injury to surgery (<12 vs ≥12 months). The methodological quality of the included studies was assessed using the Cochrane risk-of-bias tool, Jadad scale, and Newcastle-Ottawa Scale.

Results: Compared with isolated ACLR, combined ACLR with AEAP led to improved pivot-shift grades and graft failure rates, regardless of the AEAP technique or of time from injury to surgery. A limited, marginal improvement in subjective function score was observed in patients who underwent AEAP combined with ACLR. In contrast to ALLR, patients who underwent LET combined with ACLR had an increased risk of knee stiffness and adverse events.

Conclusion: Our review suggests that when there is a need to improve rotational stability and subjective function, AEAP combined with primary ACLR can be considered regardless of time from injury. ALLR appeared to be a better option for improving rotational stability compared with LET.

Keywords: primary anterior cruciate ligament reconstruction; lateral extra-articular tenodesis; anterolateral ligament reconstruction; pivot shift; graft failure
cartilaginous lesions and early secondary arthritic changes. 39 To resolve these problems and improve knee stability, several strategies have been proposed, including more lateral positioning of the femoral tunnel, 47,67 double-bundle reconstructions with an additional posterolateral bundle to control the rotation, 2,32 and different types of autografts used. 5,23 However, although there have been several randomized controlled trials (RCTs) and meta-analyses analyzing different strategies for treating rotational instability, no obvious differences in outcomes have been noted. 20,42,52

Currently, since the “rediscovery” of the anterolateral ligament (ALL) of the knee in 2013, there is great interest in the role of the anterolateral structures of the knee in controlling rotational instability. 10,53,56 Historically, several anterolateral extra-articular procedures (AEAPs) have been developed to reduce anterolateral rotational instability, including lateral extra-articular tenodesis (LET). 38,39 However, according to previous studies, there are concerns over LET being nonanatomic and potentially overconstraining the joint because of altered biomechanics. 17 In addition, overconstraint can potentially lead to graft over-tensioning and elongation and, ultimately, to increased degenerative changes in the lateral tibiofemoral compartment. 18,44 The recent renewed interest in the anterolateral structures of the knee has led to significant progress in understanding anatomy and biomechanics, which in turn has enabled the development of a relatively new procedure, ALL reconstruction (ALLR). 55

The aims of this literature review were as follows: (1) to demonstrate the clinical efficacy of primary ACLR combined with LET or ALLR (ACLR+AEAP) compared with isolated ACLR, according to functional outcomes, stability, and complications; and (2) to compare ACLR+AEAP with isolated ACLR according to AEAP type (LET vs ALLR) and time from injury to surgery (<12 vs >12 months).

METHODS

This study was performed following the guidelines of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement. 45

Search Strategy

In April 2020, two independent reviewers (B.-R.N. and J.-K.S.) searched the following databases: PubMed (MEDLINE), EMBASE, and the Cochrane Library. No restrictions were placed on language or year of publication. The databases were searched using the following keywords: (extra-articular or extra-articular or anterolateral or antero-lateral or ALL or anterior oblique band or iliotibial or IT band or IT graft or second) and (tenodesis or plasty or augmentation or procedure or reconstruction or reconstructive or surgical or surgery or technique) and (ACL or anterior cruciate ligament). To supplement the electronic database search, the reference list of relevant articles was cross-checked to identify any additional references of interest. After removing the duplicates and excluding the articles by title, the full texts of the remaining articles were assessed.

Selection Criteria

The following inclusion criteria were applied to the selected studies:

- Published peer-reviewed study: RCTs, nonrandomized comparative studies, and prospective or retrospective cohort studies
- Outcome data of primary ACLR+AEAP
- Skeletally mature patients of both sexes with ACL rupture who had undergone primary ACLR regardless of the graft type or reconstruction technique

Exclusion criteria were as follows:

- Reports on guidelines, technical notes, reviews, and systematic reviews
- Any biomechanical or radiological studies, ex vivo analysis (cadaveric, histological, or anatomical), case reports, and noncomparative studies
- Patients with >2 surgically treated knee ligaments (posterior cruciate ligament, medial or lateral ligament, or posterolateral ligament surgery)
- Extra-articular procedures performed in isolation
- Patients who had undergone revision surgery after primary ACLR

