Abstract
Awareness is one of the first steps in a lifestyle modification process. Since older adults are at a higher risk of hypertension, maintaining low sodium intake is of utmost importance. Yet, it is uncertain if older adults have an awareness of their sodium intake. This study aimed to explore self-perceived sodium intake among older Chinese people and compare it with various measures of sodium intake. A cross-sectional study was conducted in Hong Kong in 2015. Data were collected from 24-h urinary sodium excretion (UNa24) measurements, dietary sodium intake by 24-h diet recalls and self-perceived salt intake levels among the older Hong Kong population. Kappa statistics and a paired t-test were used to compare the different measures. Fifty-nine participants provided complete 24-h urine samples. The mean (±SD) UNa24 of participants was 2846 ± 1253 mg, of which 74.6% exceeded the recommended daily sodium intake. About 87.8% of participants with UNa24 values >2000 mg perceived their sodium intake as too little or just right. The kappa statistic between UNa24 and self-perception was insignificantly different from zero ($\kappa = -0.003$, p-value = 0.909). The UNa24 estimates were significantly higher than those estimated from the 24-h diet recalls by 1203 mg ($p$-value < 0.001). The findings imply that the...
low awareness of excessive sodium intake should be raised among older people to promote a healthy intake of sodium.

**Introduction**
Reducing sodium intake effectively controls hypertension.\textsuperscript{1,2} The World Health Organization (WHO) recommends a daily sodium intake of less than 2000 mg.\textsuperscript{3} In Hong Kong, sodium intake in the general population has been found to exceed the recommended level.\textsuperscript{4–6} Therefore, reducing salt intake is a high-priority goal in the effort to halt the increasing trend of hypertension. Various forms of intervention, such as nutrition education programs and public education campaigns, have been developed to help people reduce their sodium intake.\textsuperscript{7} According to the Stages of Change Model,\textsuperscript{8} those who have no intention of taking action belong to the stage of precontemplation. To promote behavioural change for people at this stage, increasing their awareness of the need for change is important.

Awareness is one of the first steps in a lifestyle modification process. If people with high sodium intake perceive themselves as having a normal or even low sodium intake, they will not realise the need to reduce the amount of sodium they consume. Therefore, a person’s self-perceived level of sodium intake could affect one’s motivation to reduce sodium intake. However, people with a high sodium intake often do not recognise that their intake is high. In a study in China, participants aged 18–69 reported themselves as having low sodium intake, even though their urinary sodium excretion was exceeding 9 g per day.\textsuperscript{9} In a US study, sodium intake estimated from the 24-h diet recall also underestimated the actual sodium intake estimated from urinary sodium excretion.\textsuperscript{10}

Since older adults are at a higher risk of hypertension, maintaining low sodium intake is of utmost importance. Yet, it is uncertain if older adults have an awareness of their sodium intake. The objectives of this study were to explore self-perception of sodium intake of Chinese older adults and compare it with laboratory measures.

**Methods**

**Study design**
A cross-sectional observational study was conducted in Hong Kong during June through August of 2015. Ethics approval was granted by the Institutional Review Board.

**Participants**
The target population consisted of older Chinese people in Hong Kong. Inclusion criteria included older Chinese aged $\geq$65 years without communication problems.
Exclusion criteria included those with renal illness who were taking diuretics, as their urinary sodium excretion might differ from normal.

The sample size calculation was based on detecting a moderate agreement between two measurements based on a kappa statistic of 0.4. According to the guidelines of a sample size requirement, a minimal sample size of 62 was required to detect such a value with 90% statistical power and 5% level of significance. It was reported that 10% of the participants were unable to provide both a urine sample and food diary; hence, it was required that 70 participants should be recruited to accommodate the missing information.

**Sodium intake measurements**

*24-h urinary sodium excretion measurement.* The 24-h urinary sodium excretion (UNa24) measurement is regarded as the gold standard for measuring dietary sodium intake. Trained research assistants instructed participants how to store urine voids for 24 h according to the standard procedure used in clinical practice. The first morning void on the collection day was discarded, and all urine voids in the subsequent 24 h were stored in a 3-L bottle. At the end of the 24-h period, the last void was made. Each participant was asked to urinate in the jug provided and then pour the urine into the given 3-L bottle. Participants were asked to place the urine collection bottle in a cool place and return it to the research team within the day of the last void. The participants recorded any missing voids. The 24-h collection was considered to be complete if the total urine volume was >500 mL, the reported collection period was ≥20 h and a ≤1 missed void was reported. The urine volume and urinary sodium excretion were estimated by an accredited laboratory.

**Dietary sodium intake based on a 24-h diet recall.** Participants had a 24-h diet recall when returning the urine sample. To minimise recall bias, participants recorded their diets and any discretionary salt and condiments. During the recall interview, pictures of food portions aided the recall of the amount of food consumed. Sodium intake was estimated using the online Food Nutrient Calculator of the Centre for Food Safety of Hong Kong.

**Self-perception.** A participant’s self-perceived salt intake level was assessed by single question: ‘What do you think of your salt intake?’ Participants could choose one of four responses: ‘too little’, ‘just right’, ‘too much’ and ‘I don’t know/not sure’.

**Procedure**

A convenience sample was recruited from two senior community centres in Hong Kong. Trained research assistants explained the study to potential participants and screened them for eligibility. After obtaining written informed consent, the research team taught the participants how to collect 24-h urine samples and record their diets. On a designated date, the participants returned the collected urine samples,
which were sent to a certified laboratory on the same day. The research assistant also assisted the participants in completing the 24-h diet recall, in which they answered the question on self-perceived sodium intake level and provided demographic information. Upon completion, each participant received a HK$50 supermarket coupon.

