(Dated: January 20, 2003)

We evaluate the ensemble averaged noise in a chaotic quantum dot subject to DC bias and a periodic perturbation of frequency $\Omega$. The noise displays cusps at bias $V_n = n\hbar\Omega/e$ that survive the average, even when the period of the perturbation is far shorter than the dwell time in the dot. These features are sensitive to the phase of the time-dependent scattering amplitudes of electrons to pass through the system, and thus provide a novel signature of phase-coherent transport that persists into the non-adiabatic limit.

Shot noise in a phase coherent conductor is a fundamentally quantum phenomenon. A charge carrier traversing the conductor may leave to each connecting terminal with some probability. Thus noise, like conductance, is in principle sensitive to the quantum dynamics of the charge carriers in mesoscopic systems. As is often the case, however, the shot noise under DC bias may be well described by semiclassical reasoning, with only small quantum corrections for large conductors. In this context it of interest to identify situations where the noise has intrinsically quantum mechanical features that are nevertheless significant in a large, but phase coherent conductor. Such a situation is the subject of this Letter.

In 1993 Lesovik and Levitov [2] (LL) - building on the work of Ivanov and Levitov [3] - demonstrated that the zero temperature noise has intrinsically quantum mechanical features that are nevertheless significant in a large, but phase coherent conductor. Specifically, they showed that the zero temperature noise in a chaotic quantum dot under DC bias and a periodic perturbation of frequency $\Omega$ is proportional to a quantity containing a constant slope $S_0 = 4e^3/h$ for the case of a single scattering channel, $n$ multiples of the field frequency $\Omega$, proportional to a quantity containing the phase of the time-dependent scattering amplitude of the electrons. This is the 'universal' limit $\bar{h}\Omega \ll 100$, so this regime is accessible. In this Letter we show that the same phenomenon may be observed when the dwell time $\tau_{esc}$ in the scattering region is not small. This question arises naturally when the scatterer is a chaotic quantum dot. Here, one may be in the regime $\Omega > \tau_{esc}^{-1}$ while remaining in the ‘universal’ limit $\bar{h}\Omega \ll E_T$, where $E_T$ is the Thouless energy, something that is not possible in a diffusive wire where $\bar{h}/\tau_{esc} \sim E_T$. For micron-sized GaAs quantum dots, with $\bar{h}/\tau_{esc}$ in the $\mu eV$ range, a frequency of $10$ GHz, as was applied in the experiment of Ref. 8, gives $\Omega\tau_{esc} \sim 100$, so this regime is accessible.

Shot noise in a phase coherent conductor is a fundamentally quantum phenomenon. A charge carrier traversing the conductor may leave to each connecting terminal with some probability. Thus noise, like conductance, is in principle sensitive to the quantum dynamics of the charge carriers in mesoscopic systems. As is often the case, however, the shot noise under DC bias may be well described by semiclassical reasoning, with only small quantum corrections for large conductors [1]. In this context it is of interest to identify situations where the noise has intrinsically quantum mechanical features that are nevertheless significant in a large, but phase coherent conductor. Such a situation is the subject of this Letter.

In 1993 Lesovik and Levitov [2] (LL) - building on the work of Ivanov and Levitov [3] - demonstrated that the zero temperature noise has intrinsically quantum mechanical features that are nevertheless significant in a large, but phase coherent conductor. Specifically, they showed that the zero temperature noise in a chaotic quantum dot under DC bias and a periodic perturbation of frequency $\Omega$ is proportional to a quantity containing a constant slope $S_0 = 4e^3/h$ for the case of a single scattering channel, $n$ multiples of the field frequency $\Omega$, proportional to a quantity containing the phase of the time-dependent scattering amplitude of the electrons. This is the 'universal' limit $\bar{h}\Omega \ll 100$, so this regime is accessible. In this Letter we show that the same phenomenon may be observed when the dwell time $\tau_{esc}$ in the scattering region is not small. This question arises naturally when the scatterer is a chaotic quantum dot. Here, one may be in the regime $\Omega > \tau_{esc}^{-1}$ while remaining in the ‘universal’ limit $\bar{h}\Omega \ll E_T$, where $E_T$ is the Thouless energy, something that is not possible in a diffusive wire where $\bar{h}/\tau_{esc} \sim E_T$. For micron-sized GaAs quantum dots, with $\bar{h}/\tau_{esc}$ in the $\mu eV$ range, a frequency of $10$ GHz, as was applied in the experiment of Ref. 8, gives $\Omega\tau_{esc} \sim 100$, so this regime is accessible.

