IFN-α-driven CCL2 production recruits inflammatory monocytes to infection site in mice

CD Conrady¹, M Zheng², NA Mandal², N van Rooijen³ and DJJ Carr¹,²

Herpes simplex virus type 1 (HSV-1) is the leading cause of corneal blindness in the developed world due to reactivation of infectious virus and the subsequent immune response. The innate response that facilitates viral control in the cornea is currently unknown. In the present study using a mouse chimera model, we found that a bone marrow component is crucial in inhibiting viral replication and identified inflammatory monocytes (F4/80⁺ Gr1⁺) as the responsible cell. CCL2 was critical for recruiting inflammatory monocytes, and a loss of this chemokine in CCL2−/− mice resulted in a loss of viral containment and inflammatory monocyte recruitment. To confirm these results, clodronate depletion of inflammatory monocytes resulted in elevated viral titers. Furthermore, siRNA targeting the innate sensor p204/IFI-16 resulted in a loss of CCL2 production. In conclusion, CCL2 expression driven by IFI-16 recognition of HSV-1 facilitates the recruitment of inflammatory monocytes into the cornea to control viral replication.

INTRODUCTION

Herpes simplex virus type 1 (HSV-1) is a double-stranded DNA virus of which 60–90% of the adult population is seropositive.¹ The pathogen is of significant clinical interest due to its role in inducing morbidity in the central nervous system and cornea.¹ HSV-1 is spread through mucocutaneous contact in which the virus will first establish a lytic infection in epithelial tissue and progress to invading local sensory fibers. Once the virus has gained access to sensory neurons, it is then transported in a retrograde fashion to the cell body housed in local neural ganglia. In the case of the initial oropharyngeal infection, HSV-1 will be transported to the trigeminal ganglia where it can persist as a latent infection indefinitely.²

Following reactivation of HSV-1, infectious virions travel in an anterograde fashion towards sites innervated by divisions of the trigeminal nerve such as the cornea. Recurrent reactivation can then initiate an inflammatory event that if perpetuated can lead to significant corneal scarring known as herpetic keratitis.³ In individuals who have had viral reactivation in the cornea, the chance of subsequent reactivations drastically increases, whereas cornea graft survival drops.⁴ Thus, identifying mechanisms to inhibit viral replication and establishment of HSV latency could drastically reduce the incidence of herpetic keratitis.

Unfortunately, highly effective anti-viral compounds such as acyclovir and penciclovir block productive infection but do not reduce the establishment of latency.⁵ In sites such as the skin, delayed responses of CD8⁺ T cells reduce the number of infected neurons as well as the amount of latent viral copies but do not thwart viral latency.⁶ These studies would suggest that neither a robust adaptive immune response nor antiviral drugs are effective in reducing initial infection of innervating ganglia to the point of blocking the establishment of latency. Our lab as well as others have shown that type I interferon (IFN) production is critical in preventing viral dissemination and subsequent death of the host.⁷,⁸ Thus, identification of other important innate mechanisms in acute control of viral replication could be tailored to help inhibit HSV replication during the primary infection and prevent establishment of latency in the trigeminal ganglia.

IFI-16/p204 has recently been identified as the innate sensor facilitating the acute anti-viral state of the cornea and other epithelial tissues to HSV by induction of IFN-α production.⁹ A loss of this critical protein or its downstream adaptor protein, STING, results in a significant rise in the viral titer.⁹ However, the role of infiltrating innate immune cells (e.g., natural killer (NK) cells, macrophages, and neutrophils) has not been evaluated relative to this sensor during acute infection. Infiltrating leukocytes, including granulocytes, monocytes/macrophages, and NK cells, are thought to contribute in the resistance to HSV-1 infection by direct or indirect means.¹⁰–¹² Specifically, NK
cells can directly target HSV-1-infected cells and target them for cytolysis. In a more indirect fashion, compounds released from immune cells such as nitric oxide (NO) have shown potent antiviral properties in cell culture. In the peripheral nervous system, macrophages secreting TNF-α (tumor necrosis factor α), NO, and IFN-γ control viral replication during the primary infection.