During June through August of 2015, 75 potential older Chinese participants from two senior community centres in Hong Kong were screened. Among 72 eligible participants, 2 withdrew because they perceived they could not comply to the protocols. A further six participants dropped out by not returning the urine sample. Among the 64 participants who returned the urine sample, 5 had incomplete urine collections. Thus, 59 participants with complete 24-h urine collection samples were included in the analysis (Figure 1).

**Statistical analysis**

UNa24 results were dichotomised into a ‘high sodium intake group’ (UNa24 >2000 mg/day) and a ‘regular sodium intake group’ (≤2000 mg/day), according to the recommended sodium intake. Kappa statistics and the Pearson’s correlation
coefficient were used to examine associations across different measures. A paired \( t \)-test was used to test the difference between estimated sodium intake based on UNa24 and a 24-h diet recall. SPSS version 23 was used. A significance level of 5% was adopted.

Results

Fifty-nine participants were included in the data analysis. The majority were women (83.1%), and the mean age was 76.6±6.8 years (Table 1). Most (>70%) had a primary education level or no formal education, and >60% had received a diagnosis of hypertension from a medical doctor.

Among the 59 participants, 16.9% perceived their sodium intake as being ‘too little’, 66.1% as ‘just right’, 12.0% as ‘too much’ and 5.1% were not sure about their salt intake level. The mean UNa24 was 2846±1253 mg/day, and 44 (74.6%) participants had values >2000 mg/day. Table 2 shows that 87.8% of participants with UNa24 values >2000 mg perceived their sodium intake as too little or just right. Three participants who reported ‘don’t know/not sure’ in the high sodium intake group were excluded in the calculation of kappa statistics. The kappa statistic between the sodium intake level based on UNa24 and self-perception was insiginificantly different from zero (\( \kappa = -0.003, p\text{-value} = 0.909 \)).

The mean estimated sodium intake based on the 24-h diet recall was 1643±1044 mg/day. The key sources of sodium intake included discretionary salt added during cooking, fried rice/noodles, rice vermicelli/noodles in soup and Dim Sum. The estimated sodium intake based on UNa24 was 1203 mg/day more than

SD: standard deviation.
that from the 24-h diet recall (p-value < 0.001). Moreover, the Pearson’s correlation coefficient between estimated sodium intake based on the 24-h diet recall and UNa24 was insignificantly different from zero (r = 0.086, p-value = 0.516).

**Discussion**

Our findings showed a systematic bias towards underestimation of sodium intake among older Chinese adults in Hong Kong, which was consistent with those from previous studies. Incomplete measurements of UNa24 are not uncommon due to subject compliance and logistic issues. Other outcome measures to be considered for the older population include estimating UNa24 from a single void or using spot urine. The low accuracy of the 24-h diet recall in sodium intake estimation could be due to reporting bias, social desirability and social approval bias. Moreover, actual sodium amounts contained in the same food category can vary substantially. Our findings were consistent with previous studies about the underestimation of sodium intake as measured by urinary excretion and the weak correlation between the estimated dietary sodium intake and the UNa24. Estimation accuracy could be improved by recording the food diary across multiple days, at the expense of a lower-income respondent’s cooperation and poorer data quality. The low education level of the older population should be taken into consideration in the data collection process.

Despite the underestimation of sodium intake by various measures, such estimates were still far above the recommended level of daily intake. Yet, most of the participants still perceived their intake as too little or just right. Older people with hypertension were willing to switch to a low sodium diet given that they learned about the potential health benefits. The first step in getting older individuals to follow low sodium diets is to encourage individuals to realise their high sodium

### Table 2. Self-perceived salt intake level and sodium intake level based on 24-h urinary sodium excretion (n = 59).

| Self-perceived salt intake level | Regular sodium intake\(^a\) (%) | High sodium intake\(^b\) (%) | Total (%) |
|---------------------------------|---------------------------------|-----------------------------|-----------|
| Too little/just right           | 13 (86.7)                       | 36 (87.8)                   | 49 (87.5) |
| Too much                        | 2 (13.3)                        | 5 (12.2)                    | 7 (12.5)  |
| Total\(^c\)                     | 15 (100)                        | 41 (100)                    | 56 (100)  |

\(^a\)24-h urinary sodium excretion \(\leq 2000\) mg per day.

\(^b\)24-h urinary sodium excretion \(>2000\) mg per day.

\(^c\)Three participants who reported ‘don’t know/not sure’ in the high sodium intake group were excluded; Kappa statistic = -0.003 (p-value = 0.909).
intake. Therefore, it is important to develop simpler methods for collecting information on biomarkers to provide objective and reliable measures of sodium intake.

The strength of this study was the use of the gold standard UNa24 to estimate daily sodium intake. Furthermore, the low education level of the majority of the study population increases the applicability of this study into populations in low- and middle-income countries where large portions of the population have low education levels. There were some limitations in our study. First, our study employed a small sample size, which may lower its statistical power. Second, a large proportion of data were lost due to attrition or incomplete collection of the 24-h urine samples. The results could be biased in that only more knowledgeable participants were included in the analysis. However, if the more knowledgeable participants showed poor agreement between self-perceived sodium intake and objective measurement, those less knowledgeable might have demonstrated even larger discrepancies.

**Conclusion**

To promote a healthy intake of sodium, an awareness of excessive sodium intake should be raised among the older population. However, objective measures like UNa24 are not user-friendly to older people. Simpler methods of collecting objective and reliable biomarkers of sodium intake are critical for the reduction of sodium intake in the older population.

**Acknowledgements**

The authors wish to thank our participants for their support and colleagues at the elderly community centres for their assistance during data collection. We would also like to thank the Food and Environmental Hygiene Department of Hong Kong for granting permission to use their photo booklet of the Food Consumption Survey to assist in the dietary recall.
