Abstract – The formation, maintenance and reorganization of the cytoskeletal filament network is essential for a number of cellular processes. While the crucial role played by active forces generated by motor proteins has been studied extensively, only recently the importance of passive forces exerted by non-enzymatic crosslinkers has been realized. The interplay between active and passive proteins manifests itself, e.g., during cell division, where the spindle structure formed by overlapping microtubules is subject to both active sliding forces generated by crosslinking motor proteins and passive forces exerted by passive crosslinkers, such as Ase1 and PRC1. We propose a minimal model to describe the stability behaviour of a pair of anti-parallel overlapping microtubules resulting from the competition between active motors and passive crosslinkers. We obtain the stability diagram which characterizes the formation of stable overlap of the microtubule pair, identify the controlling biological parameters which determine their stability, and study the impact of mutual interactions between motors and passive crosslinkers on the stability of these overlapping filaments.

Introduction. – The structural integrity of an eukaryotic cell is provided by the cytoskeleton filament network comprised of microtubules (MTs) and actin filaments [1]. The ability of the cell to reorganize itself to develop spatiotemporal structures out of these cytoskeletal filaments is vital for the process of cell division, morphogenesis and movement [1,2]. This ability hinges crucially on the activity of the motor proteins which attach and move on these cellular filaments and generate active stresses that cause reorganization of the cytoskeletal filaments [2–10]. A paradigmatic example in this context is the formation of a spindle during mitotic cell division. The spindle structure comprises of overlapping anti-parallel MTs originating from centrosome poles within the cell. These overlapping arrays of anti-parallel MTs are subject to active sliding forces exerted by bipolar motor proteins such as Eg5 and kinesin-8 [6] which attach simultaneously to the two overlapping filaments and slide them with respect to each other. These molecular motors use the stored chemical energy from ATP hydrolysis to generate the sliding forces, driving the cytoskeleton out-of-equilibrium. While in vitro and in vivo studies of mitotic spindle have established the centrality of the role played by the molecular motors in the organization of the cytoskeleton network [7–12], relatively less attention has been paid to the role of passive filament crosslinkers such as Ase1, PRC1 and MAP65 [13–17]. While it has been known earlier that these passive crosslinkers provide structural integrity of the filament network and increases the effective friction between the sliding filaments, recent experiments have also shown that these entities are capable of generating entropic forces by harnessing the thermal energy from the cellular environment and are also involved in determining the stability and reorganization of the cytoskeletal filament network along with the molecular motors [13,14].

Two mechanisms that lead to entropic forces between filaments have been identified in out-of-equilibrium cytoskeletal filament networks and in passive polymer systems. On the one hand, in a suspension of cytoskeletal filaments and small non-adsorbing polymers, such as polyethylene glycol (PEG), the volume occupied by the
filaments is unavailable for the depletant PEG polymers \[18\]. Decreasing the excluded volume due to the filaments which is achieved by filament bundling and maximizing the overlap of the filaments, is entropically favorable. The gain in free energy for two overlapping filaments is proportional to their overlap length, \( l \), and the associated entropic force acting along the long axis of the two filaments is constant, independent of the \( l \), set by the osmotic pressure of the depletant polymers and associated geometric factors \[13,18,19\]. On the other hand, overlapping microtubules in a mitotic spindle confine freely diffusing, passive crosslinkers, such as Ase1 and MAP65 \[14\]. As a result, the confined proteins exert an effective pressure which tends to increase \( l \), with a strength that increases linearly in the number of crosslinkers and inversely proportional to \( l \) \[13\]. Another mechanism of force generation between treadmilling actin filaments in the presence of crosslinking proteins has been identified in context of formation of actin rings during mitotic cell division \[20\]. It has been argued that if the treadmilling filaments are linked by passive crosslinkers, then stresses can be generated in the filament bundle due to the fact that the passive crosslinkers are simultaneously bound to filaments and the ends of the depolymerizing filament \[20\].

