ABSTRACT Regulation of gene expression by DNA-binding transcription factors is essential for proper control of growth and development in all organisms. In this study, we annotate and characterize growth and developmental phenotypes for transcription factor genes in the model filamentous fungus Neurospora crassa. We identified 312 transcription factor genes, corresponding to 3.2% of the protein coding genes in the genome. The largest class was the fungal-specific Zn2Cys6 (C6) binuclear cluster, with 135 members, followed by the highly conserved C2H2 zinc finger group, with 61 genes. Viable knockout mutants were produced for 273 genes, and complete growth and developmental phenotypic data are available for 242 strains, with 64% possessing at least one defect. The most prominent defect observed was in growth of basal hyphae (43% of mutants analyzed), followed by asexual sporulation (38%), and the various stages of sexual development (19%). Two growth or developmental defects were observed for 21% of the mutants, while 8% were defective in all three major phenotypes tested. Analysis of available mRNA expression data for a time course of sexual development revealed mutants with sexual phenotypes that correlate with transcription factor transcript abundance in wild type. Inspection of this data also implicated cryptic roles in sexual development for several cotranscribed transcription factor genes that do not produce a phenotype when mutated.

Transcriptional control by sequence-specific DNA-binding proteins is a major regulatory mechanism in all organisms (Weirauch and Hughes 2011). It has been estimated that there are >90 types of transcription factors in eukaryotes (Weirauch and Hughes 2011). Major structural classes of eukaryotic transcription factors include zinc coordinating (C2H2 and C4 zinc fingers and Zn2Cys6/C6 zinc clusters), helix-turn-helix (HTH), β-scaffold, and proteins with basic domains (basic leucine zipper/ bZIP and basic helix-loop-helix/bHLH) (Weirauch and Hughes 2011). Although zinc finger proteins predominate in eukaryotic genomes, the HTH group is the most widely conserved transcription factor group across evolution, as it comprises the majority of transcription factors in bacterial and archaeal genomes (Aravind et al. 2005; Weirauch and Hughes 2011).

Early studies proposed that transcription factors were 0.5–8% of the gene content in the genome, and that the number of genes was roughly proportional to the size of the genome (Levine and Tjian 2003). In recent years, the widespread availability of genome sequences has made it possible to annotate the actual number of transcription factor genes from numerous eukaryotic species. There are estimated to be ~19,000 protein-coding genes in humans (Ezkurdia et al. 2014). Various groups have annotated DNA-binding transcription factor genes over the years and identified >1300, with most discrepancies resulting from transcript variants for some genes (Vaquerizas et al. 2009; Wingender et al. 2013).
For example, Vaquerizas et al. (2009) annotated 1391 transcription factors, comprising 7.3% of total protein coding genes in the human genome. They found that three classes of transcription factor genes predominate in humans: C2H2 zinc finger (675 genes), homeodomain (257 genes), and bHLH (87 genes). A later study identified 1558 transcription factor genes in the human genome (8.2% of protein-coding genes), comprising 111 families in 40 classes and 10 superclasses (Wingender et al. 2013). C2H2 transcription factors were reported as the largest structural class at 53%, followed by HTH at 26%, and basic domain transcription factors at 11%. In the fruit fly Drosophila melanogaster, there are 708 genes out of 13,929 protein-coding genes (5%) that encode predicted transcription factors (Ggramates et al. 2017; Hammonds et al. 2013). C2H2 zinc fingers comprise the largest group with 255 members, followed by homeobox (101 genes), and HLH (58 genes) proteins. The model plant Arabidopsis thaliana has 1717 predicted transcription factors out of the 27,029 protein-coding genes in the genome (6.4% of genes) (Jin et al. 2015; Swarbreck et al. 2008). These genes are organized in 58 families, with the largest classes being HLH (225 genes), MYB (168 genes), AP2/ERF (139 genes), the plant-specific NAC family (138 genes), bZIP (127 genes), and C2H2 zinc fingers (116 genes).

Fungi contain several types of transcription factors not found in animals or plants, including the Zn2Cys6 (C6) zinc cluster, APSES (Neurospora crassa AS/M, Saccharomyces cerevisiae Phd1p, Aspergillus nidulans StuA, Candida albicans Efg1, and S. cerevisiae Sok2p), copper fist, STE (sterile) and Velvet classes (Iyer et al. 2002; Weirauch and Hughes 2011; Ahmed et al. 2013; Hughes and de Boer 2013). In the model yeast S. cerevisiae, there are currently 301 predicted transcription factors out of the 6604 protein-coding genes in the genome [4.6% of genes; (de Boer and Hughes 2012; Hughes and de Boer 2013; Engel et al. 2014)]. The largest class of transcription factors in the yeast genome is the C6 zinc cluster (57 genes), followed by C2H2 zinc fingers (41 proteins), bZIP (15 proteins), homeodomain (12 proteins), GATA factors (10 proteins), and bHLH (eight proteins) (Hughes and de Boer 2013).

