Running title: EpCAM upregulates multipotency of MSCs

Keywords: epithelial cell adhesion molecule (EpCAM), mesenchymal stem cell, epidermal growth factor receptor (EGFR), Lin-28 homolog A (Lin28), high-mobility group AT-hook 2 (HMGA2), multipotency, cell differentiation, osteogenesis, posttranscriptional regulation, signaling cascade
Abstract

Mesenchymal stem cells (MSCs) are widely considered to be an attractive cell source for regenerative therapies, but maintaining multipotency and self-renewal in cultured MSCs is especially challenging. Hence, the development and mechanistic description of strategies that help promote multipotency in MSCs will be vital to future clinical use. Here, using an array of techniques and approaches, including cell biology, RT-qPCR, immunoblotting and -fluorescence, flow cytometry, and ChIP assays, we show that the extracellular domain of epithelial cell adhesion molecule (EPCAM) (EpEX) significantly increases the levels of pluripotency factors through a signaling cascade that includes epidermal growth factor receptor (EGFR), signal transducer and activator of transcription 3 (STAT3), and Lin-28 homolog A (LIN28) and enhances proliferation of human bone marrow MSCs. Moreover, we found that EpEX-induced LIN28 expression reduces expression of the microRNA LET7 and up-regulates that of the transcription factor high-mobility group AT-hook 2 (HMGA2), which activates the transcription of pluripotency factors. Surprisingly, we found that EpEX treatment also enhances osteogenesis of MSCs under differentiation conditions, as evidenced by increases in osteogenic markers, including runt-related transcription factor 2 (RUNX2). Taken together, our results indicate that EpEX stimulates EGFR signaling and thereby context-dependently controls MSC states and activities, promoting cell proliferation and multipotency under maintenance conditions and osteogenesis under differentiation conditions.
Introduction

MSCs are found in compact bone, tendon, adipose, placenta and umbilical cord (1), where they have the potential to differentiate into multiple lineages, including bone, fat, cartilage and muscle (1,2). These cells are also known to be critical in the bone healing process, in particular during healing of difficult nonunion fractures resulting from blood insufficiency, trauma and other conditions. The regeneration of bone tissue is initiated by MSCs with the formation of soft and hard calluses (3). Because of these varied actions, MSCs are considered to be promising therapeutic candidates with wide-ranging clinical applications. The uses for MSCs are not only limited to tissue engineering, but also include utilization of reparative and immunomodulatory properties in wound healing and realignment of dysregulated immune systems (4). Recently, there have been many publications regarding MSC biology and clinical application, and to date, 32 clinical trials have been undertaken using MSCs to treat a variety of adult heart conditions, including acute myocardial infarction, ischemic cardiomyopathy and non-ischemic dilated cardiomyopathy (5). MSCs account for 0.1-0.01% of bone marrow cells (Glennie et al., 2005) and must be expanded to obtain sufficient numbers for clinical use. For an adult, $1.8 \times 10^8$ cells are typically required for cell therapy – or based on body weight, the number of required cells may be calculated as $6.64 \times 10^6$ cells/kg (3). Therefore, the further development of methods for efficient expansion of MSCs is an important undertaking. Aging of human MSCs is known to attenuate their proliferation, while increasing oxidative damage and senescence (6,7). Therefore, the use of aged MSCs for autologous cell-based therapies is especially challenging (6,8). Along with reduced proliferation of the MSC pool, aging is also associated with decreased proliferative capacity in MSC-derived osteo-progenitor cells, which leads to decreased osteoblast cell number and eventually hinders bone formation (7,8).

EpCAM is a type I transmembrane protein with 314 amino acids and a molecular weight of 39-42 kDa (9). It contains an extracellular domain (EpEX, 265 amino acids), a single transmembrane domain, and a short intracellular domain (EpICD, 26 amino acids). EpCAM is a well-known tumor-associated antigen, which is enriched in various carcinomas and involved in homotypic cell-cell adhesion in normal epithelium (9). Previous research demonstrated that active proliferation is associated with enhanced EpCAM expression in neoplastic tissues. Furthermore, EpCAM is known to be relatively stable within the membrane of normal epithelial tissue, but is prone to cleavage in cancer tissue (10). Maetzel et al. first shed light on the mechanisms of EpCAM activation, showing that it occurs via regulated intramembrane proteolysis (RIP). During this process, EpCAM is cleaved, generating two products (EpEX and EpICD), which then induce EpCAM-mediated proliferative signaling (10). After RIP of EpCAM, EpICD associates with FHL2, β-catenin and Lef-1 to form a nuclear complex that binds to DNA at Lef-1 consensus sites and regulates gene transcription, potentially contributing to carcinogenesis.

In a recent study, we reported that EpCAM is enriched in human embryonic stem cells (hESCs), where it not only serves as an important surface marker but also regulates the four Yamanaka factors (11). Similarly, EpCAM plays a critical role in regulating self-renewal, cancer initiating ability, and invasiveness in colon cancer cells (12). It is also notable that overexpression of EpCAM or EpICD...
decreased the levels of p53 and p21, and increased the promoter activity of Oct4 during induced pluripotent stem cell (iPSC) derivation (13). Based on these findings, we further discovered that EpCAM/EpEX, together with Oct4 or Klf4 expression, can generate iPSCs (14). Despite this growing knowledge about EpCAM function in stem cells, the function of EpCAM/EpEX in human MSCs has not been previously described.

The main purpose for our current study was to investigate whether EpCAM signaling can promote multipotency and increase cell proliferation in MSCs. Herein, we not only describe a novel molecular mechanism for the regulation of self-renewal in MSCs through EGFR-STAT3 signaling, but we also provide a new method for maintaining multipotency of MSCs that may be useful to advance research in regenerative medicine.
Results
EpEX enhances cell proliferation and self-renewal in mesenchymal stem cells

A recent study showed that CD49f increases growth of MSCs and sustains multipotency via the regulatory effects on Oct4 and Sox2 (15). We have previously defined EpCAM as a critical stem cell marker, and we showed that EpiICD can regulate Oct4 and Sox2 gene expression by binding to their promoters (11). We also recently reported that EpCAM/EpEX cooperates with Oct4 or Klf4 to induce iPSC formation from mouse embryonic fibroblasts and discovered a novel mechanism through which EpCAM/EpEX regulates STAT3-HIF2α signaling (14). Based on these previous reports, we suspected that EpEX may be beneficial for maintenance of pluripotency in MSCs.