Thus, we hypothesized that IFI-16/p204 recognition of HSV-1 was required to initiate signals to recruit bone marrow (BM)-derived macrophages to the site of infection and contain acute viral replication. Consistent with this hypothesis, we found that IFI-16-driven, IFN-α production initiated inflammatory monocyte recruitment to the site of infection in a CCL2-dependent manner. This response was a critical component of innate immunity in viral surveillance of the cornea.

**RESULTS**

**Resident cells and BM leukocytes contribute to HSV-1 surveillance in the cornea**

A functional type I IFN pathway is absolutely required for resistance to HSV-1 replication in the cornea as previously shown in IFN receptor A1–deficient mice, CD11b−/−, in which these mice no longer respond to IFN signals and rapidly succumb to viral dissemination. To dissect the contribution of resident (corneal stromal and epithelial cells) and BM-derived cells in the innate immune response to HSV-1 in the cornea, a chimera model was chosen to evaluate resistance using wild-type (WT) and highly sensitive CD118−/− mice. The 48 h post-infection (pi) time point was chosen as this period appears to be the critical period in which HSV-1 exploits the cornea in the absence of a functional type I IFN pathway. Cornea samples from WTBM > WT and CD118−/− BM > WT mice contained significantly less virus than WTBM > CD118−/− and CD118−/− BM > CD118−/− mice, highlighting the importance of IFN-responsive corneal resident cells in HSV-1 containment (Figure 1). However, WTBM > WT mouse corneas possessed significantly less virus than CD118−/− BM > WT mouse corneas, implicating a role for BM-derived leukocytes in viral surveillance of the cornea in concert with IFN-responsive resident cells (Figure 1).

**Resident cell production of CCL2 drives inflammatory monocyte recruitment into the cornea**

To identify the innate leukocyte population(s) and thus, the BM-derived component of viral surveillance in the cornea of mice that was implicated above, flow cytometric analysis of select infiltrating leukocytes was performed. Previously published work reported that viral containment in Toll-like receptor (TLR) adaptor protein–deficient mice mirrored that of WT controls in the cornea. Thus, it was hypothesized that the leukocyte population required for HSV containment would be similar in MyD88−/−, Trif−/−, and WT mice; however, recruitment of this specific cell type would be severely reduced in CD11b−/− corneas owing to their enhanced susceptibility to infection. Forty-eight hours pi, CD11b−/− mice exhibited a gross deficiency in NK cells (CD3− NK1.1+; Figure 2c,g) and inflammatory monocytes (F4/80+ Gr1+ /CD11b+ Ly6C+ Ly6G−; Figure 2d–f) residing in the cornea proper compared with all the other groups. By contrast, CD11b−/− mice possessed similar numbers of total leukocytes (CD45+; Figure 2a), macrophages (F4/80+ Gr1−; data not shown), and neutrophils (F4/80− Gr1−; Figure 2b) in the cornea compared with WT, MyD88−/−, and Trif−/− mice. Taken together, these results suggested a potential role for inflammatory monocytes and/or NK cells in viral containment in the cornea 48 h pi, while further suggesting that the influx of neutrophils was not responsible for HSV surveillance.