N. crassa is multicellular fungus and eukaryotic model system that has been studied for >75 yr (Borkovich et al. 2004; Selker 2011). A genome-wide project has resulted in a nearly complete gene knockout mutant collection for the almost 10,000 genes in the genome (Colot et al. 2006; Dunlap et al. 2007; Park et al. 2011a). We had previously annotated 182 transcription factor genes in the N. crassa genome (Borkovich et al. 2004), and attempted mutation of 103 of these genes (Colot et al. 2006). We were able to isolate viable knockout mutants for 99 genes, and these were analyzed for growth and developmental phenotypes (Colot et al. 2006). The results demonstrated that 43% of the transcription factor mutants had at least one phenotype, with greater than half of these possessing multiple defects (Colot et al. 2006).

In this study, we have cataloged functions for the majority of transcription factors in a filamentous fungus. We annotate 130 more transcription factor genes in the genome, bringing the total number in N. crassa to 312. We combine the data from our earlier study (Colot et al. 2006) with that for the additional genes, presenting phenotypes for a total of 242 available viable knockout mutants. We mine an RNAseq dataset for expression of the 312 genes during different phases of sexual development. Our results demonstrate that the majority of genes yield at least one phenotype, and that multiple transcription factors are required to control different aspects of growth and development in N. crassa.

MATERIALS AND METHODS

Transcription factor gene annotation

Data from the 182 predicted transcription factor genes identified previously (Borkovich et al. 2004; Colot et al. 2006) were included in this study. This list was augmented with additional genes obtained through searches at the FungiDB or Broad Institute Neurospora Genome databases (Neurospora crassa Genome Project 2015; Staitech et al. 2012), the CIS-BP database at http://cisbp.ccb.utoronto.ca (Weirauch et al. 2014), and from a list that was generously shared with us by Luis Larroondo (Pontificia Catholic University of Chile, Santiago, Chile). All entries were evaluated in our laboratory using BLAST homology searches (Altschul et al. 1990), followed by analysis of PFAM domains using Interpro (Hunter et al. 2012). Genes encoding domain(s) established to be DNA binding transcription factors, and with E-values <10−5, were included in our final list. An exception to the DNA binding requirement was made for WD40 domain-containing transcriptional adapters, in light of their importance to growth, development, and environmental sensing in fungi.

Media and mutant construction

Vogel’s minimal medium (VM) (Vogel 1964) was used to support asexual growth and development, while synthetic crossing medium (SCM) (Westergaard and Mitchell 1947) was utilized to assess sexual development. Formation of tight colonies on plates was facilitated by growth on sorbose-containing medium plates (Davis and deSerres 1970). Hygromycin B (Calbiochem, San Diego, CA) was used at a concentration of 200 μg/ml in media where indicated. Inoculations were performed using macroconidia harvested from VM agar slants (Davis and deSerres 1970).

Wild-type strains ORS-SL6a (FGSC 4200; mat a) and 74-OR23-IVA (FGSC 2489; mat A) were obtained from the Fungal Genetics Stock Center (FGSC; Kansas State University, Manhattan, KS). Available transcription factor mutants (homokaryons or heterokaryons) were obtained from the FGSC, or produced in our laboratory (see Supplemental Material, Table S1 for strain and phenotype information). All N. crassa gene numbers are preceded by the prefix “NCU.” We attempted purification of homokaryons from 28 heterokaryotic transformants that were available from the FGSC or our laboratory stocks (Table S1) using sexual crosses (as described in Colot et al. 2006) or streaking of macroconidia in the vegetative phase (Davis and deSerres 1970). All putative homokaryons were checked for the presence of the knockout cassette using hph and gene flank-specific primers by polymerase chain reaction as described (Ghosh et al. 2014). Those strains purified through streaking of macroconidia were also screened for the absence of the wild-type open reading frame using gene-specific primers. This step was not needed for the cross progeny, since the ascospore meiotic products are homokaryons. We were able to successfully purify 15 mutants using this approach (Table S1). Two additional mutants (NCU07430/mad-1 and NCU09496 ) were purified using this method, but were inviable after storage (Table S1). Another seven mutants were removed due to the observation in another study that the strains carry a secondary mutation that results in female sterility (Fu et al. 2011). In summary, a total of 70 mutants were not available for analysis at the time of this study, either due to failures in construction of knockout cassettes; changes in gene annotation that made the knockout mutant unusable, or resulted in the knockout mutant not being made; incorrect insertion of knockout cassettes in the genome; the inability to purify homokaryotic mutants from transformants, secondary mutations; or because the original purified knockout mutant was inviable after storage (Table S1). This left us with 242 viable homokaryotic mutants for study.

Phenotypic analysis

The 242 viable mutants were analyzed for phenotypes using methods described in Cabrera et al. (2015), Ghosh et al. (2014), Park et al. (2011b), and Turner (2011). Data were obtained from the Broad...
Institute Neurospora website (Neurospora crassa Genome Project 2015) or from experiments performed for this study. Some of the data at the Broad Institute website was previously published (Colot et al. 2006). The combined data are presented in Table S1. We have omitted measurements of pigmentation and aerial hyphae height on yeast extract-containing medium from our analysis (Cabrera et al. 2015). Near-isogenic wild type strains FGSC4200 and/or FGSC2489 were used as a control for all determinations. Race tubes made of glass or prepared from disposable plastic pipets were used for quantitative analysis of hyphal growth rates (Dharmananda and Feldman 1979; White and Woodward 1995). Multiple race tubes were analyzed for each mutant, with a minimum of four independent replicates with \( R^2 > 0.95 \) used to obtain the average growth rate. The wild-type growth rate range for data obtained from Colot et al. (2006) and the Broad Institute Neurospora Database was 70–85 mm/d, while that from this study was 75–85 mm/d (see also legend in Table S1). Binned data from Colot et al. (2006) and/or the Broad Database were averaged to allow comparison to actual growth rate measurements.