These studies have highlighted the relevance of entropic forces in biological networks \[14\], which are relevant also to understand the self-assembly of biofilament bundles \[19\], and shown to be potentially relevant in spindle geometries \[20–22\].

In this letter we identify an alternative mechanism for the generation of sliding forces by passive crosslinking proteins. In contrast to previous mechanisms \[13,14\], we take into account the exchange of passive protein crosslinkers with the environment in which the filaments are suspended. As a result, if the evolution of the overlap length, \( l \), is much slower than the exchange rate of the passive crosslinkers with the environment, the passive crosslinkers decrease the effective free energy of the complex by an amount that increases linearly with \( l \). As we will show, passive crosslinkers induce an entropic force that increases with their density, \( \phi \), independent of \( l \), unlike the entropic forces exerted by confined passive crosslinkers \[9,13,14\].

We first describe the model and obtain the phase diagram associated with the linearly stable behaviour of a pair of overlapping anti-parallel MTs. We then identify the relevant biological parameters which control the system stability. We also consider the stability of overlapping MTs for the situation where the passive crosslinking proteins in the overlap interact with the active motor crosslinkers.

**Model.** — We consider a pair of anti-parallel microtubules with an overlap length \( l \) as depicted in fig. 1. In the overlap region, kinesins motors can crosslink anti-parallel MTs and slide them away from each other, generating an active outward force which tends to decrease the overlap length \( l \). The motor proteins (un)binding kinetics in the overlap region is expressed in terms of rate equations for two populations of motors, e.g., \( n_b \) which is the average number of motors crosslinked to the MT filaments, and \( n_o \) which is the average number of motors when they are attached to only one of the two overlapping filament. Passive crosslinkers linear density, \( \phi \), in the two filament overlapping region is set by the Langmuir kinetics between bulk and the filaments.

First we describe the case corresponding to the situation where the passive crosslinkers do not interact with motor proteins. Subsequently we look at the impact that these interactions have on the stability of crosslinked anti-parallel MTs.

*Non-interacting motor-passive crosslinkers - MTs.* The binding free energy of the passive crosslinkers to the microtubule, \(-\epsilon_o\), induces a net inward force on the pair of anti-parallel MT, \( F_p = -\frac{\partial E}{\partial l} \), associated with the total free energy reduction, \( E = -\epsilon_o\phi l \), due to the passive crosslinkers. Additional details of passive crosslinker’s binding can be included, e.g., accounting for the possibility that they bind to one of or the two overlapping filaments. This will require an additional kinetic equation that describes the interconversion between these two bound states. However, we restrict ourselves to a simpler description to focus on the essential effect that passive crosslinkers have on the stability of the anti-parallel overlaps of MTs/motor complexes. While in general under *in vivo* conditions the (−) end of the filament may also be coupled to the cell cortex, we focus our attention only on the overlap dynamics resulting from the interplay of the motor proteins and the forces exerted by the passive crosslinkers in the overlap region. We consider the relative motion of a pair of anti-parallel filaments. In the absence of the crosslinkers, the overlapping filaments will slide with respect to each other with a velocity \( 2v_o \), where \( v_o \) is the motor velocity of the crosslinking motors in the absence of any external load. The load force exerted by the passive crosslinkers on the molecular motors will reduce their average sliding velocity. Assuming a linear force-velocity relation for the motor
velocity with equal load sharing between the crosslinked motors, the overlap length $l$ evolves as

$$
\frac{dl}{dt} = -2v_o \left( 1 - \frac{F_p}{n_c F_p} \right) + \frac{1}{\Gamma} F_p, \tag{1}
$$

where $f_o$ stands for the stall force for a single motor and $\Gamma$ is the friction coefficient associated to the motion of the filaments against their embedding medium [22].