Initially, we reviewed the title and abstract of each article when applying the selection criteria. On reviewing the title and abstract, if it was unclear whether the article was appropriate for inclusion, the full text of the article was assessed. Two reviewers (B.-R.N. and J.-K.S.) applied the selection criteria independently. Any differences of opinion between them on the importance and relevance of any identified article were resolved through discussion until consensus was reached. A third reviewer (H.-Y.S.) resolved any residual differences of opinion. For multiple reports with the same patient cohort and increasing duration of follow-up, only the latest publication (ie, the article with the longest follow-up) was included. There were 2 separate groups of authors with more than 1 study (Helito group 27,28 and Zaffagnini group 68,69), but they were included because there was no overlap of patients in the data analysis.
Data Extraction

Two reviewers (B.-R.N. and J.-K.S.) independently extracted data and entered them into a specifically designed spreadsheet containing headings of the selected outcomes. The following demographic data were extracted from the articles: study type, number of patients, sex, age, time from injury to surgery, type of extra-articular procedure (LET or ALLR), and follow-up time. Functional outcomes and stability were assessed using the mean values of subjective clinical scores (Lysholm, Tegner activity scale, and subjective International Knee Documentation Committee [IKDC]) and objective clinical examinations (Lachman test, pivot-shift test, and objective IKDC). Complications were assessed according to graft failure rate, adverse events (recurrent meniscal injury, infection, cyclops syndrome, screw loosening, and harvest-site pain), and knee stiffness (loss of full extension or flexion).

Quality Appraisal and Methodological Assessment

The methodological quality of the RCTs was assessed using the Cochrane risk-of-bias tool and the Jadad scale, which have been found to be reliable for quality assessment of RCTs. The nonrandomized studies were assessed using the Newcastle-Ottawa Scale, which is reliable for quality assessment of nonrandomized cohort studies and case-control studies. The methodological quality of each article was stratified. Any disagreements in the initial ratings of methodological quality between the 2 reviewers (B.-R.N. and J.-K.S.) were resolved through discussion until consensus was reached.

Statistical Analysis

All statistical analyses were performed using Review Manager (RevMan 5.3; The Nordic Cochrane Centre). Treatment effects were expressed as odds ratios (ORs) for binary outcomes and mean differences for continuous outcomes, with 95% CIs. A fixed-effects or random-effects model was used to combine the data according to the Mantel-Haenszel method. Both models provide similar results when inter-study heterogeneity is absent, but when the heterogeneity is high, the random-effects model is more appropriate. The heterogeneity of treatment effects was appraised visually by observing the overlapping confidence intervals on forest plots. In addition, I² statistics were calculated for objective assessment of heterogeneity. High heterogeneity was indicated by the absence of overlapping confidence intervals on forest plots and I² > 50%, and the reasons for heterogeneity were assessed. Subgroup analysis was performed when...
feasible. Publication bias was assessed by visual inspection of funnel plots of the primary outcomes.

RESULTS

Search Results

The literature search across all databases yielded a total of 3441 articles, and an additional 3 articles were found on reviewing the reference lists. After the removal of duplicates, 2690 articles remained. This was reduced to 64 articles after screening titles and abstracts. After full-text review, 20 articles (2376 patients) met the eligibility criteria; 11 were RCTs (1294 patients) and 9 were nonrandomized studies (1082 patients). The literature search process is summarized in Figure 1.

Demographic and Methodological Results

Of the 2376 patients, there were 1135 who had undergone ACLR + AEAP and 1241 patients who had undergone isolated ACLR (Appendix Table A1). The male-to-female ratio was 1.5:1 (1026:676); however, 8 articles did not provide patient sex. The mean age of patients at surgery was 25.1 years (range, 14–57 years), the mean time from injury to surgery was 13.5 months (range, 2 weeks–16 years), and the mean follow-up period was 42.0 months (range, 6 months–19.8 years).

The methodological quality of all the included studies was assessed. Most of the RCTs had an unclear to high risk of bias according to the Cochrane risk-of-bias tool (Figure 2), and all RCTs were of good quality (score range, 3-5 points) according to the Jadad scale (Table 1). All nonrandomized studies were of good quality according to the Newcastle-Ottawa Scale (score range, 7-9 stars) (Table 2).