Aerial hyphae height was assessed after incubation of 2-ml VM standing liquid cultures for 3 d in the dark at room temperature, with at least six replicates/strain. Mutants that displayed a growth rate <70 or >85 mm/d, or an aerial hyphae height measurement <30 or >45 mm (over 3 d), were considered significantly different than wild type (Table S1). Macroconidia production was qualitatively assessed by visual inspection of VM agar slants incubated for 3 d in the dark at 25°C, followed by 4 d in light at room temperature, with at least four replicates/strain. Three stages of sexual development were qualitatively analyzed using SCM agar slants cultured in constant light at room temperature: formation of protoperithecia after 7 d; development of perithecia from protoperithecia 7 d after fertilization with opposite mating type wild-type conidia; and ascospore shooting from mature perithecia 14 d after fertilization. The quantity and size of protoperithecia, perithecia, and ascospores were observed using a SBAP0 stereomicroscope with a DFC280 digital camera (Leica Microsystems, Buffalo Grove, IL), or an Olympus SZX9 stereomicroscope with a C-4040 digital camera (Olympus, Lake Success, NY). At least four replicates were analyzed for each strain.

### Clustering of transcription factor gene expression data and heatmap generation

A sexual development time course RNAseq dataset (Wang et al. 2014) was mined for expression of the 284 transcription factor genes essentially as described (Cabrera et al. 2015). To allow visualization of the expression data, heat maps were produced using heatmap (V1.0.2) (Kolde 2015) in R V3.1.1; (R Development Core Team 2014). The scaling function in heatmap was used to normalize expression data, with the reads per kilobase of transcript per million mapped reads (RPKM) values at each time point for a given gene normalized to the RPKM at the time point with lowest expression for that gene.

### Naming of transcription factor genes

In keeping with the N. crassa convention, and the naming used in our previous study (Colot et al. 2006), unnamed transcription factor genes whose mutations revealed phenotypes received names that reflected the defects. Strains showing abnormalities in all three phenotypes, basal hyphal extension during vegetative growth, asexual development, and sexual development are known as all development altered (ada). Strains showing altered hyphal growth and asexual development are named as vegetative asexual development (vad). Mutants with normal hyphal growth but altered sexual and vegetative development are referred to as sexual and vegetative development (svd), while those with defects in vegetative hyphal growth and sexual development are called vegetative and sexual development (vad).

### Data availability

N. crassa knockout mutants and wild-type strains are available upon request. File S1 contains detailed descriptions of Supplemental Figures. Table S1 contains genotypes and phenotypes for each mutant. Sequence data are available at the GenBank and FungiDB databases, and the NCU accession numbers for each transcription factor gene are listed in Table S1.

### RESULTS

#### Annotation of additional transcription factor genes in the N. crassa genome

In this study, we annotated an additional 130 transcription factor genes in N. crassa, bringing the total number to 312 (Table 1 and Table S1). This corresponds to 3.2% of the 9760 protein-coding genes in the genome (Stajich et al. 2012), a proportion that is comparable to S. cerevisiae. We identified 25 classes of transcription factors with a single domain, and seven groupings with two distinct domains (Figure 1 and Table 1). The largest group of transcription factors is the C6 transcription factors (Table 1). This is more than twice the number identified in S. cerevisiae (57), despite both organisms having a similar number of transcription factors (Hughes and de Boer 2013).

The second largest group in N. crassa is the C2H2 zinc finger, with 54 genes possessing only C2H2, and seven also containing a second domain, for a total of 61 genes (20% of transcription factors)—a number greater than observed for S. cerevisiae [41 genes; (Hughes and de Boer 2013)]. The third, fourth, and fifth largest groups of transcription factors in N. crassa are the bZIP (23 genes; 7.4% of total), MYB (16 genes with single domain; one gene with two domains; 5.4% of total), and bHLH (13 genes; 4.2% of total) (Figure 1 and Table 1). N. crassa has significantly more single domain bZIP (23 vs. 15), bHLH (13 vs. 8), and MYB factors (16 vs. 6) (Hughes and de Boer 2013). Finally, we identified a total of nine genes with two distinct domains, corresponding to 2.9% of the annotated transcription factors (Table 1). As noted above, the most common domain in the genes with two domains was the C2H2 zinc finger, with seven genes (Table 1).

#### Mutant production and analysis of hyphal growth phenotypes

All mutants used in this study were produced during the Neurospora Genome Project (Dunlap et al. 2007), which included a high throughput gene knockout project (Colot et al. 2006; Dunlap et al. 2007; Collopy et al. 2010; Park et al. 2011a). Each mutant carries a gene replacement mutation, with insertion of a hygromycin resistance gene cassette in place of the open reading frame (Colot et al. 2006). There were instances...