Due to the passive force experienced by the crosslinked motors, the unbinding rate of the motors from the crosslinked state to single filament bound state grows exponentially with the load force felt by the individual motors [23]. The corresponding dynamics of the average number crosslinked motors $n_c$ can then be expressed as

$$
\frac{dn_c}{dt} = k_b n_b - k^o_o n_c \exp \left( \frac{b F_p}{n_c k_B T} \right), \tag{2}
$$

where $k_b$ and $k^o_o$ are the rates with which the uncrosslinked motors are converted to crosslinked state and vice-versa in the absence of external load force, and $b$ is the length scale characterizing the activation process leading to unbinding from the crosslinked state of the motor.

The number of bound motors in the overlapped region which are not crosslinked, $n_b$, evolves due to interconversion between bound and crosslinked motor states, (un)binding process of free unbound motor on to the filament, and the incoming flux of bound motors $2J$ from the two boundaries of the overlap region. When the overlap length is much smaller than the MT length, $J = \frac{k_B T}{k^b_o} [v_o F_p + \frac{F_p}{n_c}]$ [7,23]. Thus, the dynamic equation for $n_b$ can be expressed as

$$
\frac{dn_b}{dt} = k^b_o n_c \exp \left( \frac{b F_p}{n_c k_B T} \right) - (k^o_o + k_b) n_b + k^{3D}_b \rho_{3d} l \frac{d\ell}{dt} + \frac{2k^b_o \rho_{3d}}{k^o_o} \left( \frac{v_o F_p}{n_c f_o} + \frac{F_p}{F_p} \right), \tag{3}
$$

where $\rho_{3d}$ is the density of suspended motors in the bath, and $k^{3D}_b$ is the binding rate of the free motors to the filament in the overlap region.

The behaviour of a pair of anti-parallel filaments that is subject to sliding forces due to motors and passive crosslinkers is determined by $n_c$, $n_b$ and $l$, and correspondingly, eqs. (1)–(3) describe the dynamics of the composite composed of filaments, motors and passive crosslinkers. We rescale time in units of $1/k^o_o$, overlap length in terms of the average run length of single motor, $l_p = v_o/k^o_o$ and forces in terms of $k_B T/b$. We also introduce a length scale associated with the characteristic forces experienced by the passive crosslinkers, $l_c = o_c b/k_B T$. We define dimensionless variables $\tau = t k^o_o$, $\tilde{f}_s = b f_s/k_B T$, $\tilde{l} = l/l_p$, $\tilde{\Gamma} = 2v_o T / k_B T$ and $\phi_o = l_c \phi$. Then eqs. (1)–(3) can be re-expressed in terms of these dimensionless variables as

$$
\frac{d\tilde{l}}{d\tau} = \frac{2\phi_o}{n_c} + 2\tilde{f}_s \left( \phi_o - 1 \right), \tag{4}
$$

$$
\frac{dn_c}{d\tau} = \gamma n_b - n_c \exp \left( \frac{\phi_o}{n_c} \right), \tag{5}
$$

$$
\frac{dn_b}{d\tau} = n_c \exp \left( \frac{\phi_o}{n_c} \right) + \Delta_n \left( \tilde{l} + \frac{2\phi_o}{n_c} + \frac{4\tilde{f}_s \phi_o}{\Gamma} \right) - (1 + \gamma) n_b. \tag{6}
$$

We identify the relevant control parameters associated with motor-filament interaction. The linear density of the passive proteins, $\phi_o$, is one of the biologically relevant control parameters. We also identify $\Delta_n = \frac{\rho_{3d} k^b_o v_o}{f_s k^o_o b}$, which measures the strength of the unbinding force on the molecular motors, and $\tau = \frac{t}{k^o_o}$, which quantifies the asymmetry in motor attachment/detachment at vanishing load force, as relevant biological control parameters.