It is not known whether single-particle excitations will be coherent at the high bias required to observe the effect we shall discuss. It should be stressed, however, that the inelastic transitions in the AC field that are responsible are completely coherent. That is, electrons are coherently excited or de-excited by the applied field. It is remarkable that this phase-coherent phenomenon survives into the non-adiabatic regime, where weak localization and universal conductance fluctuations do not.

At low temperatures the principal source of smearing of the cusps will be relaxation through electron-electron scattering. We will neglect this for the remainder of this paper, though this consideration will certainly be relevant for experiment.

Experimental investigation of time-dependent transport in chaotic dots has so far been concerned with the construction of charge pumps. Noise was measured in a chaotic cavity under DC bias in Ref. 8. The measurement of the noise in the presence of periodic perturbation provides a novel probe of phase coherent transport.

Fig. 1 illustrates our principal finding. For a two terminal device with $N = N_1 + N_2$ open channels in the presence of an AC field with $\Omega > \tau_{esc}^{-1}$, the constant slope
in the dependence of the noise on bias \( S = e I N_1 N_2 / N^2 \) - responsible the famous Fano factor of 1/4 for \( N_1 = N_2 \) - is split to form steps. The familiar result is recovered at large bias. In addition to the Nyquist noise, we find the contribution, depending on ‘strength’ parameter \( \mu \)

\[
S^P = \frac{\langle G \rangle \hbar \Omega}{N^2} \left\{ 2 N_1 N_2 F(|e V/h \Omega|, y, k_B T/h \Omega) x + \left( N_1^2 + N_2^2 \right) F(0, y, k_B T/h \Omega) - N_1^2 k_B T/h \Omega \right\}
\]

\( \mathcal{F}(x, y, 0) \) is a continuous piecewise linear function of \( x \) with slope \( \partial \mathcal{F} / \partial x = \text{sgn}(n) \left[ \frac{1}{2} - y |n+1| \right] \left( \frac{2 + y + y^2 + (1 - y^2) |n|}{(1 + y)^3} \right) \left| n \right| \leq |x| < |n + 1| \).

In Eq. (2) \( \langle G \rangle = (2e^2/h) N_1 N_2 / N \) is the average conductance. The parameter \( y \equiv e^{-2 \sinh^{-1} \sqrt{1/3} C} \) measures the strength of the perturbation. \( C = \tau_{\text{esc}} / \tau_{\text{tr}} \) is the ratio of the average transition rate induced by the perturbation \( \dot{V} \) in the Golden Rule approximation \((\tau_{\text{tr}}^{-1} = 2 \pi |V_{\alpha \beta}|^2 / \hbar \Delta) \) to the escape rate from the dot \((\tau_{\text{esc}}^{-1} = N \Delta / 2 \pi \hbar) \), where \( \Delta \) is the level spacing. Such a perturbation may be applied by periodic deformation of the quantum dot, as illustrated in the inset to Fig. 1. The result is derived in the limit \( N \gg 1 \). Note that unlike phase coherent signatures such as weak localization and conductance fluctuations, this effect is of order unity, not small in the number of channels.

It is possible to understand the size of the steps in \( \partial S / \partial V \) by combining the results of LL with the recent description of pumping in dots in Ref. [11]. The generalization of the result [11] is (see Eq. (6) below)

\[
\lambda_n = \sum_{m, m'} \text{tr} \left\{ A S^{(m)}_{\mu_1} P_{\mu_2} S^{(m')}_{\mu_1} \right\} \Rightarrow 0 \text{ for } n \neq m^* \text{ to vanish, as the S-matrix is only correlated on energy scales of the order of } \hbar / \tau_{\text{esc}} \text{ or less. Only the (ensemble averaged) probabilities } P^{(m)} = N (|S^{(m)}_{ij}(E)|^2) \text{ of an electron to gain or lose } m \text{ quanta while passing through the dot survive.}
\]