Functional Outcomes and Stability

Subjective Clinical Scores (Lysholm Score, Tegner Activity Scale, and Subjective IKDC).

Of the 20 included studies, 9 reported the Lysholm score (1018 patients), 5 reported the Tegner score (645 patients), and 11 reported the subjective IKDC score (1644 patients). All 3 scores were higher in the ACLR + AEAP group than in the isolated ACLR group (mean difference: Lysholm score, 3.02 [95% CI, 1.31-4.74]; $P = .0006$; $I^2 = 88\%$; Tegner score, 0.80 [95% CI, 0.08-1.52]; $P = .03$; $I^2 = 94\%$; and subjective IKDC, 2.65 [95% CI, 0.91-4.49]; $P = 0.005$; $I^2 = 96\%$).

Objective Clinical Examination (Lachman Test, Pivot-Shift Test, and Objective IKDC).

Of the 20 included studies, 7 reported the Lachman test (479 patients). A Lachman test grade of 2 or 3 indicates poor anterior knee stability. The proportion of patients with Lachman grade 2 or 3 was lower in the ACLR + AEAP group than in the isolated ACLR group (OR, 0.42 [95% CI, 0.20-0.89]; $P = .02$; $I^2 = 0\%$). Of

* A dash denotes ineligibility. Items are defined as follows: 1, Representativeness of the exposed cohort; 2, Selection of the nonexposed cohort; 3, Ascertainment of exposure; 4, Demonstration that outcome of interest was not present at start of study; 5, Comparability of cohorts on the basis of the design or analysis controlled for confounders; 6, Assessment of outcome; 7, Was follow-up long enough for outcomes to occur; 8, Adequacy of follow-up of cohorts.
* A study can be awarded a maximum of 1 star for each numbered item within the Selection and Outcome categories. A maximum of 2 stars can be given for the Comparability category.
the 20 included studies, 16 reported the pivot-shift test (1233 patients). A grade 2 or 3 on the pivot-shift test indicates poor knee rotational stability. The proportion of patients with grade 2 or 3 pivot shift was lower in the ACLR + AEAP group than in the isolated ACLR group (OR, 0.30 [95% CI, 0.18-0.49]; P < .00001; I² = 0%). Of the 19 included studies, 10 reported the objective IKDC results (798 patients), in which scores are reported as A (normal), B (nearly normal), C (abnormal), or D (severely abnormal). The proportion of patients with an IKDC score of C or D did not differ between the 2 groups (OR, 0.76 [95% CI, 0.50-1.16]; P = .21; I² = 7%) (Figure 3).

Complications (Graft Failure, Adverse Events, Knee Stiffness)

Of the 20 included studies, 14 reported graft failure (2099 patients). The rate of graft failure was lower in the ACLR + AEAP group than in the isolated ACLR group (OR, 0.31 [95% CI, 0.20-0.48]; P < .00001; I² = 0%). Of the 20 included studies, 14 reported adverse events (1972 patients). The rates of overall adverse events did not differ between the 2 groups (OR, 1.20 [95% CI, 0.68-2.09]; P = .53; I² = 53%). Of the 20 included studies, 10 reported knee stiffness (1284 patients), indicated as loss of full extension or flexion of >5°. The rates of

Figure 8. Comparison of pivot shift after ACLR according to time from injury to surgery. The forest plot shows that regardless of whether the procedure was early (<12 months) or delayed (>12 months), a significantly lower proportion of patients with grade 2 or 3 pivot shift was seen after additional extra-articular procedure combined with ACLR versus isolated ACLR. ACLR, anterior cruciate ligament reconstruction; ALLR, anterolateral ligament reconstruction; LET, lateral extra-articular tenodesis; M-H, Mantel-Haenszel.
knee stiffness did not differ between the 2 groups (OR, 1.65 [95% CI, 0.52-5.23]; \( P = .39 \); \( I^2 = 71\% \)) (Figure 4).