Table 1 Phenotype summary
where gene annotation changes or issues with primer, knockout cassette or strain construction rendered some mutants unusable, or unable to be produced (see Materials and Methods and Table S1 for details). In the end, we were able to assemble a group of 242 viable mutants for phenotypic analysis (78% of the total genes; Table 1). The mutants included homokaryons for the four putative essential genes described in our earlier study (Colot et al. 2006), which were isolated by streak-purifying in vegetative phase or by screening many ascospores: NCU00340/ pp-1, asl-1/NCU01345, ts (formerly asl-2; NCU01459), and cpc-1/ NCU04050.

We analyzed the 242 viable mutants for an array of growth and developmental phenotypes, beginning with the linear growth rate on minimal medium (Colot et al. 2006; Turner 2011). N. crassa grows by polar extension, branching, and anastomosis (fusion) of tube-like structures called hyphae to form the web-like multicellular structure termed the mycelium (reviewed in Springer 1993; Borkovich et al. 2004; Glass et al. 2004; Selker 2011). Hyphae contain incomplete crosswalls (septa) that separate cellular compartments, but allow distribution of metabolites and organelles throughout the mycelium (Glass et al. 2004).

We assessed the hyphal growth rate of the mutants on minimal medium using race tubes (Dharmananda and Feldman 1979; White and Woodward 1995). The results demonstrated that 105 mutants had growth rates significantly different from wild type (43% of viable mutants), and altered growth rate was the predominant phenotype in the transcription factor mutants (Figure 2 and Table 1). Consistent with its size, the transcription factor class (present alone or with a second domain) with the largest absolute number of mutants with hyphal growth defects was the C6 family (31/103 viable mutants; 30%; Figure S1 in File S1 and Table 1). The C2H2 group had a slightly higher proportion of mutants with hyphal growth phenotypes (19/51 mutants; 37%; Figure S1 in File S1 and Table 1). However, there were several transcription factor classes with 65–100% of the mutants exhibiting a hyphal growth phenotype. For example, 100% of the mutants with CP2, HSF, and WD40 domains had a hyphal growth defect. Similarly, 10/12 BHLH genes yielded phenotypic data, and nine of these had a growth rate phenotype (75% of viable mutants; Figure S1 in File S1). For genes with the MYB domain, 13/17 were represented as viable mutants, and 8/13 (62%) had a hyphal growth defect (Figure S1 in File S1 and Table 1).

Less than half of the mutants possessed a growth rate significantly slower than wild type (range of 70–84 mm/d; Figure 3A and Table S1). Several mutants displayed a growth rate within the 60–64 and 65–69 mm/d increments, while far fewer were found in the groups with the slowest growth rates (Figure 3A). The <59 mm/d groups contained representation from several transcription factor classes, with loss of the WD40 gene, rco-1/NCU06205 (Yamashiro et al. 1996), resulting in the slowest growth rate observed in our study (Figure 3A and Table S1). Only two mutants grew faster than wild type: one lacking the C6 zinc finger gene fgr-1/NCU10597, and one deleted for the APSES gene vsd-S/NCU07587 (Figure 3A and Table S1).

Figure 1 Relative distribution of N. crassa transcription factor genes into major classes. Each “slice” of the pie represents the fraction of mutants with the indicated domain. The number of mutants with each domain is indicated. The MISC (Miscellaneous) group includes the 20 domain classes with four or fewer members (see Table 1).
Asexual development defects

_N. crassa_ produces two types of asexual spores, microconidia, and macroconidia (Springer and Yanofsky 1989; Springer 1993; Bistis et al. 2003). Microconidia are small, unicellular, and relatively non-abundant, and are difficult to observe under laboratory conditions (Springer 1993; Bistis et al. 2003). In contrast, the multinucleated macroconidia are produced profusely in wild-type cultures (Springer and Yanofsky 1989). The macroconidiation (hereafter referred to as conidiation) pathway is regulated by oxygen/reactive oxygen species, carbon and nitrogen availability, high temperatures, blue light, and the circadian rhythm (Springer and Yanofsky 1989; Hansberg et al. 1993; Springer 1993; Greenwald et al. 2010; Baker et al. 2012). Due to these multiple layers of regulation, wild type does not form conidia in submerged liquid cultures unless subjected to heat shock, carbon stress, or nitrogen stress (Cortat and Turian 1974; That and Turian 1978; Plesofsky-Vig et al. 1983; Guignard et al. 1984; Madi et al. 1997). The conidiation pathway begins with adhesion of basal hyphae, followed by growth of aerial hyphae that rise perpendicular to the growth surface (Springer and Yanofsky 1989; Hansberg et al. 1993; Springer 1993). Aerial hyphae form branches, with some transitioning from hyphal growth to apical budding as constrictions form between cellular compartments at the hyphal tip (Springer and Yanofsky 1989). With time, the constrictions tighten to separate the mature multinucleated conidia.

Several transcriptional regulatory proteins have been identified that regulate aspects of conidiation in _N. crassa_. For example, mutants lacking the transcription factor _fluffy_ ([fl/NCU08726; (Bailey and Ebbole 1998)] and the transcriptional adapter _rco-1_/NCU06205 (Yamashiro et al. 1996) are blocked at distinct points in the process. Other work has demonstrated transcription factors that influence conidiation under different environmental conditions or the extent of conidiation, including _vad-5_/NCU06799 (Sun et al. 2012), _chc-1_/NCU00749 (Sun et al. 2011) and _hsf-2_/NCU08480 (Thompson et al. 2008). The _white collar complex_ (WCC) containing the transcription factors _wc-1_/NCU02356 and _wc-2_/NCU00902 has been demonstrated to directly control expression of 24 transcription factor genes under blue light regulation (Smith et al. 2010; Chen et al. 2009).