In order to identify the predominant signal for inflammatory monocyte and NK cell recruitment into the infected cornea, chemokine levels of CXCL1, CCL2, and CCL5, known chemotaxants for early-responding leukocyte populations, were evaluated in TLR adaptor–deficient mice. In the absence of infection, CXCL1, CCL2, and CCL5 were below the level of detection in the cornea (data not shown). Forty-eight hours pi, there were no appreciable differences in CXCL1 production among all the groups (Figure 3a). Conversely, CCL5 expression levels were diminished, while CCL2 production was severely abated in CD11b−/− mouse corneas compared with WT, MyD88−/−, and Trif−/− mice (Figure 3a). Furthermore, to negate TLR redundancy, DKO mouse chemokine production resembled that of Trif−/− and MyD88−/− mice (Figure 3a). Even though CCL2 production was significantly elevated in TLR adaptor–deficient mice compared with CD11b−/− mice, HSV-1-infected MyD88−/−, DKO, and Trif−/− mice displayed lower levels of CCL2 compared with those of WT mice (Figure 3a). We interpret these results to suggest that TLR activation contributes to CCL2 production but additional pathways have the predominant role in response to HSV-1. By 72h pi, high CCL2 levels began to subside in WT mice and by 120h pi, CD11b−/− mice produced significantly more CCL2 in the cornea than WT controls (Figure 3b).
To localize the source of CCL2 production in the cornea, the previously described mouse model chimera was utilized. At 48 h pi, CCL2 levels were significantly elevated in WTBM > WT and CD118<sup>-/-</sup> BM > WT mice compared with WTBM > CD118<sup>-/-</sup> and CD118<sup>-/-</sup> BM > CD118<sup>-/-</sup> mice establishing resident, IFN-responsive corneal cells as the primary source of CCL2 (Figure 3c). There was no significant difference between CD118<sup>-/-</sup> mice suffering from a significant rise in infectious virus in the cornea compared with WT animals at 48 h pi but viral levels returned to those of WT controls 120 h pi, whereas more virus was recovered in the trigeminal ganglia 5 days pi (Figure 4a,b). Changes in replicating virus levels occurred despite similar numbers of NK cells (Figure 4a,b), neutrophils (Figure 4e), and total leukocytes in the cornea proper (data not shown). CCL2 levels were readily detectable in the cornea of WT mice compared with

![Figure 2](image-url)
Inflammatory monocytes secrete NO to inhibit HSV-1 replication

Inflammatory monocytes have been shown to restrict HSV-1 replication in vitro likely due to the secretion of antiviral compounds driven by IFN and nuclear factor (NF)-κB signaling such as NO. In order to test this hypothesis and to identify one likely key antiviral compound secreted by infiltrating activated monocytes, we had to first establish the presence or absence of inducible NO synthase (iNOS). Within 48 h pi, iNOS transcript levels in the cornea of both infected CD118−/− and CCL2−/− mice were indistinguishable from uninfected controls (Figure 5c). In stark contrast, iNOS expression was elevated twofold in the cornea of WT animals. Furthermore, gel electrophoresis of RT-PCR (PCR with reverse transcriptase) products confirmed a reduction or absence of iNOS in uninfected CD118−/− and WT mouse corneas (Figure 5c,d). To determine the significance of NO production in viral containment, HSV-1 levels were determined following iNOS inhibition with aminoguanidine. Viral titers were significantly elevated in aminoguanidine-treated mice compared with vehicle-treated WT controls 48 h pi (Figure 5e). Taken together, these results suggested a reduction of inflammatory monocyte migration into the corneas of CD118−/− and CCL2−/− mice results in the loss of the primary source of NO production and consequential rise in virus output.

CCL2 production driven by IFN-γ

We previously identified the innate sensor, p204/IFI-16, as the crucial regulator of IFN-γ in response to HSV infection of the cornea and thus, hypothesized that signals such as CCL2 were induced by the sensor to recruit the BM arm of innate immunity. To first identify a potential role of IFI-16/p204 in CCL2 production, CCL2 transcript expression was evaluated 24 h pi in human corneal epithelial cells transfected with nonspecific siRNA or that directed to IFI-16. A loss of IFI-16 (~70% reduction) resulted in a significant reduction in CCL2 mRNA transcript solidifying a role of the innate sensor in CCL2 production (Figure 7a). This was confirmed in vivo with mice deficient in the adaptor protein for IFI-16, STING, in which CCL2 levels mirrored those of CD118−/− mice and were severely diminished compared with those of WT controls (Figure 7b). We interpret these results suggested that signals emanating from IFI-16/p204 were responsible for regulating CCL2 production.