We used human bone marrow-derived MSCs to study the effects of EpEX, first investigating whether EpEX promotes cell proliferation. We assayed MSC doubling time after applying different doses of EpEX and found it was decreased in a dose-dependent manner. The most effective dose of EpEX was 3 µg/mL (Table S1), and EpEX shortened the doubling time of MSCs from 38.2 h to 22.5 h (Table 1, Figure 1A). Next, we examined the effect of EpEX on cell cycle progression by flow cytometry with propidium iodide (PI) staining. We found that EpEX increased the percentage of cells in G2/M phase from 6.5% to 29.3% at 18 h (Figure 1B and 1C). EpCAM has been reported to enhance cell cycle progression through upregulation of the proto-oncogene c-Myc and cyclin A/E (16). Additionally, EpCAM is known to upregulate cyclin D1 via its direct interaction partner, FHL2, and downstream events such as phosphorylation of the retinoblastoma protein, Rb (17). Therefore, we further asked whether EpEX can upregulate the expression of cell cycle regulators and pluripotency markers. We first performed Western blotting and found that EpEX significantly increased the protein expression of cell cycle regulators, including cyclin A2, cyclin D1, cyclin D2, cyclin D3 and cyclin E1 (Figure 1D), as well as CDK4 and CDK9 (Figure 1E). Surprisingly, EpEX also significantly increased the protein expression of pluripotency markers, including Oct4, Sox2, c-Myc and Lin28 (Figure 1F). We then used flow cytometry to confirm that EpEX increased the protein levels of the stemness markers, Oct4, Sox2, c-Myc and EpCAM, and we used qPCR to probe mRNA expression levels (Figure 1G, 1H). From these experiments, we found that EpEX accelerates MSC proliferation and enhances expression of multipotency markers.

EpEX induces cell proliferation and self-renewal through EGFR signaling

The EGF-EGFR signaling pathway has been shown to be critical for cell proliferation (18) and self-renewal in MSCs (19). Based on the knowledge that EpEX contains an EGF-like domain and activates EGFR signaling, as measured by a receptor kinase array, we hypothesized that EpCAM/EpEX may serve as a cytokine or a growth factor to activate EGFR signaling and regulate cell growth and multipotency. Hence, we evaluated the phosphorylation state of EGFR by an EGFR membrane antibody array. We found that EpEX induced the phosphorylation of EGFR at Tyr845 (Figure 2A). By Western blotting, we confirmed EpEX induced EGFR phosphorylation at Tyr845 in a time-dependent manner (Figure 2B).

We also showed that both EGFR inhibitor (AG1478) and EGFR shRNA attenuated EpEX-induced cell cycle progression (Figure 2C-2F). By Western blotting, we showed that inhibition of EGFR by shRNA or inhibitor abolished EpEX-induced protein expression of cell
cycle regulators, cyclin D1, cyclin D2, cyclin E1, CDK4 and CDK9 (Figure 2G and 2I), and pluripotency markers, Oct4, Sox2, c-Myc and Lin28 (Figure 2H and 2J). By qPCR, we found that shEGFR also reversed the EpEX-induced increases in transcript levels of pluripotency markers, including Oct4, Sox2, c-Myc and Lin28 (Figure 2K). Taking these results together, we conclude that EpEX may induce cell proliferation and multipotency in MSCs through activation of EGFR.

**EpEX induces cell proliferation and self-renewal via STAT3**

Previous studies have shown that STAT3 is a potent downstream effector of EGFR (20) and also that STAT3 plays a crucial role in pluripotency maintenance (21). Furthermore, we have demonstrated that STAT3 signaling is essential for EpCAM/EpEX promotion of iPSC reprogramming (14). Here we found that EpEX stimulates STAT3 phosphorylation shortly after treatment (Figure 3A). Moreover, we found that EpEX-induced phosphorylation of STAT3 was abolished by EGFR knockdown, suggesting that EpEX induces STAT3 signaling through EGFR activation (Figure 3B).

Because EGF is a cognate ligand of EGFR, we also tested the effects of EGF on EGFR activation and STAT3 phosphorylation. Results showed that EpEX can induce EGFR phosphorylation as well as EGF (Supplementary Figure 1A). Moreover, we found that pretreatment of EGFR inhibitor, AG1478, can attenuate the activation of EGFR by either EGF or EpEX (Supplementary Figure 1A). Interestingly, we also confirmed that EGF can induce the phosphorylation of STAT3, similar to EpEX (Supplementary Figure 1B), and that AG1478 can attenuate the activation of STAT3 by either EGF or EpEX (Supplementary Figure 1B).

We further investigated whether STAT3 signaling is involved in EpEX-induced cell growth and stemness of MSCs. By flow cytometry, we showed that STAT3 inhibitor (WP1066) and knockdown of STAT3 both attenuated EpEX-induced changes in cell cycle progression (Figure 3C-3F). By Western blotting, we also found that inhibition of STAT3 blocked EpEX-induced protein expression of cell cycle regulators, cyclin D1, cyclin D2, cyclin D3, cyclin E1, CDK4 and CDK9 (Figure 3G and 3I) and pluripotency markers, Oct4, Sox2, c-Myc and Lin28 (Figure 3H and 3J). By qPCR, we showed that inhibition of STAT3 prevented EpEX-increased gene expression of stemness markers, Oct4, Sox2, c-Myc and Lin28 (Figure 3K).

**EpEX suppresses let-7 through EGFR-STAT3 signaling**

Previous studies have shown that Lin28 inhibits the miRNA, let-7, thereby increasing the levels of pluripotency factors (22-26). Thus, we further examined if EpEX affects the level of let-7. By qPCR, we showed that EpEX decreased the level of let-7 (Figure 4A). We next tested whether EpEX-induced inhibition of let-7 expression occurs via STAT3 and EGFR and found that EpEX suppression of let-7 expression was attenuated by shEGFR, shSTAT3 or shLin28 (Figure 4B-4F). These results indicated that EGFR, STAT3 and Lin28 are necessary in EpEX regulation of let-7 expression.

Next, we used a let-7 mimetic to test whether let-7 suppression is necessary for EpEX-induced increase of pluripotency markers. We found that pretreatment with the let-7 mimetic abolished EpEX-induced gene and
protein expression of Oct4, Sox2, c-Myc and Lin28 (Figure 4G and 4H), confirming the importance of let-7 suppression in this process.

Similar to our findings, Lin28 was previously shown to decrease the level of let-7 (22); let-7 was further shown to suppress transcription of Oct4 and Sox2 through inhibition of transcription cofactors, AT-rich interaction domain molecule 3B (ARID3B) and high-mobility group AT-hook 2 (HMGA2) (27-29). The expression of HMGA2 is ubiquitous and abundant, and it has an important role during embryonic development (30). Moreover, HMGA2 expression has been shown to promote stem cell self-renewal, while decreased expression is associated with stem cell aging (31-34). In normal adult tissues, the level of HMGA2 is very low, but the protein is highly expressed in many types of cancer cells, where it facilitates oncogene expression (35-38). In addition, Lin28, which can suppress let-7 and upregulate expression of HMGA2, is important for self-renewal (39) and maintenance of an undifferentiated state in cancer cells (40,41). Based on this information, we hypothesized that EpEX may also regulate HMGA2. Interestingly, we found that EpEX not only induced the level of HMGA2, but also induced its nuclear translocation, as evidenced by Western blotting (Figure 5A) and immunofluorescent staining (Figure 5B).