In this study, we identified 92 transcription factor mutants (38% of total mutants) with a defect in aerial hyphae height and/or conidia production (Figure 2 and Table 1). Of these 92 strains, the majority (87; 95%) displayed an aerial hyphae phenotype, either singly (69 mutants; 75%) or in combination with a conidiation defect (18 mutants; 20%) (Table S1). A total of five mutants (5%) had a conidiation defect with normal aerial hyphae height (Table S1). Similar to what was observed for hyphal growth rate, and in keeping with the large number of genes in this family, the C6 transcription factor class had the largest number of mutants with a phenotype (37; 36% of all mutants with C6 domain; Figure S1 in File S1 and Table 1). However, other domain classes had a larger proportion of viable mutants with an asexual development defect, including HSF (2/2; 100%), GATA (5/7; 71%), WD40 (2/3; 67%), HMG-box (2/3; 67%), and MYB (7/13; 54%) (Table 1).

Of the mutants with an aerial hyphae height defect, the majority had shorter aerial hyphae (60 mutants; 65%; Figure 3B and Table S1). However, in comparison to the hyphal growth rate analysis described above, there were more mutants with aerial hyphae height greater than wild type (27 mutants; 29%; Figure 3, A and B and Table S1). The large C6 family dominated the mutants at both ends of the aerial hyphae height spectrum, while other groups appeared in only one section. For example, the _Fap1_ (tah-9/NCU06551) and _CP2_ (csp-2/NCU06905) class transcription factor mutants were all taller than wild type, with the _csp-2_ mutant the tallest in our study (Table S1). The other end of the spectrum includes mutants lacking genes with two transcription factor domains: the _C2H2 + STE_ mutant _pp-1_/NCU00340, the _ARID + MYB_ mutant _svd-1_/NCU04079 and the _ARID + APSES_ mutant _ada-9_/NCU01238, which were all shorter than wild type (Table S1). Similar to observations for hyphal growth rate, the WD40 mutant _ico-1_/NCU06205 had the shortest aerial hyphae overall (Table S1).

Inspection of the qualitative data for conidia production in agar slants showed that a total of 23 mutants was affected (Table S1). Three mutants were increased (lacking the _C2H2 cre-1_/NCU08807, _C2H2 + STE_ _pp-1_/NCU00340, and _MYB ada-22_/NCU08003), and 16 reduced, relative to wild type (Table S1). Three mutants (lacking the _C6_ gene _fl_/NCU08726, the _BZIP ada-1_/NCU00499, and the _ARID/BRIGHT ada-20_/NCU05891) did not form any conidia (Table S1), and the _kal-1_/NCU03593 homeodomain mutant had an abnormal conidiation pattern (Colot et al. 2006). The mutant lacking the _MYB_ gene _rco-1_/NCU07834 had a conidiation defect as its only phenotype (Table S1).

Sexual development phenotypes

_N. crassa_ is a hermaphrodite, in that a single colony produces female and male gametes. However, _N. crassa_ is not self-fertile, requiring that the female and male cells be of opposite mating type [ _matA_ and _mata;_ (Raju 1992)]. Nitrogen starvation induces differentiation of female reproductive structures (_protoperithecia_ (Raju 1992)) from the basal hyphae of the mycelium (see wild-type image in Figure 4B). Protoperithecial development begins with coiling, extension, adhesion, and then septation and branching of hyphae to form a coil (Lord and Read 2011). Enveloping hyphae encircle the coil, and then grow and branch to form the protoperithecum. Mating occurs when male-receptive hyphae (trichogynes) from the mature female structure grows toward a male (typically an asexual spore; macro- or microconidium) of opposite mating type in a process involving a pheromone response (Bistis 1983). After fusion of the trichogyne and conidium, the nuclei from the male and female divide synchronously to form the ascogenous hyphae within the developing peritheicum (Raju 1992) (see wild-type image in Figure 4B). Nuclear fusion and meiosis takes place in a specialized cell type (crozier). The peritheciun enlarges, meilanezes, and forms a beak at the tip as the meiotic progeny (ascospores) mature within. Ascospores are then forcibly ejected from a hole (ostiole) in the tip of the beak (Raju 1992). The entire sexual cycle can be completed within 2.5 wk (Davis and deSerres 1970). Blue light is an important
environmental cue for sexual development, regulating the abundance of protoperithecia.

In the budding yeast *S. cerevisiae*, only a few genes necessary for sexual development and meiosis are transcription factors (Chu et al. 1998; Kassir et al. 1988, 2003; Primig et al. 2000; Enyenihi and Saunders 2003). Our earlier study revealed 15 transcription factor genes that regulate aspects of sexual development in *N. crassa*, and mutation of 13 of these genes resulted in a complete block in ascospore production.
Work from other laboratories has identified genes encoding the transcription factors *asm-1*/NCU01414 (Aramayo et al. 1996), *asd-4*/NCU15829 (Feng et al. 2000), *pp-1*/NCU00340 (Li et al. 2005), and *tan spore [ts]/NCU01459; (McCluskey et al. 2011) all of which influence sexual development.