IFI-16 has been shown to activate both NF-κB and IRF-3 (interferon regulatory factor 3) IFN cascades, and CCL2 is a known NF-κB-driven chemokine through a phospholipase C-dependent mechanism. Both an IFN-stimulated regulatory element and NF-κB binding site are found upstream of the start site at position −580 to −566 and −490 to −480, respectively (Figure 7c). To evaluate the role of NF-κB on CCL2 production, western blot analysis was performed on nuclear extracts on TLR adaptor protein–deficient mice to explain the differences seen in CCL2 production (Figure 3a). However, there were no appreciable differences between any of the groups tested, suggesting that NF-κB activity was not responsible for CCL2 production 48 h pi (Figure 7d). To then evaluate the role of IFN, human corneal epithelial cells were treated with recombinant...
IFN-α and CCL2 mRNA was evaluated. CCL2 transcript levels rose 10-fold 6 h post treatment but returned to near baseline 6 h later, suggesting that IFN alone could drive CCL2 production (Figure 7c). To further solidify this point, WT mice topically treated with rIFN-α had significantly higher levels of CCL2 24 h post treatment than PBS-treated controls and CD118−/− mice treated with PBS or IFN (Figure 7f).

**DISCUSSION**

We have previously shown IFI-16 was responsible for the recognition of HSV in epithelial tissue and once activated, the sensor drove IRF-3-dependent IFN production critical in containing viral replication.9 However, we did not explore the contribution of infiltrating leukocytes.9 In the study described herein, we have identified inflammatory monocytes (F4/80+Gr1+) as the BM component of innate immunity within the cornea proper that contributes to HSV-1 surveillance. To substantiate the BM arm of innate immunity, a loss of any part of the CCL2-inflammatory monocyte response results in a significant reduction in the host’s ability to contain viral replication.

The chemokine CCL2 is widely studied because of its up-regulation in autoimmune diseases, tumors, and infections.17,28,29 CCL2 attributes can be favorable or unfavorable to the host. From a negative aspect, the chemokine facilitates tumor metastasis and HIV entry into the CNS.30,31 However, CCL2 is also needed in muscle repair32 and as we have found, is required
in the cornea to recruit inflammatory monocytes to contain HSV-1 replication. Additionally, CCL2 production has been shown to be regulated by both TNF-α and STAT-2 signals. However, we show that the CCL2 upstream promoter contains an IFN-responsive element, and cells treated with recombinant IFN alone up-regulate CCL2 mRNA. Such results imply multiple host signals elicit CCL2 expression dependent upon the initiating stimulus. We hypothesize that the timing of CCL2 production is facilitated by different signals and is likely tissue specific. This notion is best observed in CD118−/− mice that lack downstream IFN signals. Forty-eight hours pi, CD118−/− mice produced very low levels of CCL2 in the cornea; however, by 5 days pi, CCL2 concentrations were significantly higher in CD118−/− mice than WT controls. Furthermore, we have previously shown in peripheral nervous system tissue such as the trigeminal ganglia that there were no identified differences in CCL2 production comparing HSV-1 infected WT with CD118−/− mice. This was in stark contrast to the brain stem where the only difference in levels of the chemokine was detected 5 days pi when CD118−/− mouse brain stem possessed significantly more CCL2. Thus, the regulation of CCL2 is complex and warrants further inspection. Furthermore, while we