Interacting motor-passive crosslinkers - MTs. Until now, in formulating the evolution equations governing the dynamics of overlapping filaments, we have not taken into account the mutual interaction between the passive crosslinkers with the motors. However, in general the passive crosslinker proteins will interact with motor proteins [15–17,21]. For instance, in experiments with reconstituted system comprising of MT and crosslinking protein PRC1, it has been observed that these crosslinking proteins had an effective attractive interaction with kinesin motors in the overlap region [16,17]. We quantify the interaction strength between passive proteins and motor crosslinkers with a coupling parameter, $a$, in terms of which we propose a simple interaction free energy $F = -\phi(l_o = a n_c + a n_b)$ and a corresponding force, $F^+_p = \phi(c + a n_c + a n_b)$. Although it has been argued on theoretical grounds that excluded volume interactions between diffusing passive proteins and motors can lead to phase segregation in the overlap region [21], for the sake of simplicity, we consider homogeneous admixture of motors and passive crosslinkers in the overlap region and focus on the impact of the simplest coupling between the passive crosslinkers and the molecular motors. We quantify this coupling through the dimensionless coupling constant $\alpha_v \equiv ab/l_c k_B T$. Accordingly, the relevant dimensionless force becomes $\tilde{F}^+_p = \phi_o + \alpha_v \phi_o n_c + \alpha_v \phi_o n_b$. While positive values of $\alpha_v$ correspond to a repulsive interaction between the passive crosslinkers and the motors, negative values of $\alpha_v$ correspond to an attractive interaction between the crosslinking motors and the passive proteins.

The corresponding scaled equations of motion describing the dynamics of the system read as

$$
\frac{d\tilde{l}}{d\tau} = \frac{2\phi_o}{n_c} + 2\tilde{f}_s \left( \phi_o - 1 \right) + 2 \alpha_v \phi_o \left( 1 + \frac{n_b}{n_c} + \frac{\tilde{f}_s (n_c + n_b)}{\Gamma} \right), \tag{7}
$$

58003-p3
\[
\frac{dn_c}{d\tau} = \gamma n_b - n_c \exp\left(\frac{\phi_o + \alpha_o \phi_o + \alpha_o \phi_o n_b}{n_c}\right),
\]
(8)

\[
\frac{dn_b}{d\tau} = -(1 + \gamma) n_b + n_c \exp\left(\frac{\phi_o + \alpha_o \phi_o + \alpha_o \phi_o n_b}{n_c}\right)
+ \Delta_n \left( \frac{\tilde{l}}{n_c} + 4\tilde{f} \phi_o \frac{\Delta_n}{\Gamma} \right)
+ 2\Delta_n \alpha_o \phi_o \left(1 + \frac{n_b}{n_c} + 2\tilde{f} (n_c + n_b)\right).
\]
(9)

Equations (7)–(9) describe the dynamical behavior of the system when the motors interact with passive proteins. In order to analyze the stability behavior for this system (with and without mutual interaction between crosslinking motors and passive proteins), we first obtain steady-state solutions for \(n_c, n_b\) and \(l\) and perform a linear stability analysis about the fixed point to obtain the stability diagram for obtaining a stable overlap of the anti-parallel MTs. For the case of motors interacting with the passive crosslinkers, the fixed points can be obtained numerically and the corresponding stability curve separating regions of stable overlap with the unstable region is also obtained numerically. If the passive proteins interact preferentially with the crosslinked motors alone, then the corresponding sliding force acting on the overlapping filaments simplifies to \(F_p = \epsilon_o \phi + \alpha o n_c\). Equations (7)–(9) simplify accordingly, and the analytical expression for the fixed points and the corresponding linear stability boundaries can be obtained.

**Results.** – We analyze the stability of a complex composed by overlapping anti-parallel MT that traps kinesin motors and passive crosslinkers. We analyze the impact that the different types of interactions induced by the passive crosslinker have on the stability of the MT-motor complex as a function of the relevant biological control parameters. Equations (7)–(9) highlights the relevance of \(\Delta_n\) and concentration of passive crosslinkers \(\phi_o\), and we focus on their impact on the mechanical properties of these active complexes.