Because HMGA2 belongs to the high mobility group with AT-hook DNA binding domain family of proteins, it changes DNA conformation by binding to AT-rich regions in the DNA and interacts with other transcription factors, rather than directly activating transcription (34,42). Therefore, we asked whether EpEX treatment induces HMGA2 to bind to the promoters of pluripotency genes. By ChIP, we showed that EpEX can induce HMGA2 binding to the promoters of Oct4 and Sox2, while ablation of EGFR, STAT3 or Lin28 prevented the effect (Figure 5C-5H). We further tested whether EpEX-induced HMGA2 binding is dependent on let-7. Pretreatment with let-7 mimic abrogated the effect of EpEX, while treatment of the let-7 inhibitor was sufficient to induce the binding of HMGA2 to the promoters of Oct4 (Figure 5I). In addition, we showed that the let-7 mimic abolished EpEX-induced gene and protein expression of HMGA2 (Figure 5J and 5K).

The result showed that EpEX can induce HMGA2 binding to the promoters of Oct4 and Sox2, while ablation of EGFR prevented the effect. We further tested whether EpEX and EGF induced HMGA2 binding is dependent on regulation of EGFR. Pretreatment with EGFR inhibitor AG1478 abrogated the effect of EpEX and EGF induce the binding of HMGA2 to the promoters of Oct4 and Sox2 (Figure 6A and 6B). Next, we investigated whether EpICD and HMGA2 could form a complex to bind to the promoter of Oct4 and Sox2. We sequentially pulled down EpICD and HMGA2, followed by probing of the binding site within the Oct4 and Sox2 promoter (Figure 6C and 6D). The result showed EpEX and EGF induction of EpICD-HMGA2 complex binding to Oct4 and Sox2 promoter is dependent on EGFR. Pretreatment with EGFR inhibitor AG1478 abrogated the effect of EpEX, and EGF induced binding of EpICD-HMGA2 to the Oct4 and Sox2 promoters.

Because we showed that EpEX treatment can induce Oct4 gene expression, we examined the binding of EpICD to the Oct4 promoter by single ChIP and double ChIP assays. We pulled down EpICD and probed for a specific binding site in the Oct4 promoters, finding that EpICD can indeed associate with the Oct4 promoter after cells are
treated with let-7 inhibitor or mimetic (Supplementary Figure 2A). We then wanted to investigate whether EpICD and HMGA2 form a complex to bind to the promoter of Oct4. In order to do so, we sequentially pulled down EpICD and HMGA2 and then probed for the binding site within the Oct4 promoter in the presence of let-7 inhibitor or mimetic (Supplementary Figure 2B). Pretreatment with let-7 inhibitor enhanced the EpEX-induced binding of HMGA2 or EpICD-HMGA2 to the promoter of Oct4, while pretreatment with let-7 mimetic abrogated the effect. Indeed, we found that EpEX facilitates EpICD-HMGA2 complex binding to the Oct4 promoter through the let-7 inhibition pathway.

EpEX promotes MSC osteogenesis by upregulating RUNX2

A previous study demonstrated that the upregulation of Oct4 and Sox2 can promote osteogenesis of MSCs (43). Therefore, we surmised that EpEX may also promote osteogenesis via upregulation of Oct4 and Sox2. Our results show that EpEX treatment during osteo-induction promoted osteogenesis when compared to cells without EpEX treatment (Figure 7A and 7B). We also measured gene expression of the osteogenic marker, RUNX2, and found that EpEX increased the transcript level (Figure 7C). We then analyzed whether RUNX2 participates with let-7 in EpEX-enhanced osteogenesis. First, we examined whether EpEX-enhanced osteogenesis is dependent on downregulation of let-7. We found that pretreatment of let-7 mimetic can abolish EpEX enhancements in osteogenesis, while let-7 inhibitor can increase osteogenesis (Figure 7D and 7E). Finally, we showed that let-7 mimetic attenuated EpEX-induced gene expression of RUNX2 (Figure 7F), while let-7 inhibitor increased RUNX2 gene expression (Figure 7G). We also showed that treatment of RUNX2 inhibitor roxithromycin (RXM) can abolish the EpEX-enhanced osteogenesis in MSCs (Figure 7H). In contrast with osteogenesis, EpEX treatment during adipo-induction inhibited adipogenesis (Supplementary Figure 3).

EpEX induces the phosphorylation and activity of TACE and γ-secretase

Previous studies indicate that EpCAM can be cleaved by the sheddase, Tumor necrosis factor-alpha converting enzyme (TACE), leading to the release of soluble EpEX. This release may then trigger an autocrine cell signaling response (10). Because EpCAM signaling is processed both by TACE and γ-secretase, we investigated the effect of EpEX on TACE and γ-secretase activities. We detected the phosphorylation and activation of TACE and γ-secretase in EpEX-stimulated MSCs. The results of these assays showed that the activation of TACE and γ-secretase were induced by EpEX treatment in MSCs (Supplementary Figure 4A and 4B). We also showed the phosphorylation of TACE and γ-secretase were induced by EpEX (Supplementary Figure 4C and 4D). Next, we used an EGFR inhibitor to examine whether EpEX-induced activation of TACE and γ-secretase requires EGFR signaling. We also investigated the upstream signaling that may result in activation of the TACE enzyme. ERK1/2 has been reported to regulate the activity of TACE, and we showed that EpEX can induce the EGFR-dependent phosphorylation of ERK1/2 (Supplementary Figure 4E and 4F).

We showed that EpEX-induced phosphorylation of TACE and presenilin-2 can be abolished by the addition of EGFR inhibitor (Supplementary Figure 4G and 4H). Next we wanted to examine whether TACE and γ-secretase play roles in maintaining protein levels of cell cycle regulators and pluripotency factors. We
found that knockdown of TACE or γ-secretase can inhibit the expression of cell cycle regulators and pluripotency markers (Supplementary Figure 5).
Discussion

In this study, we provide evidence for the novel concept that EpEX/EGFR signaling may aid multipotency and self-renewal of MSCs by providing a mitogenic signal. We further elucidated the signaling mechanism that underlies this phenomenon. We found that EpEX induces the phosphorylation of EGFR, which then initiates downstream events, including the sequential upregulation of STAT3 and Lin28. Lin28 and STAT3 are responsible for inhibiting expression of the miRNA, let-7, which acts to control the expression of cell cycle regulators and pluripotency factors. Expression of these factors culminates in the stimulation of cell proliferation and enhancement of multipotency. These findings are consistent with a previous report that activation of the EGFR axis is important for cell proliferation and self-renewal in MSCs (19). Thus, our study uncovers a novel molecular mechanism in the sophisticated regulation of MSCs multipotency and self-renewal.