Figure 5 Clodronate depletion of inflammatory monocytes significantly reduces immune control of herpes simplex virus (HSV) infection due to loss of the antiviral agent nitric oxide. Wild-type (WT) mice were infected with HSV-1 and then treated with a subconjunctival injection of clodronate or phosphate-buffered saline (PBS) containing liposomes. Twenty-four hours later, the liposome treatment was repeated. Forty-eight hours post infection (pi), WT mice were euthanized and corneal viral content was quantified by (a) plaque assay or immune cell infiltration was assessed by (b) flow cytometry. Graphs are represented as the mean ± s.e.m. (n = 6–8 corneas/group). **P < 0.01; *P < 0.05. (c, d) RT-PCR (PCR with reverse transcriptase) products were analyzed by gel electrophoresis and data and image are representative of two independent experiments. (c) Normalized (to β-actin) intensity of each sample can be seen above gel and (d) mean normalized intensity ± s.e.m. of the entire experiment is expressed in (d). (e) Forty-eight hours pi (1,000 PFU (plaque-forming units) HSV-1/eye), mRNA was isolated from whole corneas of WT, CD118−/−, and CCL2−/− mice (n = 3–10) and RT-PCR was performed to determine the presence of inducible nitric oxide synthase (iNOS). The results were normalized to uninfected (UI) controls and the housekeeping gene β-actin. (d) WT mice were topically treated with aminoguanidine (0.05 mg) or vehicle three times daily starting 48 h before infection with HSV-1 (1,000 PFU/eye). Viral titers in the cornea were evaluated 48 h pi and compared with vehicle-treated WT mice (n = 6–8 corneas/group). Data is presented as the mean ± s.e.m. **P < 0.01.
Loss of neutrophils does not enhance corneal susceptibility to herpes simplex virus (HSV) infection. Wild-type (WT) mice were infected with HSV-1 (1,000 PFU (plaque-forming units)/eye) and then given a subconjunctival injection of either immunoglobulin G (IgG) control or anti-Ly6G antibody. Forty-eight hours post infection (pi), viral content was evaluated by plaque assay and presented as the Log PFU/cornea ± s.e.m. (n=7/group, two experiments). To confirm depletion, flow cytometry was used to evaluate total neutrophils residing within the cornea and is representative of two independent experiments. Values are presented as the total neutrophils ± s.e.m.

Although the role of inflammatory monocytes in controlling parasitic and bacterial infections is well described, the contribution of these cells in HSV infection was ambiguous. Most studies would suggest neutrophils and NK cells are the predominant immune cell required to contain HSV replication during the innate immune response. However, we show in mice that recruit inflammatory monocytes with far less efficiency (CD11b-/- and CCL2-/- mice) than WT animals, such mice suffer from significantly more virus in the cornea that correlates with a reduction in NO levels. Although NO is likely only one of several viral replication inhibitors secreted by infiltrating monocytes (e.g., TNF-α), its ability to antagonize viral replication has been previously noted. To further substantiate the role of inflammatory monocytes in innate immunity of the cornea, localized clodronate depletion was performed and resulted in significantly higher HSV-1 titers. The one caveat to these results is that the treatment resulted in a loss of neutrophils (F4/80- Gr1+) as well. However, CD11b-/- and CCL2-/- mice have similar numbers of neutrophils despite significantly more infectious virus in the cornea than those of WT controls. Additionally, specific depletion of neutrophils in WT mice did not result in an increase in viral titers recovered from the cornea following HSV-1 infection. This would suggest and be supported by previous work with herpetic lesions in the skin showing that depletion of Ly6G+ cells (neutrophils) did not compromise the anti-viral response. However, this study did suggest the loss of Gr1+ cells (includes both neutrophils and inflammatory monocytes) resulted in a deficiency in viral containment. Thus, the role of neutrophils in HSV surveillance of the cornea is likely only minimal at best with a notable contribution to ocular pathology. Additionally, viral resistance mediated by NK cells during acute HSV infection of the cornea is likely minimal compared with that of inflammatory monocytes and a later response than that of monocytes. This is evident in CCL2-/- mice that are compromised in viral surveillance 48 hr pi but activity (CD94 expression) and total numbers of NK cells does not differ from those of WT controls. Studies implicating NK cells in ocular surveillance have used depletion techniques to confirm their role within the first 96 h; however, the antibody targeting NK cells (anti-ASGM-1) has also been reported to reduce inflammatory monocyte recruitment into the cornea proper. Furthermore, we identified that the major contribution of inflammatory monocytes occurs within the first 48 h after infection. Thus, it is unclear what role, if any, NK cells contribute to the earliest phases of the inflammatory monocyte-driven innate immunity within the cornea and how these responses are orchestrated.