**Non-interacting motor-passive protein-MT system.** The passive crosslinker entropy is the only contribution to the stability of the complex in this regime. The steady-state state solutions, which correspond to the fixed points of eqs. (4)–(6), read

\[n'_c = \phi_o / g,\]
\[n'_b = \phi_o \exp(g) / \gamma g,\]
\[\tilde{l}' = \phi_o \exp(g) / \gamma g \Delta_n - 2g - 4\tilde{f} \phi_o / \tilde{\Gamma},\]
(10)

where \(g = \tilde{f}\left(1 - \phi_o / \Gamma\right)\). Since \(n'_c > 0\), all steady-state morphologies must satisfy \(\phi_o < \tilde{\Gamma}\). Analogously, the restriction that \(\tilde{l} > 0\) implies \(\Delta_n < \Delta_n^c\), which implicitly depends on the force \(\tilde{F}_p\). A linear stability analysis around those steady solutions leads to the eigenvalue equation which is of the form

\[\lambda^3 + a_1 \lambda^2 + a_2 \lambda + a_3 = 0,\]

where \(a_1 = 1 + \gamma - (g - 1) \exp(g), a_2 = 2g^2 \gamma \Delta_n / \phi_o - (g - 1) \exp(g)\) and \(a_3 = 2g^2 \gamma \Delta_n / \phi_o\).

When one of the roots is real and negative, the other two are complex conjugate, the stability boundary corresponds to the curve \(a_3 = a_2 a_1\), as the real part of the complex conjugate pair changes sign. Accordingly, the phase boundary separating stable from unstable morphologies of anti-parallel overlapping MTs, reads

\[\Delta_n = \frac{\phi_o G}{2g^2 \gamma} \left(1 + \frac{1}{\gamma - G}\right),\]
(11)

where \(G = (g - 1) \exp(g)\) is a function of \(\phi_o = \ell \phi\). On the linear stability boundary the real part of the relevant complex eigenvalue vanishes. Hence the pure imaginary eigenvalues lead to a finite frequency \(f_{\omega}\), which characterizes the intrinsic oscillations of the MT complex at the threshold of linear stability. The expression for \(f_{\omega}\) reads as

\[f_{\omega} = \frac{1}{2\pi} \sqrt{\frac{2g^2 \Delta_n \gamma}{\phi_o} - G}.\]
(12)

As shown in fig. 2, the linear stability analysis has allowed us to span the whole phase diagram of the anti-parallel MT complex as a function of concentration of passive crosslinkers, \(\phi_o\), and \(\Delta_n\), a measure of motor flux in the overlap

\[\text{Fig. 2: (Color online) Phase diagram of the system in } \phi_o-\Delta_n \text{ plane, when there is no interaction between passive crosslinkers and the molecular motors (} \alpha_o = 0\). The solid (red) line is the linear stability boundary. The dashed (blue) curve corresponds to } \tilde{l}' = 0 \text{ with } \Delta_n = \Delta_n^c. \text{ The dash-dotted (green) line corresponds to } n'_c = 0 \text{. The enclosed region (bounded by the red, blue and green curves) denoted by } s \text{ corresponds to the stable physical overlap of the MT filaments. For this region, } n'_c > 0 \text{ and } l' > 0 \text{ and the overlap is stable. } u_1 \text{ and } u_2 \text{ are the subregions within the linearly unstable region where the fluctuations about the fixed points grow with and without oscillations, respectively. Here } \tilde{l}' = 1.9, \gamma = 1, \tilde{\Gamma} = 1.\]
Fig. 3: (Color online) Effect of the variation of $\gamma$ on stability: (a) $\gamma = 3$, (b) $\gamma = 5$, (c) $\gamma = 10$ and (d) $\gamma = 20$. $u$ denotes the unstable region, while $s$ indicates the stable region. Here $\alpha_o = 0$ (no interaction between passive crosslinkers and motors). Other parameter values are $f_s = 1.9$, $\Gamma = 1$.

region. Overlapping anti-parallel MTs requires a positive overlap $\bar{U} > 0$, which restricts the physically meaningful region of phase diagram, and leads to an upper bound for the strength of the motor flux $\Delta_n^c = \frac{\phi_o e^{\frac{s}{2}}}{{\gamma}(2s^2+4f_s\phi_o)}$ as a function of the passive crosslinker density.