**Subgroup Analysis: AEAP Technique (ALLR vs LET)**

Analyses were performed to determine whether outcomes after ACLR varied according to the AEAP technique. Use of ALLR combined with ACLR (ALLR group) was reported in 10 of 20 included studies. The Lysholm and subjective IKDC scores were higher in the ALLR group than in the isolated ACLR group; however, the Tegner and objective IKDC scores, Lachman test grade, and the rate of knee stiffness were not different between the 2 groups. The proportion of patients with grade 2 or 3 pivot shift and the rates of graft failure and adverse events were lower in the ALLR group than in the isolated ACLR group.

LET combined with ACLR (LET group) was reported in 10 of the 20 included studies. The Lysholm, Tegner, and subjective IKDC scores were higher in the LET group than in the isolated ACLR group; however, the Lachman test grade and objective IKDC score were not different between the 2 groups. The proportion of patients with grade 2 or 3 pivot shift and the rates of adverse events and knee stiffness were higher in the LET group.

The Tegner scores and the rates of adverse events and knee stiffness were statistically different between the ALLR and LET groups (Figures 5–7). The rates of adverse events were lower in the ALLR group, and higher in the LET group, compared with the isolated ACLR group. The rate of knee stiffness was higher in the LET group compared with the isolated ACLR group, and there was no significant difference between the ALLR group and the isolated ACLR group.

**Subgroup Analysis: Time From Injury to Surgery (≤12 vs >12 Months)**

Analyses were performed to determine whether outcomes after ACLR varied according to time from injury to surgery. In 8 of 20 included studies, ACLR was performed within 12 months of the index ACL injury. The Lysholm score was higher in the ACLR+AEAP group than in the isolated ACLR group. There were no differences in Tegner, subjective IKDC, and objective IKDC scores; Lachman test grade; or adverse event and knee stiffness rates between the 2 treatment groups. The proportion of patients with grade 2 or 3 pivot shift and the rate of graft failure were lower in the ACLR+AEAP group versus the isolated ACLR group; this was true regardless of early or delayed reconstruction (Figures 8 and 9). However, the rate of adverse events was higher in the ACLR+AEAP group.
DISCUSSION

This systematic literature review indicated that performing ALLR or LET with ACLR led to a statistically significant reduction in the pivot-shift grade and graft failure rate compared with ACLR alone. No difference was observed in objective IKDC, adverse event rate, or knee stiffness rate between isolated ACLR and ACLR+AEAP. In contrast to ALLR, the LET procedure was associated with increased knee stiffness and adverse events. Subjective clinical scores and Lachman test grade were only marginally superior in the ACLR+AEAP group. Some advantages in knee stability were observed with AEAP; however, it remains unclear whether these advantages are justified at the cost of an additional procedure.

Subjective clinical scores (Lysholm, Tegner, and subjective IKDC) were only marginally improved in the ACLR+AEAP group, indicating that the added stability obtained with the extra-articular procedure did not greatly influence the final subjective clinical results. Previous studies have demonstrated an association between objective clinical examinations of ligament stability and subjective functional outcomes. Studies have also shown that statistically significant differences may not be clinically significant. Therefore, performing or not performing AEAP is not a major concern in all ACLR surgery and is only an additional procedure to be considered for improving rotational instability. The primary aspects of ACLR surgery, such as fixation method, correct tunnel placement, and graft type, possibly have a greater influence on the final clinical outcome and should be addressed before considering an additional procedure.

Objective clinical examinations (Lachman test, pivot-shift test, and objective IKDC) generally demonstrated improved outcomes. The proportion of patients with grade 2 or 3 pivot shift was significantly reduced in the ACLR+AEAP group, suggesting that the extra-articular procedure played a role of secondary restraint to rotational stability. Some ACL injuries damage only the central structure, but sometimes in pivot-shift injuries a combination of central and peripheral structures is damaged. Previous studies have demonstrated that AEAP can reduce rotational instability. Therefore, it is thought that AEAP should be considered during ACLR in patients diagnosed with rotational instability on preoperative pivot-shift test, as well as in patients with damage to the peripheral structures on magnetic resonance imaging. The Lachman test grade was improved in the ACLR+AEAP group; however, this appeared to be a secondary effect, and the interpretation requires attention. AEAP does not directly improve anterior stability after ACLR; however, it reduces the deformation of the graft by dissipating forces during ligamentization. The protective effect during ligamentization may lead to a reduction in graft elongation and eventually to a reduction in graft failure. The results of the current study confirm these findings, as the rate of graft failure decreased in the ACLR+AEAP group.