All strains were cultured on synthetic crossing medium plates in constant light at room temperature for 7 d to facilitate development of protoperithecia (top panels). Cultures were then fertilized using macroconidia from a wild-type strain of opposite mating type. Plates were then incubated under the same conditions for a further 7 d to allow production of fertilized perithecia and beak development (bottom panels). Images of protoperithecia were captured using an Olympus SZX9 stereomicroscope with a C-4040 digital camera, while perithecia were photographed using a S8APO stereomicroscope with a DFC280 digital camera. White arrows indicate unfertilized protoperithecia (top panels), while black arrows show protoperithecia (*fmf-1*) or perithecia (wild-type and *vsd-5* mutant) 7 d after fertilization (bottom panels). The beak at the tip of a perithecium can be seen as the darkened circular area above the black arrow in wild type (bottom left panel), while *vsd-5* mutant perithecia lack this structure (bottom right panel).

**Figure 4** Transcription factor mutants with defects in sexual development. (A) Summary of sexual cycle phenotypes. The total number of mutants with the indicated sexual cycle phenotype is shown in each lobe of the Venn diagram. Mutants with reduced number or abnormal phenotypes (red font) or complete block (black font) are scored according to the stage of their earliest defect. (B) Examples of mutants with different sexual cycle phenotypes. All strains were cultured on synthetic crossing medium plates in constant light at room temperature for 7 d to facilitate development of protoperithecia. Cultures were then fertilized using macroconidia from a wild-type strain of opposite mating type. Plates were then incubated under the same conditions for a further 7 d to allow production of fertilized perithecia and beak development. Images of protoperithecia were captured using an Olympus SZX9 stereomicroscope with a C-4040 digital camera, while perithecia were photographed using a S8APO stereomicroscope with a DFC280 digital camera. White arrows indicate unfertilized protoperithecia (top panels), while black arrows show protoperithecia (*fmf-1*) or perithecia (wild type and *vsd-5* mutant) 7 d after fertilization (bottom panels). The beak at the tip of a perithecium can be seen as the darkened circular area above the black arrow in wild type (bottom left panel), while *vsd-5* mutant perithecia lack this structure (bottom right panel). (C) Clustering of mRNA expression data for *N. crassa* transcription factors during a time course of sexual development. Left side of figure: RNAseq data were obtained from Wang et al. (2014). Expression data for 43 of the 47 transcription factor genes with a sexual cycle phenotype were contained in the data set. Clustering analysis and heatmap generation were performed as described in the Materials and Methods. Red shading denotes greater levels of expression, while blue indicates lower expression. The numbers along the left side of the figure indicate groupings (1–6) based on similar patterns of expression during sexual development. The table on the right side of the figure is a phenotype summary for the mutants lacking each transcription factor. The open circles denote that the indicated structure is abnormal or that a reduced number is formed, while closed circles show that the indicated structure is not formed. The absence of a circle indicates there was no defect observed. PP, Protoperithecia; P, Perithecia; A, Ascospores.
sub-1/NCU01154 produced protoperithecia that were submerged in the agar. Six different transcription factor families contribute to proper perithecial bead development; the homeodomain mutant bek-1/NCU000997 (Krystofova and Borkovich 2006), the C6 mutant bek-2/NCU07139, the BHLH mutant vsd-3/NCU08999 and the BZIP mutant ada-1/NCU00499 completely lacked perithecial beads, while four mutants had a reduced number of perithecial beads (C2H2 genes cre-1/NCU08807 and vsd-9/NCU07952, BHLH bsd-3/NCU05970, and APSES vsd-5/NCU07587; Table S1). The bead defect of vsd-5 is presented in Figure 4B.

**Correlation between phenotypes and gene expression during sexual development**

We took advantage of a publicly available dataset for a time course during perithecial and ascospore development (Wang et al. 2014) to investigate expression of transcription factor genes. This dataset includes eight time points (0, 2, 24, 48, 72, 96, 120, and 144 hr) after fertilization with opposite mating type wild type. Time = 0 corresponds to nitrogen-starved vegetative hyphae and unfertilized protoperithecia just before application of wild type conidia. Perithecia are obvious at the 24 hr time point, while croziers (evidence of meiosis) appear at 48–72 hr. Asci containing the meiotic progeny are formed after 96 hr, and perithecial beads at 120–144 hr.

We first interrogated the data for transcription factor genes that yielded a sexual cycle phenotype (Figure 4C). There were several genes for which phenotypes and gene expression showed a correlation (Figure 4C). For example, Group 1 genes, with expression peaking early from 0 to 2 hr, included 6/9 mutants with defects in protoperithecial development, and 100% with perithecial phenotypes. The expression pattern and high proportion of perithecial defects suggests roles in fertilization for this group. Group 2 genes peak at 48 hr (time of meiosis), with 100% of the mutants possessing an ascospore defect. Group 4 genes are highly expressed from 72 to 144 hr and 4/5 of the corresponding mutants have a defect in perithecial formation and ascospore development/shooting. The large Group 6 is generally highly expressed late (120–144 hr), with 11/14 and 12/14 of the mutants exhibiting defects in perithecial and ascospore development, respectively. The more heterogeneously expressed Group 2 and 5 genes did not follow strict expression patterns, but all but one gene yielded a protoperithecial phenotype.