In fig. 2, the unshaded region corresponds to physically meaningful overlapping MTs for which both ($\bar{U} > 0$) and $n_c > 0$. This region is bounded by the dashed blue curve, above which $\Delta_n^c$ region of phase diagram, and leads to an upper bound for the amplitude of oscillations diminished with time, when the time to eventually disintegrate the overlap of MTs for the unstable region, while $s$ indicates the stable region. Here $f_s = 1.9$, $\Gamma = 1$.

Interacting motor-passive protein-MT system. From eqs. (7)–(9) we can identify the two distinct sets of fixed points that quantify the steady states when there is mutual interaction only between the passive crosslinkers and crosslinked motor proteins, which read as

$$n_s^f = 1/\omega_{\pm} = \left\{ -\eta \pm \sqrt{\eta^2 - 4\alpha_o \phi_o^2 f_s \bar{U}} \right\} / 2\alpha_o \phi_o f_s,$$

$$n_s^f = \exp(\phi_o \omega_{\pm} + \alpha_o \phi_o) / \gamma \omega_{\pm},$$

$$\bar{U} = \exp(\phi_o \omega_{\pm} + \alpha_o \phi_o) / \gamma \Delta_n \omega_{\pm} - 2 \phi_o \omega_{\pm} - 2 \alpha_o \phi_o - 4f_s \phi_o / \Gamma - 4f_s \alpha_o \phi_o / \omega_1 \Gamma,$$

where $\eta = \Gamma (\alpha_o \phi_o - g)$

For attractive interactions between passive crosslinkers and motors ($\alpha_o < 0$), the solution of the fixed point corresponding to $\omega_+$ cannot be sustained since $\omega_+$ is always negative, leading to $n_s^f < 0$. For repulsive interactions ($\alpha_o > 0$), the solution of the fixed point corresponding to $\omega_+$ leads to an unstable fixed point. Thus, only the solution corresponding to $\omega_-$ leads to physically relevant steady states. The corresponding expression for the stability boundary is

$$\Delta_n = \frac{\Omega \left(1 - \frac{1}{\Omega - \gamma}\right)}{2\gamma \left[ \omega_1^2 \phi_o + \alpha_o \phi_o / \Gamma \left(1 - \frac{1}{\Omega - \gamma} - 2\right) \right]},$$

where $\Omega = (\phi_o \omega_- - 1) \exp(\phi_o \omega_- + \alpha_o \phi_o)$. In this regime also intrinsic, spontaneous, oscillations develop at the

When $\alpha_o > 0$, the set of fixed points corresponding to $\omega_+$ has always at least one real positive root for the eigenvalue equation for the fluctuation spectrum which corresponds to a linearly unstable fixed point.
The stable physical overlap. Here $\alpha$ denotes the unstable region, while $s$ denotes the region of the stable physical overlap. Here $f_s = 1.9$, $\Gamma = 1$, $\gamma = 1$ and $\alpha_o = 0.2$.

The expression of the frequency of oscillation on the linear stability boundary is

$$f_\omega = \frac{1}{2\pi} \sqrt{\frac{4\alpha_o \Delta n \gamma f_s - \alpha}{\Gamma}} \Omega (14)$$

Figure 4 displays the phase diagram in the $\phi_o$-$\Delta_n$ plane for different interaction strengths, $\alpha_o$, when passive proteins only interact with crosslinked motors. Both for attractive, $\alpha_o < 0$, and repulsive, $\alpha_o > 0$, interactions, increasing the interaction, $\alpha_o$, reduces the region of stable physical overlap of MTs. Significantly, when $\alpha_o < 0$ there is no upper bound of passive crosslinkers, $\phi_o$ (fig. 4(a) and fig. 4(b)), beyond which a stable MT physical overlap can be obtained. This is in contrast to the situation for which there is no interaction ($\alpha_o = 0$) as illustrated in fig. 1 or when there is attractive interaction between the crosslinked motors and crosslinking passive proteins as shown in fig. 4(c) and fig. 4(d), for which there is an upper bound of $\phi_o$, beyond which physical overlap of MTs cannot be obtained.