We surmise inflammatory monocytes and IFI-16-driven IFN production act together to contain viral replication in the cornea and likely other epithelial tissues. These two arms of the innate immune response are required during acute HSV infection and as such would be potential targets for vaccine development. Current attempts of incorporating HSV glycoproteins in vaccine designs have failed, suggesting additional factors are likely required to provide protective immunity. Thus, attenuated strains of HSV that provide host epithelial cells with viral DNA to activate IFI-16-driven cascades would likely facilitate a more robust immune response strengthening the overall vaccine, while reducing the establishment of latency. Furthermore, the widely used adjuvant, alum, is known to elicit IFN-γ-dependent cascades owing to the release of host DNA from dying cells. We hypothesize that this could be due, at least in part, to IFI-16 activity as a result of the ability of the protein to respond to both host and viral DNA and thus, boost the overall immune response to the vaccine. Consequently, activating the IFI-16 pathway may be more fruitful in preventing early viral replication and establishment of latency owing to its significant role in initiating the innate immune response to HSV-1 and HSV-2 in epithelial tissue.

In conclusion, we propose that IFI-16 activates IFN production and NF-kB signaling through a STING-dependent manner in response to HSV-1 within resident cells of the cornea and likely other epithelial tissues. Up-regulated products of IFN signaling such as CCL2, PKR, and RNase L facilitate an antiviral state in the cornea. The CCL2 chemokine gradient recruits inflammatory monocytes to the infectious lesion, where the leukocytes secrete compounds such as NO to antagonize HSV-1 replication. IFN-responsive proteins such as PKR and RNase L initiate an antiviral state within infected and uninfected cells of the cornea to further inhibit viral spread. These two orchestrated processes act synergistically to contain HSV-1 replication in the cornea even in the absence of TLR signaling.

MATERIALS AND METHODS

Mice and virus. C57BL/6J WT Trif-/- (Ticam-/-; C57BL/6J background) and CCL2-/- mice were purchased from Jackson Laboratory and housed in the Dean McGee Eye Institute’s and Presbyterian Health Foundation’s animal facilities alongside MyD88-/-, CD11b-/-, and STING-/- mice. Animal treatment was consistent with the National Foundation’s animal facilities alongside MyD88-/-, CD11b-/-, and STING-/- mice. Animal treatment was consistent with the National...
ARTICLES

Institutes of Health Guidelines on the Care and Use of Laboratory Animals. All experimental procedures were approved by the University of Oklahoma Health Sciences Center and Dean A. McGee Eye Institutes’ Institutional Animal and Care Use Committees. HSV-1 McKrae was passaged as previously described. In vivo HSV-1 infection. Six- to ten-week-old male and female mice were anesthetized by an intraperitoneal (i.p.) injection of xylazine (6.6 mg kg⁻¹) and ketamine (100 mg kg⁻¹). Corneas were scarified with a 25 gauge 1 1/2" needle, and the tear film was blotted. HSV-1 McKrae was resuspended (1,000 PFU (plaque-forming units)/eye) in 3 μls of sterile 1×PBS and topically applied onto each cornea.

Plaque assays. The corneas of infected mice were harvested at designated times, resuspended in RPMI 1640 media supplemented with 10% fetal bovine serum, antibiotic/antimycotic, and gentamicin (normal media, Invitrogen, Grand Island, NY), and homogenized with a tissue mixer for approximately 20–30s as previously described. Supernatant was then clarified with a 10,000×g spin for 1.5 min and serially diluted onto a confluent lawn of HSV-1 susceptible green monkey kidney (Vero) cells. Plaques were allowed to develop for 24–36h and then counted with the aid of an inverted Zeiss microscope (Thornwood, NY).