We will see that this arises from \( \mathcal{F}(x, y, 0) \) of the form

\[
\mathcal{F}(x, y, 0) = \frac{1}{4} \sum_{m, n} |n - x| + |n + x| \cdot P^{(m)} P^{(n-m)}.
\]

These formulae have the following meaning. Noise arises from the creation of zero energy particle-hole pairs in the outgoing channels. The quantities \( \sum_m P^{(m)} P^{(n-m)} \) are the probabilities for a pair of energy \( n \hbar \Omega \) in the incoming channels to be scattered to a zero energy pair. Their weight in the sum [11] measures the number of \( n \hbar \Omega \) pairs. The disappearance of the noise contribution from \( n \hbar \Omega \) pairs as \( V \) increases through \( \hbar \Omega / e \) is the origin of the cusps. The statistical independence of these contributions indicates that exchange effects have been lost in the average, as this is the only source of correlation in the noninteracting system.

In the limit of strong pumping \( C \gg 1 \), where an electron makes many transitions, its energy diffuses so that \( \Delta E_t = (\hbar \Omega)^2 / \tau_{\text{tr}} \). Assuming a Gaussian distribution of \( \Delta E_t \) and combining with the exponential distribution of dwell times in a quantum dot leads to the estimate of the probability

\[
P^{(m)} \sim \int_0^\infty dt \frac{1}{\tau_{\text{esc}}} \sqrt{\frac{\tau_{\text{tr}}}{2 \pi t}} \exp \left( -\frac{t}{\tau_{\text{esc}}} - \frac{m^2 \tau_{\text{tr}}}{2 t} \right) \sim \sqrt{\frac{\tau_{\text{tr}}}{2 \tau_{\text{esc}}} \exp \left( -\sqrt{\frac{\tau_{\text{tr}}}{\tau_{\text{esc}}} |m|} \right)}.
\]
By substituting into Eq. (5), one can recover the given properties of $F(x, y, 0)$ in the limit $C \gg 1$.

Thus despite the completely randomized behavior of the $S$-matrix on the scale of $\hbar \Omega$, the cusps in the noise persist provided that the Fermi distribution of the incoming electrons is sufficiently sharp. What cannot be achieved in this limit is the tuning of the step size to zero through complete destructive interference of the multi-particle amplitudes, the direct analogue of the Aharonov Bohm effect discussed by LL. Now we turn to the details of the calculation. General formulae for the shot noise in terms of $\mathcal{S}(t, t')$ have recently been given by Polianski et al. They separate the noise into $S = S^N + S^P$, with $S^N$ the Nyquist noise, and $S^P$ the non-equilibrium contribution.

The matrices $\mathcal{N}(t)$ and $\tilde{\mathcal{N}}(t)$ are given by

$$\mathcal{N}(t) = I - \tilde{\mathcal{N}}(t) = \mathcal{P}_1 n_1(t) + \mathcal{P}_2 n_2(t),$$

where $n_{1,2}(t)$ are the Fourier transforms of the distribution functions in the leads $n_{1,2}(\epsilon) = (e^{\epsilon - \mu_{1,2}/k_B T} + 1)^{-1}$. The factor of two in Eq. (6) assumes spin degeneracy.

$S^N$ is related to the time-averaged conductance through the fluctuation-dissipation theorem $S^N = 2kT \tilde{G}$. The time-averaged conductance has been analyzed extensively in Refs. [6, 13]. Polianski et al. analyzed Eq. (6) in the context of quantum pumps.