Figure 5(a) and fig. 5(b) show the comparison of the phase diagrams for the case in which passive proteins interact only with crosslinked motors with the case for which the passive crosslinkers interact with both bound and crosslinked motors. For the latter case, there is substantial reduction of the region in the phase diagram for which physical stable overlapping MTs can be obtained. Finally, fig. 6 shows that increasing $\gamma$ decreases the region where overlapping MTs are stable when passive proteins interact with both the bound and the crosslinked motors.

**Experimental relevance.** We can estimate the typical overlap length of MTs and motor numbers using experimental data known for biological systems. For single motor velocity, $v_o = 1\mu \text{m s}^{-1}$ [24,25], and the bare unbinding rate $k_o = 1\text{s}^{-1}$ [24,25], the typical processivity length $l_p = 1\mu \text{m}$. Using the value of thermal energy, $k_B T = 4.2 \text{pN nm}$ [26], and length scale associated with unbinding process of motors, $b = 1.3\text{nm}$ [27], an estimate for the additional reference length scale, $l_c = 2.6\text{nm}$, is obtained. Experimental measurement for the stall force for kinesin, $f_s = 6\text{pN}$ [24,25], in turn implies $f_s \sim 1.9$. For an experimental estimate of the binding rate, $k_b = 5\text{s}^{-1}$ [24,25], we get $\gamma \sim 5$. Indeed under different physiological conditions, $\gamma$ may vary one order of magnitude [26]. Furthermore, we consider that passive crosslinkers bind with a characteristic energy, $\epsilon_o = 2k_B T$. Quantitative estimate of the friction coefficient of passive crosslinkers at low concentrations [13] implies that the scaled friction coefficient $\Gamma \sim 1$. Assuming a linear density of passive crosslinkers, $\phi = 0.35\text{nm}^{-1}$, and choosing the bath motor concentration such that $p_{BD} = 0.17\text{µm}^{-1} \text{s}^{-1}$ (corresponding to $\phi_o = 0.9$, $\Delta_n = 0.9$, the point is marked with “s” in fig. 2) we obtain an estimate of the stable overlap length $\sim 0.45\mu \text{m}$ with bound and crosslinked motor numbers being $n_o \sim 7$, and $n_c \sim 6$, respectively. These estimates fall well within the scale of cellular processes and thus suggest that the interplay between the active forces due to motors and the passive crosslinkers is a biologically relevant mechanism in determining the stability of overlapping MT filaments.

**Summary and discussion.** In summary we have shown that the presence of passive crosslinkers qualitatively impacts the mechanical properties of arrangements of overlapping biofilaments that are subject to active sliding forces due to molecular motors. These forces arise due to the interaction of passive crosslinkers with overlapping filaments in the presence of a passive crosslinker bath. This is a distinct mechanism from other passive force generating mechanisms such as entropic forces due to confinement or forces due to depletant molecules. We have shown that for a pair of anti-parallel MTs, the interplay of sliding forces due to such passive proteins crosslinkers with
active sliding forces due to molecular motors can stabilize the overlapping filament pair. Further, we have identified that this passive mechanism is necessary to ensure the emergence of stable overlaps. The effect of attractive mutual interaction between passive crosslinkers and active motors leads to an enhanced range of passive crosslinker density for which stable overlapping MT pair can be obtained while a repulsive interaction between the motors and passive crosslinkers tends to diminish the domain of stable overlaps.