BM chimeras. Six- to ten-week-old male and female mice were lethally irradiated with two 650-rad doses of γ irradiation separated by 4h.

Figure 7  IFI-16 drives CCL2 production by way of type I interferon (IFN). (a) Transfected human corneal epithelial (THCE) cells were transfected with control or siRNA specific to IFI-16 and infected with herpes simplex virus type 1 (HSV-1). Twenty-four hours post infection (pi), mRNA transcript expression was evaluated for CCL2 and normalized to uninfected (UI) controls and the housekeeping gene β-actin. Results are expressed as the mean±s.e.m. (b) STING−/−, CD118−/−, and wild-type (WT) mice (n=4–8) were infected with 1,000 PFU (plaque-forming units)/eye. Forty-eight hours pi chemokine content was evaluated by suspension array and is presented as the mean pg mg⁻¹±s.e.m. (c) Evaluation of the upstream promoter of CCL2 identified IFN (red) and nuclear factor (NF)-κB (green) responsive elements. (d) WT, MyD88−/−, Trif−/−, and CD118−/− mice were infected and NF-κB nuclear translocation was assessed 44 h pi by Western blot and compared with UI controls. Image is representative of two independent experiments. (e) THCE cells (n=9) were treated with rIFN-α and CCL2 mRNA transcript assessed at 6 or 12 h post treatment. Results were normalized to ddH₂O controls and the housekeeping gene β-actin. Values are expressed as the mean±s.e.m. of 2–3 independent experiments. (f) To confirm IFN was responsible for driving CCL2, WT, and CD118−/− mice were treated with phosphate-buffered saline (PBS) or 30,0000 U rIFN-α. Twenty-four hours later, chemokine levels were assessed and are presented as the mean±s.e.m. of three independent experiments of 2–3 corneas/group. *P<0.01; **P<0.05. ISRE, IFN-stimulated regulatory element; IU, units; Tx, treatment.
Cellular immunity and host defense. Human corneal epithelial cells (a gift from Dr Jerry Shay, UT-Southwestern) were grown in six-well plates to 50–70% confluence in keratinocyte media containing bovine pituitary extract and recombinant epithelial growth factor (Invitrogen). The cells were then transfected with 2 or 4 pmols of either nonspecific (5'-UUCUCCGAACGUCAUGUGT-3') or siRNA specific to IFI-16 (5'-GGUGCUAGAGCAACAGAACAGAUUUU-3') (Invitrogen, medium GC-rich content backbone) in serum-free keratinocyte media. Following a 4-h incubation, serum-free media was removed and replaced with normal media. Twenty-four hours post transfection, cells were infected at a multiplicity of infection of 0.01 of HSV-1 McKrae. Media was then replaced after 1 h at 37°C, and the cells and supernatant harvested 24 h pi.

Macrophage/neutrophil depletion. Mice were anesthetized and infected with 1,000 PFU/eye HSV-1. Thirty minutes after infection, mice were given a 10 μl subconjunctival injection of PBS liposomes; clodronate liposomes, IgG control antibody, or anti-Ly6G (eBioscience, San Diego, CA). For clodronate experiments, mice were given a second injection 24 h later. Forty-eight hours pi, viral content was evaluated by plaque assay. Macrophage/neutrophil depletion was determined by flow cytometry.

RT-PCR. Corneas were harvested at the indicated time pi, and mRNA transcript was isolated as previously described.5 iNOS primers were purchased from Origene (Rockville, MD) and the other primer sequences can be seen below.

**Table 1**

| Primer | Sequence |
|--------|----------|
| mβj-ActinF | 5'-CTTCTACACCTCAAGCTGGGCTGGTG-3' |
| mβj-ActinR | 5'-TTGAAAGGTCTCAAACTAGTCTGG-3' |