The formula (8) for the steps may be obtained by passing to the representation (4). To apply Eq. (6) to chaotic quantum dots, we need to average over realizations. We will need the two-point correlation function of $S$-matrices, valid in the limit $N \gg 1$, in the presence of a time-dependent perturbation $x(t)\dot{V}$ (we set $k_B = \hbar = 1$). The matrices $\langle S_{ij}(\tau, \sigma)\tilde{S}_{ij}^\dagger(\tau', \sigma') \rangle = \delta(\tau - \sigma - \tau' + \sigma')\theta(\tau - \sigma)
\times D(\tau, \sigma; \tau', \sigma')$(7)

Though Eq. (9) contains a product of four $S$-matrices, only the two point function is required. The non-gaussian connected correlator of four $S$-matrices (arising from diagrams containing a Hikami box) does not contribute. This is because it has the structure $\langle S_{ij}S_{kl}S_{mn}S_{op} \rangle_{\text{Hik}} \propto \delta_{ij}\delta_{km}\delta_{np}\delta_{os}$, so that its use in Eq. (4) gives factors of $\text{tr}[\Lambda] = 0$. Similarly the $\langle S\Lambda S^\dagger \rangle$ pairings are absent. The choice of current operator $I = (N_2 I_1 - N_1 I_2)/N$ is responsible for the traceless $\Lambda$ vertex. Using (7) to average (8) yields

$$S^P = -2e^2 N_1 N_2 \tau_0 \int_0^{\tau_0} dt dt' \left( \frac{T}{2 \sinh(\pi T(t - t' + i0))} \right)^2 \times \left( [N_1^2 + N_2^2 + 2N_1 N_2 \cos(eV(t - t'))] \left( \int_0^\infty D(t, t - \xi; t', t' - \xi) d\xi \right)^2 - 1 \right).$$

We evaluate Eq. (8) for a perturbation $x = \sin \Omega t$ in the high frequency regime $\Omega \gg \tau_{\text{esc}}^{-1}$. In this limit the Diffusion may be written

$$D(\tau, \sigma; \tau', \sigma') = \frac{\Delta}{2\pi} e^{-\tau_{\text{esc}}^{-1}(1 + C \sin^2 \left( \frac{\pi (\tau - \sigma')}{2} \right)) |\tau - \sigma|},$$

Substituting this into (3), and performing the integrals in the $\tau_0 \to \infty$ limit - it is convenient to Fourier transform.
gives the result \(2\) where the function \(F(x, y, z)\) is

\[
F(x, y, z) = \sum_n N(x, z, n)y^{\left| n \right|} \left( \frac{1 - y}{1 + y} \right)^2 \left( 1 + \frac{y^2}{1 - y^2} + |n| \right)
\]

\[
N(x, z, n) = \frac{1}{4} \left[ (n - x) \left( \coth \left( \frac{(n - x)}{2z} \right) + 1 \right) + (n + x) \left( \coth \left( \frac{(n + x)}{2z} \right) + 1 \right) \right]
\]

The zero temperature result involves the function \(F(x, y, 0)\) described earlier. It has the form \(3\) with the probabilities given by \(P^{(m)} = y^{\left| m \right|} \sqrt{1 + 2C}\), which coincides with our earlier estimate at \(C \gg 1\).

We may instead evaluate Eq. (8) in the time domain. In this case, the cusps in the noise arise from poles in the integrand over \(t - t'\) at \((\pm 2i \sin^{-1} \sqrt{1/2C + 2\pi p})/\Omega\) for integer \(p\). This is the origin of the phase dependence of the noise: \(t\) and \(t'\) are the initial times in the two electron trajectories that comprise the Diffuson, see Eq. (7). A characteristic imaginary time is typical of the quasiclassical treatment of an AC driven quantum system \(4\). By contrast the zero temperature shot noise is determined by a pole at \(t - t' = 0\), corresponding to trajectories which start at the same instant, so that the phase of the time dependent amplitude is irrelevant.

Naturally the cusps also exist in the adiabatic limit considered by LL: \(\Omega \ll \tau_{esc}^{-1}\). In this case it is convenient to express the \(\lambda_n\) in the form

\[
\sum_n \lambda_n \exp(-i n \Omega \tau) = \frac{(N_1 N_2)^2}{N^3} \frac{1 + 2C \sin^2 (\Omega \tau/2)}{(1 + 4C \sin^2 (\Omega \tau/2))^{3/2}},
\]

and one can verify the sum rule \(\sum_n \lambda_n = (N_1 N_2)^2/N^3\) required to recover the DC result at high bias.

Thanks to Piet Brouwer for discussions. This research is supported in part by the David and Lucille Packard foundation.