MSCs are characterized by their ability to self-renew and differentiate into tissues of mesodermal origin, including bone, cartilage, adipose and connective tissues. Thus, they contribute to many types of tissue regeneration (44). MSCs play vital roles in the repair and reconstruction of normal and injured tissue, mainly via interactions with other cell types, such as endothelial cells, vascular SMCs, and leukocytes (45). Therefore, it is of great interest to identify factors that may have a role in MSCs expansion and maintenance of MSCs stem cell plasticity.

The molecular mechanisms that regulate proliferation and multipotency of MSCs are not well understood. In contrast, the molecular basis of proliferation and multipotency of embryonic stem cells (ESCs) has been the focus of intense research and is described in detail. In ESCs, the expression of three transcription factors, Oct4, Sox2 and Nanog, are essential for the maintenance of the stemness, self-renewal and pluripotency (46,47). Among these transcription factors, Oct4 belongs to the family of Pou-domain transcriptional factors, and is found in developing embryos, developing endoderm and developing neuroectoderm (48-50). Together with Sox2, Oct4 can upregulate the expression of Nanog (51), and it is a dose-dependent pluripotency regulator that controls lineage commitment of ESCs (52). In addition to ESCs, the Oct4 gene has been found to be expressed in tumor cells, but has not differentiated cells (53,54). Instead, Oct4 expression has been confirmed in bone marrow (55), dental pulp (56), heart, liver (57) and adipose tissue-derived stem cells (58). Another of these core pluripotency transcription factors is Sox2. This protein is a member of the SRY-related HMG-box (SOX) transcription factor family and plays a diverse role in stem cell potency and maintenance, embryonic development, and cancer (59-62). It is closely co-regulated alongside core pluripotency factors Oct4 and Nanog in ESCs, embryonic carcinoma cells and induced pluripotent stem cells (62-64). Recently, Sox2 has been implicated in the maintenance and differentiation of adult stem cells, and its expression has been reported in bone marrow, neuronal tissues and sensory epithelia (55,65). However, the roles of Oct4, Sox2 and Nanog are not well described in MSCs.

It has been speculated that the core pluripotency transcription factors play an important role in the maintenance of multipotency and self-renewal of adult stem cells, including MSCs. Adult stem cells exist within various tissues, with the purpose of repopulating the tissue after injury or physiological loss. Human MSCs, which are derived from bone marrow, are progenitors that can
differentiate into cells of multiple types, including osteogenic, chondrogenic, adipogenic and myogenic lineages (44,66,67). Like human ESCs, human MSCs depend on fibroblast growth factor (FGF) to maintain self-renewal and pluripotency (68). FGF inhibits differentiation by bone morphogenetic protein (BMP) signaling and sustains expression of Oct4, Sox2 and Nanog pluripotency associated genes (69). Upon differentiation, expression of pluripotency transcription factors is expected to be downregulated (70). However, there is some controversy among different research groups regarding the expression of pluripotency regulators in adult tissues (71).

Oct4 is a transcription factor that is highly expressed in undifferentiated embryonic stem cells and embryonic germ cells (72). A network of key factors, which includes Oct4, Nanog and Sox2, is necessary for the maintenance of pluripotency, and downregulation of Oct-4 has been shown to trigger differentiation (50,73). Recent studies have also demonstrated that Oct4 is a useful germ cell tumor marker (74).

EpCAM was recently found to be highly expressed in ESCs and promote pluripotency (13). Previously, we found that EpCAM expression in hESCs is regulated by an epigenetic mechanism, and it activates gene expression of c-Myc, Oct4, Nanog, Sox2 and Klf4 via EpICD nuclear activity. These events result in promotion of self-renewal and the maintenance of pluripotency in ES cells (11). However, the underlying molecular mechanisms of EpCAM-mediated effects on reprogramming are unclear.

We previously found that EpCAM plays an important role in regulating cancer-initiating abilities in colon cancer. In tumor initiating cells, elevation of EpCAM enhanced the formation of tumor spheres in vitro and tumors in vivo, and led to increased production of EpICD, which upregulated expression of reprogramming factors (11). Meanwhile, another study showed that knockdown of EpCAM inhibited the expression of reprogramming factors and epithelial-mesenchymal transition-related genes, thereby suppressing tumor initiation, self-renewal, and invasiveness (12). Moreover, it has been reported that overexpression of EpCAM or EpICD decreased the expression of p53 and p21, and activated the promoter activity of Oct4 in the reprogramming of MEFs (13). However, the mechanistic role of EpCAM in pluripotency reprogramming is still unknown. In the present study, we found that EpICD can associate with the Oct4 promoter and that this association may occur in a complex with HMGA2. Thus, we suggest that EpCAM not only regulates Oct4 by EpEX signaling, but EpICD also directly regulates Oct4 transcription.

The interaction between EGFR and EpCAM was explored previously (75). Liang et al. showed that extracellular domain of EpCAM (EpEX) can function as a growth factor and activate ERK and AKT through EGFR signaling. EpEX enhances colon cancer cell proliferation through activating EGFR to induce EpICD shedding and downstream β-catenin and HIF1α-mediated signaling (75). Bidirectional co-immunoprecipitation (co-IP) of endogenous proteins was performed in FaDu, Cal27 and HCT8 cells, revealing co-precipitation of EGFR and EpCAM. The report also used cross-linking experiments to show that EpEX binds directly to the extracellular domain of EGFR (76). Another previous study revealed that the GTP-binding protein, RAS associated with diabetes (RRAD), can physically associate with EGFR to activate STAT3 and induce expression of the stem cell expression factors, Oct4, Nanog and Sox2, thereby enhancing self-renewal in malignant glioblastoma.
Our results are consistent with this finding. We showed that EpEX can activate EGFR signaling, induce STAT3, and upregulate cell cycle regulators and pluripotency factors (Figure 1). Furthermore, our study shows that the EGFR-STAT3 axis may induce Lin28, which then blocks let-7 and upregulates cell cycle regulators and stemness markers in MSCs (Figure 2). Thus, EpEX can serve as a growth factor to stimulate EGFR signaling and trigger the cascade which can help MSCs to cell proliferation and increase the expression of stemness markers.

Several studies have reported that Lin28 inhibits let-7 (78,79) and that Sox2 plays a fundamental role in regulating Lin28, allowing neural progenitor cell proliferation and preventing neuronal differentiation (79). Moreover, Lin28 can rescue neural progenitor cell proliferation and maintain neurogenic potential in the absence of Sox2 (79). Since Lin28 function is important in these ectoderm-derived progenitor cells, it is consistent that the Lin28/let-7 pathway is also important for MSC proliferation and self-renewal. Interestingly, STAT3 has been shown to downregulate let-7 family members and miR-200 (80). According to Guo et al., STAT3 enhances Lin28 expression by directly binding to the Lin28 promoter, resulting in the repression of let-7 and concomitant upregulation of the let-7 target, HMGA2 (80). In this way, the STAT3-Lin28B–let-7-HMGA2 circuit can participate with miR-200-ZEB1 to coordinate cytokine-mediated reprogramming of breast cancer cells (80).