We next mined the expression data to identify cotranscribed genes in the same class of transcription factors (Figure S2 in File S1). This analysis revealed several instances of similarly expressed genes where one produced a moderate (nonblocking) sexual cycle phenotype, and the second a nonblocking defect or no phenotype, suggesting possible redundancy. The MYB genes rca-1/NCU01312 (no sexual phenotype) and vsd-4/NCU09329 (severely reduced ascospores) are expressed at lower levels from 0 to 48 hr, with steady, elevated expression from 72 to 144 hr (Figure S2A in File S1), suggesting redundant roles late during sexual development. The C2H2 genes vsd-3/NCU06487 (reduced number of ascospores) and vsd-12/NCU05035 (no sexual phenotype) are highly expressed at 120–144 hr, the time of ascospore production (Figure S2B in File S1). The C2H2 genes NCU02487 (no sexual phenotype) and vsd-3/NCU06487 (reduced number of ascospores) are highly expressed in unfertilized protoperithecia (t = 0), and from 120 to 144 hr, when ascospores are produced (Figure S2B in File S1). The C2H2 genes vsd-9/NCU07952 (reduced ascospores) and NCU03699 (no sexual phenotype) are coordinately expressed, with a dip at 48 hr (time of meiosis) and 144 hr (ascospore maturation) (Figure S2B in File S1). The C6 class genes vsd-4/NCU01243 (reduced number ascospores) and acu-15/NCU06656 (normal sexual development) are both highly expressed in protoperithecia, and then peak again from 24 to 48 hr, at the time of meiosis (Figure S2C in File S1).

**Associations between phenotypes during different phases of the lifecycle**

We identified a total of 154 mutants with at least one phenotype during growth or development (64% of viable mutants; Table 1). Inspection of mutants with two defects revealed 34 with growth and asexual development phenotypes, 12 with growth and sexual development defects, and six with phenotypes in asexual and sexual development, totaling 21% of the viable mutants (Figure 2 and Table 1). There were 19 strains with defects in all three stages assayed (growth, asexual development, and sexual development), comprising 4.1% of the mutants (Figure 2 and Table 1). Of interest, the majority of mutants with a conidiation defect also exhibited reduced hyphal growth rate (27/92 mutants; 82%). A lesser proportion also possessed sexual cycle defects (17/28 mutants; 61%). These observations suggest a possible linkage between the ability to produce conidia and growth rate and/or sexual development.

As our quantitative data for growth rate and aerial hyphal height were both obtained using vegetative (asexual) cultures, we investigated a possible relationship between these two phenotypes in our entire population of mutants (Figure 3C). Visual inspection of the plot did not reveal a clear correlation, and regression analysis of a line drawn through the global data had an R^2 value of only 0.165 (Figure S3 in File S1), not supporting a linear relationship between growth rate and aerial hyphal height. When we restricted the data to mutants with a defect in at least one trait, the R^2 value dropped to 0.144 (data not shown). Therefore, the growth rate of basal hyphae and aerial hyphal height appear to be independent traits in our group of transcription factor mutants.

We also investigated phenotypes for the group of 24 WCC-regulated transcription factor genes (Smith et al. 2010). We were most interested in whether two major phenotypes that are known to be light-regulated—asexual and sexual development—were prevalent in this group of genes. Three of the genes did not pass our requirements to be classified as transcription factors (NCU002275, NCU06534, and NCU07846). Of the remaining 21 genes, we have complete phenotypic data for 18 mutants (Table S1), while phenotypes for another mutant (ve-1/NCU05964) have been published (Bayram et al. 2008). Nine of these 19 mutants have defects in asexual sporulation, two have both asexual and sexual sporulation phenotypes, and three mutants have only sexual cycle defects, for a total of 14 mutants (74%) with a sporulation phenotype (Figure S4A in File S1). Of interest, two of the mutants that lack phenotypes in asexual or sexual sporulation (NCU07705 and/or-1 and NCU08000) are similarly expressed during sexual development (Figure S4B in File S1; neighbors on the heat map), suggesting possible redundancy during this process. Taken together, our results mesh well with the findings of the earlier study (Smith et al. 2010), and support these transcription factors as potential second-level regulators in the blue light gene expression hierarchy that regulates asexual and sexual development in *N. crassa*.

**DISCUSSION**

We have analyzed phenotypes in available mutants for annotated transcription factor genes in *N. crassa*. Overall, 64% of the mutants analyzed possessed at least one growth or developmental phenotype. The largest proportion of mutants exhibited defects in hyphal growth rate, either alone or in combination with another defect. This result underscores the importance of transcriptional regulation to the various steps of hyphal growth, including spore germination, hyphal growth...
and polarity, branching, and anastomosis. The latter two phenomena are often accentuated in slow-growing mutants (so-called colonials; Brody and Tatum 1966; Kolmark 1969) and this may contribute to the slow growth rate of some of the mutants in our study.

Inspection of data for individual transcription factor classes revealed several with a large number of genes with defects and/or skewing toward specific defects. For transcription factor classes represented by more than two mutants, 100% of the ARID/BRIGHT, NDT80 and WD40 mutants possessed phenotypes. The majority (83%) of GATA factor mutants possessed defects in asexual development, while 75% of the BHLH and 62% of the MYB domain mutants had a growth rate phenotype. There was less concentration of sexual development defects in certain classes, with WD40 (67%) and MYB (58%) having the largest proportion of mutants with sexual cycle phenotypes.

