We present experimental studies of nanosecond electric modification of the order parameter (NEMOP) in a variety of nematic materials with negative dielectric anisotropy. The study demonstrates that NEMOP enables a large amplitude of fast (nanoseconds) electro-optic response with the field-induced birefringence on the order of 0.01 and a figure of merit (FoM) on the order of $10^4$ $\mu$m$^2$/s; the latter is orders of magnitude higher than the FoM of the Frederiks effect traditionally used in electro-optic nematic devices. The amplitude of the NEMOP response is generally stronger in nematics with larger dielectric anisotropy and with higher natural (field-free) birefringence.

Nematic liquid crystals (NLCs) have numerous electro-optic applications enabled by anisotropy of their properties. The optic axis of the NLC is called the director $\mathbf{n}$. In typical electro-optic applications, an AC electric field applied to a dielectrically anisotropic NLC is used to realign the director and, thus, to change the effective birefringence $\delta n$ or phase retardance $\Gamma = d\delta n$, where $d$ is the length of pathway of light in the NLC. Very often, in applications such as displays, optical shutters, modulators, switches, and beam steers, a desirable mode of operation is to switch large retardance within a short period of time, characterized by a figure of merit $\text{FoM} = \Gamma^2/(\pi^2\tau_{\text{off}})$, where $\tau_{\text{off}}$ is the relaxation time of retardance to its field-free state. The process of dielectric reorientation is relatively slow, on the scale of milliseconds, especially, during the field-off stage. The typical FoM is on the order of a few $\mu$m$^2$/s. The speed of switching can be accelerated by a variety of approaches, such as optimizing the viscoelastic parameters of the NLCs, overdriving, realigning an NLC in a submicrometer-templated polymer network with the response time on the order of 0.1 ms or by employing a dual-frequency NLC in a special geometry with layers of unidirectionally rubbed polyimide PI-2555 (HD MicroSystems). The cells are assembled in a parallel fashion. The field applied across the cell does not change the orientation of $\mathbf{n}$ and only modifies the orientational order.

We explore materials of different birefringence $\Delta n = n_{||} - n_{\perp}$ and dielectric anisotropy $\Delta \varepsilon$, as specified in Table I: HNG705800-100, HNG715600-100 (purchased from Jiangsu Hecheng Display Technology), MCT-5 (Kingston Chemicals), MLC-2079, MLC-2080, ZLI-2806, ZLI-4330, MJ961200, MJ97731, MJ951152, MAT-03-382, MAT-08-192 (all Merck), and CCN-47 (Nematel GmbH). The RC time $\tau_{\text{RC}}$ was less than 4 ns for all cells.

In order to measure the electric field induced optical response, we use a laser beam (He-Ne, $\lambda = 632.8$ nm) linearly polarized along the direction that makes an angle of 45° with the incidence plane of the NLC slab, Fig. 1. The beam passes through the cell, Soleil-Babinet compensator, and the analyzer crossed with the polarizer, see Ref. 4 for the detailed description. The transmitted light intensity is measured using a photodetector TIA-525 (Terahertz Technologies, response time <1 ns). The test cells are...
sandwiched between two prisms, so that the incident angle of light beam is 45° with respect to the normal to the cell, in order to eliminate the contribution of director fluctuations to the optical response,4 Fig. 1.

The temperature of cell assemblies is controlled with Linkam LTS350 hot stage. A voltage pulse of duration 400 ns is applied using a pulse generator HV 1000 (Direct Energy). The pulse generator creates voltage pulses with sharp rise and fall edges of characteristic time 1 ns. The applied voltage pulses and photodetector signals were measured with 1 G sample/s digital oscilloscope TDS2014 (Tektronix).

The NEMOP response is observed in all the materials studied, Table I and Figs. 2 and 3. For a given driving voltage applied to cells of approximately the same thickness (ranging from 4.5 to 5.1 μm), the field-induced birefringence \( \delta n \) depends strongly on the NLC used. Among all the studied materials, the mixture HNG715600-100 displays the largest NEMOP effect, with \( \delta n \approx 0.013 \) at applied voltage pulse of amplitude \( U_0 = 873 \) V, which is an order of magnitude higher than the one achieved in CCN-47, Fig. 2(a) and Table I.

Fig. 2(b) shows the optical response of HNG715600-100 cell of thickness 5.1 μm to the applied voltages of different amplitude \( U_0 \). The experimentally determined profile of the optical response is well fitted by the theoretical model,4 in which

\[
\delta n(t) = \frac{1}{\sqrt{2\pi \Delta n_{LC}}} \left( \frac{1}{2} \delta_{nu}(t) + \frac{3}{4} \delta_{nb}(t) \right),
\]

where \( \Delta n_{LC} \) is the average refractive index of NLC, \( \delta_{nu} \) and \( \delta_{nb} \) are the uniaxial and biaxial contributions to the optic tensor. The dynamics of \( \delta_{nu} \) and \( \delta_{nb} \) is modeled within the Landau-Khalatnikov approach12

\[
\frac{d\delta_{nu}(t)}{dt} = \chi_n E^2(t) - \delta_{nu}(t),
\]

with the solution

\[
\delta_{nu}(t) = \int_0^t \frac{\chi_n E^2(t')}{\tau_i} \exp \left( \frac{t' - t}{\tau_i} \right) dt'.
\]

FIG. 1. Experimental setup: A test cell sandwiched between two right angle prisms, probed with a linearly polarized laser beam that propagates inside the nematic slab at the angle 45° with respect to the cell normal.