HMGA2 is enriched in hESCs (32) and is known to interact with nucleosomes to create a specific type of chromatin domain, which is critical for the establishment of both hESC identity and the regulation of differentiation (33). HMGA2 is critically involved in the regulation of hESC proliferation, where it acts through undifferentiated transcription factor 1 (UTF1) to exert its function (33). Additionally, high-mobility group B protein 2 (HMGB2) has been shown to be expressed in stem cells and to inhibit differentiation in MSCs (81). In the present study, we not only showed that EpEX upregulates EGFR-STAT3-Lin28-let-7, but we also report the novel finding that EpEX can regulate cell proliferation and enhance multipotency via the chromatin remodeling protein, HMGA2. Furthermore, we show that EpICD-HMGA2 complex can associate with the promoter of Oct4, suggesting that HMGA2 can associate with EpICD to regulate Oct4 in transcriptional level.

Osteoblasts and adipocytes are known to be derived from multipotential MSCs (82), and increased adipogenesis in bone marrow has been associated with a decrease in osteogenesis. A probable mechanism underlying the commitment of MSC differentiation is the activation of RUNX2, the key transcription factor for osteoblast and adipose differentiation (83,84). In addition, we found that EpEX can increase the osteogenic markers during osteogenic induction (Figure S6). A previous report indicated that adiponectin increased osteoblast differentiation by inhibiting osteoclastogenesis and osteoclast activity (85). Moreover, fully differentiated 3T3-L1 adipocytes significantly decreased mRNA and protein expression of RUNX2 in osteoblastic cells. The present results suggest that EpEX promotes MSC osteogenesis by upregulating RUNX2, meanwhile inhibiting adipogenesis. These findings prompted us to further examine the impact of EpEX on adipogenesis, chondrogenesis, and myogenesis by detecting specific markers of these processes (Figure S7...
and S8). Interestingly, we showed that EpEX treatment increased the mRNA and protein levels of chondrogenesis marker, SOX9, in chondrogenesis-induced cultures (Figure S7 and S8). However, in adipogenic and myogenic-induced cultures, EpEX had no significant impact on the mRNA and protein levels of specific markers, including: adipogenesis marker PPARγ and myogenesis marker MyoD (Figure S7 and S8). We also found that the protein levels of adipogenesis markers, adiponectin, fatty acid synthase and Acetyl-CoA carboxylase, were not increased by EpEX (Figure S8). Thus, we conclude that EpEX can promote osteogenesis and may promote chondrogenesis, but does not affect adipogenesis.

Because Notch1 signaling is also regulated by RIP, we further examined whether EpEX is capable of promoting Notch1 cleavage. We found that EpEX has no significant impact on the mRNA level for Notch1 or protein levels of Notch1 and cleaved Notch1 (Figure S9).

In conclusion, our investigation into the effects of EpEX/EGFR/STAT3 signaling in MSCs has produced fundamental knowledge that elucidates the role of EpCAM in promoting multipotency in this cell type. Our data allow us to propose the possible pathway shown in Figure 8. These findings not only support the concept that EpEX serves as a cytokine with pleiotropic effects in MSCs, but they also suggest a new strategy for enhancing cell proliferation and multipotency of MSCs.
Experimental procedures

Cell culture

All experiments with primary human cells were conducted in accordance with relevant guidelines and regulations. Human primary bone marrow mesenchymal stem cells (BMMSCs) were purchased from LONZA and were cultured with Dulbecco’s Modified Eagle Media-low glucose (DMEM-LG) medium containing 16.6% FBS, 1 mM L-glutamine (Invitrogen), 100 µg/ml Penicillin/Streptomycin (Gibco). All cells were cultured at 37°C and 5% CO₂. All experiments on primary cells were performed within 10 passages.

Production and purification of EpEX-Fc recombinant protein

The DNA fragment encoding EpEX (amino acid residues 24–262) was amplified by PCR with PfuTurbo DNA polymerase (Stratagene). The PCR product was digested and ligated into pSecTag2 vector (Invitrogen) with C-terminal Fc tag to generate pSecTag2-EpEX-Fc. The EpEX-Fc fusion protein was produced using the Expi293F™ Expression System (Thermo Fisher Scientific) and purified with protein G affinity chromatography (GE Healthcare Bio-sciences) (75).

Plasmids and Lentivirus Preparation

For knockdown experiments, human EGFR, EpCAM, STAT3 and Lin28 shRNAs in the pLKO vector were obtained from RNAi core facility (Academia Sinica, Taipei). Lentivirus was produced according to standard protocols with minor modifications. In brief, 293T cells were seeded at a density of 70% in a 100-mm dish and transfected with packaging vectors (pCMV-ΔR8.91, containing gag, pol and rev genes), envelope vectors (pMD2.G; VSV-G expressing plasmid), and an individual shRNA vector. The shRNA plasmids were transfected into 293T cells by poly-jet transfection reagent (SignaGen Laboratories). After overnight incubation, the medium was changed to BSA-containing media. MSCs were infected with viral supernatant, containing polybrene (8 µg/ml), for 24 h. The infection procedure was repeated, and cells were incubated in puromycin (2 µg/ml) for 7 days to select cells with stable shRNA expression.

Osteogenic differentiation

Human primary BMMSCs were cultured in DMEM-LG medium with 10% FBS. Fibroblasts were cultured in DMEM-HG with 10% FBS. To induce differentiation, cells (1 × 10⁴ cells/cm²) were cultured with osteogenic induction medium (90% DMEM-HG, 10% FBS, 0.1 µM dexamethasone, 10 mM β-glycerophosphate, and 0.05 mM L-ascorbic acid phosphate). The media was replaced twice per week during the differentiation period.

Adipogenic differentiation

BMMSCs were cultured in adipogenic induction medium (Biological Industries, Kibbutz Beitz-Haemek, Israel). The medium was replaced every 3 days during the differentiation period.

Chondrogenic differentiation

BMMSC pellets were formed by centrifugation at 500 × g for 10 min, and the pellets were incubated with chondrogenic induction medium (Biological Industries) overnight. The next day, the cell pellets formed a spherical aggregate and were treated with chondrogenic induction medium for 14 days.

Myogenic differentiation

BMMSCs were incubated in myogenic induction medium (DMEM (Dulbecco's modified Eagle's medium)/Ham's F - 12. DM1 (differentiation medium 1) contained 2% DHS (donor horse serum, Biochrom AG) and 1% L-glutamine; DM2 (differentiation medium 2) contained 2% DHS, 1% L-glutamine, 1 ng/ml bFGF (Sigma-Aldrich) + 0.4
μg/ml dexamethasone (Sigma-Aldrich). The medium was replaced every 3 days during the differentiation period.