The finding of reduced graft failure rates in the ACLR+AEAP group held despite different surgical techniques being performed across the included studies. Because we found similar results across the various series of studies, it can be concluded that the general control of rotation and the protective effect of the graft is more important than the specific AEAP technique itself.

The results of subgroup analyses according to ALLR versus LET techniques showed increased knee stiffness and adverse events in the LET group. One possible explanation for this finding could be that more nonanatomic reconstruction was performed in LET than in ALLR. These nonanatomic procedures were almost completely discontinued in the United States after 1989, and additional ALLR procedures were attempted to compensate for the concerns of nonanatomic graft placement. A review of recent biomechanical studies revealed inconsistencies depending on the anatomic attachment site of ALLR, but several studies indicated that there was no concern for overconstraint in ALLR. These concepts are consistent with the results of our meta-analysis—no increase in knee stiffness and adverse events were observed with ALLR. Although the protective effect of the graft is more important than the technique, ALLR appears to be a better option for rotational stability.

The results of the subgroup analyses according to time from injury to surgery showed that ACLR+AEAP led to improved pivot-shift grade and graft failure compared with isolated ACLR, regardless of the timing of reconstruction. Similar findings were reported in a recent systematic review on this topic. Devitt et al concluded that although LET did not provide additional benefit in early primary ACLR, it was effective in delayed ACLR. The findings on delayed reconstruction are consistent with those of our meta-analysis; however, the findings on early reconstruction are different. This difference may be partially explained as differently defined pivot-shift results. Devitt et al defined a positive pivot shift as a grade of 1, 2, or 3 and a negative pivot-shift as a grade of 0. However, we defined a high-grade pivot shift as a grade of 2 or 3 and a low-grade pivot shift as a grade 0 or 1. Our interpretation was based on several studies that focused on the association between the amount of lateral compartment translation and the clinical grade of the pivot shift. In a cadaveric study, isolated ACL transection rarely produced a pivot shift of grade 2 or 3 in a laboratory setting. Mostly, when an ACL deficiency combined with damage to the anterolateral structures is present, it produces a pivot shift of grade 2 or 3.

Limitations

This review has some limitations. First, a limited number of studies with different study designs were evaluated. This could raise serious concerns on the quality of data and possible overlap of patients. The heterogeneity of studies, including ACLR graft selection, ALLR graft selection, attachment points, and surgical techniques, limit direct comparisons when evaluating clinical outcomes. Second, an uncertainty on the degree of preoperative rotational instability and a potential for injury to other structures that may affect rotational instability existed. Third, although the pivot-shift test is considered to be one of the most common and sensitive methods for evaluating rotational instability, it is subjective, and interexaminer variability has been observed previously. However, although many attempts have been made to objectify the pivot-shift test with...
mechanical and optical tracking devices, it is still the most widely used method to assess rotational stability. Therefore, despite the amount of variabilty present, we had to compare these indicators in our meta-analysis. Despite these limitations, this review highlights the lack of literature on the use of the additional procedures in primary ACLR and provides encouraging results for future studies.

CONCLUSION

Patients who underwent AEAP combined with ACLR had improved pivot-shift grades and graft failure rates compared with isolated ACLR, regardless of early or delayed reconstruction. ALLR combined with ACLR appeared to be a better option for treating rotational instability, as LET combined with ACLR led to an increased risk of knee stiffness and adverse events.