![Experimental setup](image)

FIG. 2. (a) Dynamics of field-induced birefringence \( \delta n(t) \) in response to a voltage pulse \( U(t) \) (filled triangles) for HNG715600-100 (disks), HNG705800-100 (open squares), MLC-2080 (open triangles), CCN-47 (open circles), and MCT-5 (diamonds). (b) Dynamics of \( \delta n(t) \) for HNG715600-100 in response to voltage pulse of amplitudes \( U_0 = 337 \) V (crosses), 522 V (open triangles), 706 V (disks), and 873 V (open circles). Fitting with \( \tau_u = 33 \) ns, \( \tau_b = 3 \) ns, \( \chi_n = 9.2 \times 10^{-19} \text{ m}^2/\text{V}^2 \), and \( \chi_b = 6.8 \times 10^{-19} \text{ m}^2/\text{V}^2 \) is shown by the solid line. All data were determined at room temperature (22 °C), except those for CCN-47 (43 °C) and MCT-5 (90 °C).
despite the fact that most of the materials in Table I represent complex mixtures of different chemicals.

The two important parameters of the NEMOP response are the amplitude of field-induced birefringence $\delta n$ and the response time $\tau$, Fig. 3. The voltage dependence of $\delta n$ is generally quadratic, Fig. 3(a), with some deviations observed at high voltages. The highest values of $\delta n$ are achieved in the two mixtures HNG715600-100 and HNG05800-100 which also demonstrate the highest dielectric anisotropy. However, the dielectric anisotropy is not the only factor that determines the amplitude of NEMOP: As seen from Table I, CCN-47 with high dielectric anisotropy yields a relatively weak response. The natural birefringence $\Delta n$ is also not a clear single indicator of how strong is the NEMOP response might be, as HNG705800-100 with a relatively modest $\Delta n = 0.08$ produces a high $\delta n \approx 0.008$.

The dynamics of optical response is determined by the uniaxial and biaxial modifications of the order parameter, so that $\tau = \max(\tau_u, \tau_b)$. In most of the studied materials, the slowest process is the relaxation of uniaxial contribution with the characteristic time $\tau_u$ that is on the order of tens of nanoseconds, Fig. 3(b), much slower than $\tau_b \approx 1$ ns. As seen in Fig. 3(b), the values of $\tau$ are voltage-independent, as expected by the model. In some materials, such as MCT-5, $\tau$ is extremely short, 1 ns or so, which is again an order of magnitude better than the case of the previously studied CCN-47, Table I. Extreme smallness of $\tau$ requires further exploration of the physical mechanisms behind the order parameter dynamics in these materials.

To conclude, we explored the nanosecond switching in a number of NLCs with negative dielectric anisotropy in which the applied electric field causes uniaxial and biaxial modifications of the order parameter but does not realign the director. We found that all of the explored nematics demonstrate a substantial field-induced birefringence, ranging from 0.01 to 0.001 at applied field on the order of $10^4$ V/m. The corresponding FoM that characterizes how much of optical retardance can be switched within a certain time, is on the order of $10^5$ $\mu m^2$/s, which is at least one order of magnitude higher than the FoM for dual-frequency nematics and two-three orders of magnitude higher than the values achieved in Frederiks switching of regular nematics. The significant improvement of the FoM is rooted in the very nature of the NEMOP effect in which the dynamics is controlled by the molecular response and in which the field-on and field-off relaxation times are essentially the same, being in the range of nanoseconds and tens of nanoseconds. The latter fact is a distinct beneficial feature of the NEMOP electro-optics, since in the Frederiks effects involving director reorientation within the timescale of milliseconds, the field-on time can be accelerated by a very high field, but the field-off state is typically much slower. Instead of the voltage pulses, one could also employ optical light pulses. The efficiency and versatility of optical driving can be greatly expanded by using photosensitive azobenzene-based LCs that respond to nanosecond laser pulses and show a broad variety of relaxation times ranging from 1 ms to many hours, depending on the chemical structure, as described by Hrozhyk et al.

The very high FoM demonstrated in this work is achieved in relatively thin cells of thickness about 5 $\mu m$. Note that the switching time in the NEMOP effect does not depend on the thickness of the cell, which allows one to further increase the FoM defined in the case of NEMOP as $(\delta dn)^2/\pi^2 \tau$, by increasing the pathway of light $d$ (say, by using thicker cells) while preserving the time of switching $\tau$. In the regular Frederiks effect, the response time typically grows as the square of the cell thickness.

The data also demonstrate that the electro-optic performance of NEMOP effects depends strongly on the material parameters such as dielectric and optical anisotropy. The level of optimization achieved in this work might be potentially advanced by further exploration of different materials. The NEMOP effect can enable ultrafast electro-optic effects in applications ranging from displays to shutters, limiters, modulators, switches, and beam steerers, as the switchable optical retardance reaches the required levels of half-wavelength.