**Alizarin Red S staining**

After 14 days of osteogenic differentiation, cells were fixed with ice-cold 70% ethanol at -20 °C for 1 h and then washed with PBS. The cells were then stained with 40 mM Alizarin Red S (ARS) (pH 4.2) for 10 min and subsequently washed five times with ddH$_2$O before being air dried. For quantification, the cells were incubated with 1 mL of acetyl pyridinium chloride buffer for 1 h to extract ARS, and the O.D. at 550 nm was recorded.

**Quantitative real time RT-PCR**

Total RNA was extracted using TRI reagent (Invitrogen, CA, USA), and 5 μg of total RNA was reverse transcribed using oligo (dT) primer (Fermentas, Glen Burnie, MD, USA) with SuperScript III reverse transcriptase (Invitrogen). Quantitative real time RT-PCR (qPCR) was performed on cDNA using the Light Cycler 480 SYBR Green I Master kit (Roche Applied Science, Indianapolis, IN) and the LightCycler480 System (Roche Applied Science). The gene expression levels of each sample were normalized to the expression levels of glyceraldehyde 3-phosphate dehydrogenase (GAPDH).

**Western blot analysis and Phospho-Kinase Array**

Western blotting was performed as previously described (86). Cells were lysed in lysis buffer (150 mM NaCl, 50 mM Tris-HCl (pH 7.4), 1% Nonidet P-40), containing a protease inhibitor mix (Roche Applied Science). Nuclear fractions and cytoplasmic fractions were separated by the Nuclear/Cytoplasm Fractionation Kit according to the manufacturer’s instructions (BioVision Inc., Milpitas, CA, USA). Protein samples were separated by SDS-PAGE under denaturing conditions, and transferred to a PVDF membrane (Millipore). To probe for pluripotency markers, membranes were incubated with the indicated antibodies against Oct4 (1:1000, Abcam, Cambridge, UK), Nanog (1:1000, Genetex), Lin28 (1:1000, Genetex) or Sox2 (1:1000, Genetex). The CDK and cyclin antibodies were from the CDK and Cyclin Antibody Sampler Kits (Cell Signalling Technology, #9868 and #9869 respectively), including antibodies against cycin D1, D2, E1, and CDK4, CDK9 (1:1000). EpCAM (1:1000, Genetex), phospho-EGFR (1:1000, Cell signaling), EGFR (1:1000, Cell signaling), Notch1 (1:1000, Cell signaling), cleaved Notch (1:1000, Cell signaling), adiponectin (1:1000, Cell signaling), PPARγ (1:1000, Cell signaling), Acetyl-CoA carboxylase (1:1000, Cell signaling), SOX9 (1:1000, Cell signaling), Osterix/Sp7, (1:1000 R&D), Thrombopoietin, (1:1000, R&D), MEPE/OF45 (1:1000 R&D), HMGA2 (1:1000, Cell signaling) or GAPDH (1:10000, Abcam) were also used. After incubation with primary antibody, the membranes were incubated with horseradish peroxidase (HRP)-conjugated secondary antibodies, goat anti-mouse IgG (1:3000, Santa Cruz, CA) or goat anti-rabbit IgG (1:3000, Santa Cruz, CA). Finally, membranes were washed three more times, and developed using Chemiluminescence Reagent Plus (Thermo Fisher Scientific, Runcorn, UK). The Phospho-Kinase Array Kit (Proteome Profiler Antibody Array, R&D Systems) was used according to the manufacturer’s instructions.

**Flow cytometry analysis**

Cells were dissociated with 0.25% trypsin-EDTA (1 mM) (Invitrogen) for 3 min, washed with fluorescence-activated cell sorting buffer (FACS buffer, PBS containing 1% fetal bovine serum), fixed in 4% PFA, and then permeabilized with 0.1 % Triton X-100 in PBS. Subsequently, cells were stained with Oct4, Sox2 or Nanog antibodies (1:100,
ab107156, Abcam, UK), washed and suspended in FACS buffer, and incubated with secondary antibody (1:200, Jackson ImmunoResearch) for 60 min at room temperature. Flow cytometry analysis was performed with a BD FACSCanto II flow cytometer (BD Biosciences, CA, USA).

**Immunofluorescence staining**

MSCs were seeded onto Millicell EZ slides (Millipore), and then iPSCs or ESCs were seeded. Cells were washed, fixed in 4% PFA for 10 min, and then permeabilized with 0.1% Triton X-100 for 10 min. Cells were stained with HMG2 antibody (1:1000, Cell Signaling) for 60 min at room temperature and then washed with PBS. Then the slides were incubated with goat anti-rabbit antibody conjugated with Alexa Fluor 568 (1:250; Invitrogen) for 1 h. After washing, the nuclei were stained with 4',6-diamidino-2-phenylindole (DAPI) (1:1000) (Invitrogen). Cells were observed by confocal microscopy (TCS SP5; Leica, Wetzlar, Germany).

**Chromatin Immunoprecipitation**

We performed chromatin immunoprecipitation (ChIP) with the Pierce™ Magnetic ChIP Kit (Thermo Fisher Scientific), according to the manufacturer's instructions. In brief, the protein-DNA complexes were cross-linked with 1% formaldehyde and quenched by adding glycine to a final concentration of 200 mM. The chromatin complexes were sonicated to an average size of 250 bp by a MISONIX Sonicator 3000. For immunoprecipitation, 4 µg of anti-HIF2α (Novus) was incubated with protein G beads (Invitrogen) for 4 h. The immunocomplexes were further incubated with chromatin for another 4 h. The bound fraction was isolated by protein G beads according to the manufacturer's instructions, and the immunocomplexes were subjected to reverse cross-linking. In double ChIP analysis, sequential (double) immunoprecipitation of two chromatin-binding proteins was performed to detect co-occupancy of proteins on promoter regions of pluripotency genes. We followed a previously described protocol (87). Briefly, we performed the first-round ChIP by using the anti-HMG2 antibody (Cell Signaling Technologies). The cross-linked DNA-protein complex was washed and eluted with 10 mM dithiothreitol (DTT) at 37 °C for 1 h. The eluents were then diluted 50-fold in a ChIP buffer (0.01% SDS, 1.1% TX-100, 1.2 mM EDTA, 16.7 mM Tris–HCl pH 8.1, 167 mM NaCl). A second-round of ChIP was performed with anti-HIF2α (Novus) or the control IgG antibody (Thermo Fisher Scientific). Chromatin was collected from the protein G-agarose beads after washing by elution with sodium bicarbonate-SDS buffer.