Comparison of our current data with our original analysis of 99 viable transcription factor mutants revealed several phenotypes that were greatly under-represented in the earlier study. For example, there has been a fivefold increase in mutants with only a basal hyphal growth rate phenotype, and a fourfold increase in mutants with defects in both growth rate and asexual development. There were zero and one mutants with hyphal growth/sexual development and asexual development/sexual development phenotypes, respectively (Colot et al. 2006); there are now 12 mutants in the first group and six mutants in the second (Figure 2). In general, the more than doubling of the number of mutants analyzed has resulted in discovery of more genes that affect basal hyphal growth and asexual development. This difference also contributes to the increase in the relative number of genes that yield phenotypes, from 40% (Colot et al. 2006) to 64% (this study).

We have previously applied our phenotypic screening platform to other large gene families in N. crassa, including serine-threonine protein kinases [77 mutants; (Park et al. 2011b)], serine-threonine protein phosphatases [24 mutants; (Ghosh et al. 2014)] and G protein coupled receptors [GPCRs; 36 mutants; (Caberra et al. 2015)]. The percentage of transcription factor mutants with at least one growth/developmental phenotype (64%) is less than that for the protein phosphatases (91%), but greater than that observed for GPCRs (47%) and protein kinases (57%). Comparison between these groups reveals that the proportion of mutants with hyphal growth rate defects is relatively low for GPCRs (14%), but similar for the protein kinase (42%), transcription factor (43%), and protein phosphatase (50%) genes. In the case of asexual sporulation, the fraction of affected mutants was identical/near identical for transcription factors (38%), GPCRs (39%) and protein kinases (40%), but significantly higher for protein phosphatases (58%). For sexual development, GPCRs and transcription factors had a much lower proportion of genes with phenotypes (17 and 19%, respectively) than the protein kinases (42%) and protein phosphatases (63%). There were also striking differences in the percentage of mutants with defects in all three categories among the four groups, from GPCRs with no such mutants, to 8% of transcription factor, 26% of protein kinase, and 29% of protein phosphatase mutants. The lower number of transcription factor and GPCR mutants with sexual development defects or phenotypes in all three categories analyzed may reflect greater gene redundancy in transcription factors and GPCRs. We hypothesize that there may be greater functional redundancy in genes at the opposite ends of the environmental sensing spectrum (receptors and transcription factors), than with those more involved in signal transduction and integration (kinases and phosphatases). This may be more obvious during sexual development due to the large number of cell types involved (Bistis et al. 2003), and the need to coordinate cell morphogenesis with meiosis. Alternatively, the greater apparent redundancy may reflect functions for receptors and transcription factors that are not currently being analyzed in our phenotypic assays. Testing of these and other alternative hypotheses will require further investigation.

Transcription factor genes have been annotated in several other filamentous fungal species. In the genus Trichoderma, the biological control agents and mycoparasites Trichoderma virens and Trichoderma atroviride, and the efficient cellulose degrader and industrial species T. reesei have 641, 592, and 448 transcription factor genes, respectively (Schmoll et al. 2016) (51, 50, and 49% of the genes in each genome). The two mycoparasitic species exhibited a large expansion in the C6 zinc cluster transcription factor family, with 382 genes for T. atroviride and 422 for T. virens, compared to 258 in T. reesei. In Aspergillus nidulans, there are 490 annotated transcription factors, corresponding to 4.6% of the predicted genes (Wortman et al. 2009). Similar to Trichoderma species, A. nidulans has significantly more C6 genes than N. crassa [330 genes; (Wortman et al. 2009)]. A more recent study reported the number of C6 zinc cluster transcription factor genes in three Aspergillus species, with 180 in A. clavatus, 276 in A. nidulans, and 306 in A. flavus (Chang and Ehrich 2013). In contrast to C6 proteins, the number of C2H2 proteins reported for other species is similar to, or even less than in, N. crassa, with 60 in A. nidulans (Wortman et al. 2009), 61 in T. virens, 53 in T. atroviride, and 49 in T. reesei (Schmoll et al. 2016). Thus, the larger number of C6 proteins in these other fungi is not due to a proportional increase in all transcription factor families. Rather, it appears that the expansion of the fungal-specific C6 class is a major contributor to the greater number of transcription factors overall in Trichoderma species and A. nidulans relative to N. crassa. The reduced size of the C6 class in N. crassa may result, at least in part, from Repeat-Induced Point Mutation (RIP), a mechanism that mutants duplicated DNA sequences during the sexual cycle and that has been hypothesized to limit the size of gene families in the N. crassa genome (Galagan et al. 2003; Selker 1990).

In this study, we investigated functions for 242 predicted transcription factor genes during growth and asexual and sexual development in N. crassa. Considering the significant sample size and the accompanying penchant for gene redundancy, our results revealed a surprisingly large proportion of mutants with at least one phenotype. We identified numerous genes that lack sexual cycle phenotypes that are coordinately expressed with other genes with nonblocking phenotypes during sexual development. This suggests that these genes possess overlapping functions during sexual differentiation, a hypothesis that can be addressed in future experiments through construction of mutants lacking multiple transcription factor genes. This work has augmented our knowledge of the functions of transcription factors during growth and development in filamentous fungi.