### Table A1: Demographic Data of Included Studies

| Study Author | Year | Study Type | (1) Study Group | (2) Control Group | N (Sex, M:F) | Age, y | Time From Injury, mo | Follow-up, mo | Anterolateral Procedure Technique (Graft) | ACLR Technique (Graft) |
|--------------|------|------------|----------------|-------------------|-------------|-------|-------------------|--------------|--------------------------------------|----------------------|
| Acquitter (2003) | RCT | BPTB + ALLR | 50 | 27.2 (16-59) | 23 ± 29 (3-156) | 58 | SB (ST + gracilis) | BPTB (patellar) |
| Branch (2015) | Prosp | BPTB + ALLR | 6 | 40 (28-48) | NR | 108 (99-237) | SB (gracilis) | BPTB (patellar) |
| Goncharov (2019) | RCT | BPTB + ALLR | 18 | NR | 24 | SB (ST + gracilis) | BPTB (patellar) |
| Helito (2018) | Retrosp | SB | 33 (30:3) | 33.1 ± 8.8 | 15 (13-18) | 25 (24-28) | SB (ST + gracilis) | SB (ST + gracilis) |
| Helito (2019) | Retrosp | SB | 50 | 26 (21-32) | 3 (2-0.4-6) | 27 (25-30) | SB (ST + gracilis) | SB (ST + T-tenodesis) |
| Sonnery-Cottet (2017) | Prosp | SB + ALLR | 221 (152:59) | 21.8 ± 4.0 (16-30) | 5.3 ± 9.0 | 56 ± 8.4 | SB (gracilis) | SB (ST) |
| Zaffagnini (2006) | RCT | SB + ALLR | 25 (18:7) | 26.7 ± 7.7 (15-49) | 11 (11-14) | 60 | SB (ST + gracilis) | SB (ST + gracilis) |
| Zaffagnini (2008) | RCT | SB + ALLR | 35 (20:15) | 26 ± 10.2 (19-45) | 8.2 ± 10.4 (1-48) | 46.8 (36-60) | SB (ST + gracilis) | SB (ST + gracilis) |
| Zhang (2016) | RCT | SB + ALLR | 20 (12:8) | 26 ± 5.8 | 16 ± 5.6 | 12 | SB (ST + gracilis) | SB (ST + T-tenodesis) |
| Anderson (2001) | RCT | SB + Losee | 34 | 22 (14-40) | <2 wk (n = 13) | 35.7 ± 12.1 | Losee (ITB) | SB (ST + gracilis) |
| Depour (2013) | Prosp | BPTB + Lemaire | 25 (20:5) | 21.4 ± 5 (14-34) | 10.78 (3-80) | 25.6 (14-33) | Modified Lemaire (gracilis) | SB (ST + gracilis) |
| Ferretti (2016) | Retrosp | SB + MacIntosh | 68 (56:12) | 27.5 ± 7 (18-46) | 3.4 | 126 ± 2.4 (122-130) | MacIntosh (ITB) | SB (ST + gracilis) |
| Goertzen (1993) | Retrop | SB + Jager-Wirth | 32 (21:11) | 28.4 (17-46) | 9.6 (3-25) | 14.2 | Jager-Wirth (ITB) | SB (ST + gracilis) |
| Noyes (1991) | Retrosp | SB + Losee | 40 | 26.7 (19-43) | 9.6 (3-25) | 14.2 | Losee (ITB) | BPTB (allo graft) |
| Strum (1989) | Retrosp | Various + tenodesis | 43 | 27.8 (17-57) | 31.5 (20-122) | 25.3 (28-90) | 25 Eilon modified | BPTB (patellar); 3 Marshall (patellar); 31 meniscal (patellar or meniscal) |
| Trichine (2014) | RCT | Kenneth Jones + ITB tend:osis | 55 | 28.6 ± 4.69 | 35.4 | 20.4 (6-45) | ITB tenodesis (ITB) | BPTB - Kenneth Jones (patellar) |
| Vadalà (2013) | RCT | SB + MacIntosh | 27 (12:7) | 26 (15-40) | 25.7 (0.5-192) | 41.3 (24-85) | 7 BPTB | 2 Marshall (patellar); 75 meniscal (patellar or meniscal) |

**Notes:**
- Dashes indicate not applicable.
- ACLR, anterior cruciate ligament reconstruction; ALLR, anterolateral ligament reconstruction; BPTB, bone–patellar tendon–bone; DB, double bundle; F, female; ITB, iliotibial band; M, male; NR, not reported; Prosp, prospective study; RCT, randomized controlled trial; Retrosp, retrospective study; SB, single bundle; ST, semitendinosus tendon.
- Data are reported as mean (range).