The immunoprecipitated DNA was recovered by a PCR purification kit (Thermo Fisher Scientific), and the purified DNA was subjected to real time quantitative PCR for further analysis. The primers for the promoter of Oct4 and Sox2 were according to (29). Immunoprecipitation/input was calculated for each gene and each gene was further normalized to the level of mouse β-actin promoter.

**TACE activity and γ-secretase activity assay**

ADAM17 activity was measured using the ImmoZyme ADAM17 activity kit (Calbiochem). In brief, cell lysates were harvested and loaded into a TACE antibody-coated plate. After 1 h incubation, the lysate was removed and the plate was washed twice. Substrate was added into each well for 5 h at 37 °C. After incubation, the fluorescence signal of the reaction product was detected at excitation of 324 nm and emission of 405 nm. For the detection of γ-secretase activity, cell lysates were
extracted and 500 µg protein was used. γ-secretase activity was detected by γ-secretase substrate (35 µM).

**Statistical analysis**

All data are presented as mean ± SEM for the indicated number of experiments. Unpaired Student's *t*-test was performed to calculate the statistical significance of the expression percentages versus those of control cultures. A *p*-value of less than 0.05 was considered statistically significant.
Acknowledgments

We thank Dr. Jean Lu for providing human bone marrow MSCs. We also thank the technical assistance of Imaging Core Facilities at ICOB, and RNAi core at genomics research center, Academia Sinica.

Conflict of Interest

The authors have no conflicts of interest to disclose.

Author contributions

I-I Kuan, Chi-Chiu Lee, Chien-Hsu Chen, Han-Chung Wu conducted experiments and analyzed data; I-I Kuan, Chi-Chiu Lee, Yuan-Sung Kuo, Han-Chung Wu designed experiments. Jean Lu provides human bone marrow MSCs. I-I Kuan, Chi-Chiu Lee wrote the manuscript. Jean Lu and Yuan-Sung Kuo edited the manuscript. Han-Chung Wu supervised research, and wrote and edited the manuscript.

Table 1. The effect of EpCAM and EpEX on MSC doubling time

| EpEX (µg/mL) | 0              | 3              |
|--------------|----------------|----------------|
| P3           | 17.6 ± 0.3 h   | 16.1 ± 0.1 h   |
| P9           | 38.2 ± 1.7 h   | 22.5 ± 0.4 h   |
Figure legends

Figure 1. EpEX increases cell proliferation and multipotency factors in mesenchymal stem cells. (A) The proliferation of MSCs was examined by measuring doubling time. MSCs were treated with EpEX (3 µg/mL) for 24 and 48 h. Cell number was counted and then doubling time was calculated. (B, C) MSCs were treated with EpEX for the indicated times. Flow cytometry and propidium iodide (PI) staining were performed to examine cell cycle progression. Fraction of cells in each phase (G1, S, G2/M) of the cell cycle was evaluated. (D-F) MSCs were treated with EpEX (3 µg/mL) for the indicated times. After treatment, protein expression of cell cycle regulators (cyclin D1, cyclin D2, cyclin D3, cyclin E1, CDK4 and CDK9) and pluripotency factors (Oct4, Sox2, c-Myc, and Lin28) was examined by Western blotting. The results of figure 1D and 1E were from one and the same experiment and showed separately because of the size of the image; therefore 1D and 1E were with the same GAPDH. (G) MSCs were treated with EpEX (3 µg/mL) for the indicated times. After treatment, the protein expression of pluripotency factors (SSEA4, Oct4, Sox2, c-Myc and Lin28) was examined by flow cytometry. (H) MSCs were treated with EpEX (3 µg/mL) for the indicated times. After treatment, the gene expression of pluripotency factors (Oct4, Sox2, c-Myc and Lin28) was examined by qPCR. Data represent the mean ± SD. *P < 0.05.
Figure 2. EpEX upregulates cell cycle regulators and stemness markers via EGFR signaling. (A) MSCs were treated with EpEX (3 µg/mL) for 15 min and the phosphorylation of EGF receptors was detected by an EGFR phosphorylation antibody array. (B) MSCs were treated with EpEX (3 µg/mL) for the indicated times. Phospho-EGFR (Tyr845) was detected by Western blotting. (C, D) MSCs were pretreated with or without an EGFR inhibitor (AG1478, 25 µM) for 30 min and then cells were incubated with EpEX for 18 h. After treatment, cell cycle progression was investigated by flow cytometry with PI staining. Fraction of cells in each phase (G1, S, G2/M) of the cell cycle was evaluated. (E, F) Cells that expressed EGFR shRNA or shLuc were treated with EpEX for 18 h. After treatment, cell cycle progression was investigated by flow cytometry with PI staining. Fraction of cells in each phase (G1, S, G2/M) of the cell cycle was evaluated. (G, H) MSCs were pretreated with or without AG1478 and then stimulated by EpEX. The protein expression of cell cycle regulators (cyclin D1, cyclin D2, cyclin E1) and pluripotency factors (Oct4, Sox2, c-Myc, Lin28) was examined by Western blotting. (I, J) MSCs expressing EGFR shRNA were stimulated by EpEX. After treatment, the protein expression of cell cycle regulators (cyclin D1, cyclin E1, CDK4 and CDK9) and pluripotency factors (Oct4, Sox2, c-Myc, and Lin 28) was examined by Western blotting. The results of figure 2I and 2J were from one and the same experiment and showed separately because of the size of the image; therefore 2I and 2J were with the same EGFR and GAPDH. (K) MSCs expressing EGFR shRNA were stimulated with EpEX. After treatment, the gene expression of pluripotency factors (Oct4, Sox2, c-Myc, Lin28 and EpCAM) was examined by qPCR. Data represent the mean ± SD. *P < 0.05.
Figure 3. EpEX upregulates cell cycle regulators and stemness markers via EGFR-STAT3 signaling. (A) MSCs were treated with EpEX (3 µg/mL) for the indicated times. After treatment, the protein levels of total STAT3 and phospho-STAT3 (Tyr705) were examined by Western blotting. (B) MSCs were treated with EGFR shRNA or shLuc, and total STAT3 and phospho-STAT3 (Tyr705) were examined by Western blotting with or without EpEX treatment. The results of figure 2I, 2J and 3B were from one and the same experiment and showed separately because of the size of the image; therefore 2I, 2J and 3B were with the same EGFR. (C, D) Cells were pretreated with a STAT3 inhibitor (WP1066, 5µM), followed by stimulation with EpEX for 18 h. Cell cycle progression was investigated by flow cytometry with PI staining. Fraction of cells in each phase (G1, S, G2/M) of the cell cycle was evaluated. (E, F) Cells expressing STAT3 shRNA were treated with EpEX for 18 h, after which cell cycle progression was investigated by flow cytometry with PI staining. Fraction of cells in each phase (G1, S, G2/M) of the cell cycle was evaluated. (G, H) MSCs were pretreated with or without WP1066 and then stimulated by EpEX. The protein levels of cell cycle regulators (cyclin D1, cyclin D2, cyclin E1, CDK4 and CDK9) and pluripotency factors (Oct4, Sox2, c-Myc, Lin28) were examined by Western blotting. The results of figure 3G and 3H were from one and the same experiment and showed separately because of the size of the image; therefore 3G and 3H were with the same GAPDH. (I, J) MSCs expressing STAT3 shRNA or shLuc were stimulated with EpEX. After treatment, the protein levels of cell cycle regulators (cyclin D1, cyclin D2, cyclin E1, CDK4 and CDK9) and pluripotency factors (Oct4, Sox2, c-Myc, and Lin28) were examined by Western blotting. (K) MSCs expressing STAT3 shRNA or shLuc were stimulated with EpEX. After treatment, the gene expression of pluripotency factors (Oct4, Sox2, c-Myc, Lin28 and EpCAM) was examined by qPCR. Data represent the mean ± SD. *P < 0.05.
Figure 4. EpEX suppresses miRNA, let-7, through EGFR-STAT3-Lin28 signaling. (A) Cells were treated with EpEX (3 µg/mL), and the expression of let-7 was detected by qPCR. (B, C) MSCs were pretreated with or without AG1478, or WP1066, and then stimulated with EpEX. The expression of let-7 was detected by qPCR. (D, E and F) MSCs expressing EGFR shRNA, STAT3 shRNA or Lin28b shRNA were stimulated with EpEX. The expression of let-7 was detected by qPCR. (G) MSCs were transfected with a let-7 inhibitor or a let-7 mimetic, and then stimulated with EpEX. Expression of pluripotency factors (Oct4, Sox2, c-Myc and Lin28) was examined by qPCR. (H) MSCs were transfected with a let-7 mimetic, and then stimulated with EpEX. Protein levels of pluripotency factors (Oct4, Sox2, c-Myc, and Lin28) were examined by Western blotting. Data represent the mean ± SD. *P < 0.05.
Figure 5. EpEX upregulates HMGA2 and increases its binding to the promoters of Oct4 and Sox2 through EGFR-STAT3-Lin28-let-7 signaling. (A) MSCs were treated with EpEX (3 µg/mL) for the indicated times, and expression of HMGA2 was detected by Western blotting. (B) MSCs were treated with EpEX (3 µg/mL), and the expression of HMGA2 was detected by immunofluorescence staining. Scale bar = 50 μm. (C-H) MSCs expressing EGFR shRNA, STAT3 shRNA or Lin28b shRNA were treated with EpEX (3 µg/mL) for 12 h. The promoter binding of HMGA2 was examined by chromatin immunoprecipitation (ChIP) assay. HMGA2 protein was pulled down by a specific anti-HMGA2 antibody. To detect the binding of HMGA2 to the Oct4 and Sox2 promoters, cross-linked DNA was isolated and then amplified with specific primers by qPCR. (I) MSCs were treated with let-7 mimetic or let-7 inhibitor and then treated with EpEX (3 µg/mL) for 12 h. To detect the binding of HMGA2 to Oct4 promoters, cross-linked DNA was isolated and then amplified with specific primers by qPCR. (J) MSCs were treated with let-7 mimetic and then treated with EpEX (3 µg/mL) for 12 h. The gene expression of HMGA2 is detected by qPCR. (K) MSCs were treated with let-7 mimetic and then treated with EpEX (3 µg/mL) for 12 h. The protein abundance of HMGA2 was examined by Western blotting. The results of figure 4H and 5K were from one and the same experiment and showed separately because of the size of the image; therefore 4H and 5K were with the same GAPDH.
Figure 6. EpEX increases the binding of HMGA2 and EpICD to the promoter of Oct4 and Sox2. MSCs were treated with EGF inhibitor AG1478 then treated with EpEX (3 µg/mL) and EGF (50 nM). Binding of HMGA2 to the (A) Oct4 and (B) Sox2 promoter was examined by chromatin immunoprecipitation (ChIP). HMGA2 was pulled down by a specific anti-HMGA2 antibody. The cross-linked DNA was isolated and then probed by qPCR with specific primers for the Oct4 and Sox2 promoter. MSCs were treated with EGF inhibitor AG1478 then treated with EpEX (3 µg/mL) and EGF (50 nM). Binding of HMGA2-EpICD was examined by sequential ChIP. EpICD was pulled down by a specific anti-EpICD antibody, followed by pull-down with a HMGA2 antibody. To detect bound (C) Oct4 and (D) Sox2 promoter, the cross-linked DNA was isolated and then amplified by qPCR with specific primers. N.D.: Not detected. Data represent the mean ± SD. *P < 0.05, compared with control without EGF, EpEX and AG1478 group.
Figure 7. EpEX enhances MSC bone formation by upregulating RUNX2. (A) MSCs were treated with EpEX for 14 days during osteo-induction. Calcium precipitation was measured by Alizarin Red S (ARS) staining to probe the efficiency of osteogenesis. This method shows higher calcium precipitation in EpEX (Day 14) treated cells than non-treated controls. (B) Quantification of osteogenesis, as measured by ARS staining, is shown for each group. (C) MSCs were induced by osteogenetic medium and treated with EpEX at indicated doses. The gene expression of RUNX2 was examined by qPCR. (D) MSCs were pretreated with let-7 mimetic and then treated with EpEX for 14 days during osteo-induction. ARS staining was performed to check the efficiency of osteogenesis. (E) MSCs were pretreated with let-7 inhibitor and then treated with EpEX for 14 days during osteo-induction. ARS staining was performed to check the efficiency of osteogenesis. (F) MSCs were pretreated with let-7 mimetic and then induced by EpEX. RUNX2 gene expression was measured by qPCR. (G) MSCs were pretreated with let-7 inhibitor and induced by EpEX. RUNX2 gene expression was examined by qPCR. (H) MSCs were treated with 0 or 5 μM RUNX2 inhibitor roxithromycin (RXM) then treated with EpEX (3 μg/mL) for 21 days during osteo-induction. Calcium precipitation was measured by Alizarin Red S (ARS) staining to probe the efficiency of osteogenesis (Left panel). The quantification results of the ARS staining (Right panel). Data represent the mean ± SD. *P < 0.05, compared with control without RXM and EpEX group.
Figure 8. A schematic showing the functional roles of EpCAM/EpEX in MSCs is shown. Upon EpEX stimulation, phosphorylation of EGFR-STAT3 signaling is induced and subsequently upregulates the level of Lin28 which inhibits let-7. When let-7 is inhibited, the transcription factor, HMGA2, is increased and binds to the promoters of Oct4 and Sox2. The EpEX-mediated increases of Oct4 and Sox2 can promote osteogenesis of MSCs during osteo-induction.
