ABSTRACT
We use K-band spectroscopy of the counterpart to the rapidly variable X-ray transient XMMU J174445.5-295044 to identify it as a new symbiotic X-ray binary. XMMU J174445.5-295044 has shown a hard X-ray spectrum (we verify its association with an Integral/IBIS 18-40 keV detection in 2013 using a short Swift/XRT observation), high and varying $N_H$, and rapid flares on timescales down to minutes, suggesting wind accretion onto a compact star. We observed its near-infrared counterpart using the Near-infrared Integral Field Spectrograph (NIFS) at Gemini-North, and classify the companion as $\sim$M2 III. We infer a distance of $3.1^{+1.8}_{-1.1}$ kpc (conservative 1σ errors), and therefore calculate that the observed X-ray luminosity (2-10 keV) has reached to at least $4 \times 10^{34}$ erg s$^{-1}$. We therefore conclude that the source is a symbiotic X-ray binary containing a neutron star (or, less likely, black hole) accreting from the wind of a giant.

Key words: (stars:) binaries: symbiotic – stars: late-type – stars: neutron – infrared: stars – X-rays: binaries – X-rays: individual: XMMU J174445.5-295044

1 INTRODUCTION
Symbiotic binaries transfer mass via the winds of cold (usually late K or M) giants onto compact objects: white dwarfs, neutron stars or black holes (Kenyon 1986), with orbital periods typically in the 100s to 1000s of days (Belczyński et al. 2000). They were first identified by the presence of high-periods typically in the 100s to 1000s of days (Belczyński et al. 2000). They were first identified by the presence of high-amplitude periodicities in the X-ray light curves (Nespoli et al. 2010). Several other likely candidate systems have also been proposed (e.g. Nucita et al. 2007; Masetti et al. 2011, Hynes et al. 2014). The identification and characterization of a symbiotic X-ray binary requires clear information on the nature of the accretor (e.g. from pulsations or unusual luminosities) and the donor (e.g. from spectroscopy). Heinke et al. (2009) identified XMMU J174445.5-295044 as a rapidly variable (timescales down to 100s of seconds) Galactic transient, using nine XMM-Newton, Chandra, and Suzaku observations. It showed 2-10 keV X-ray fluxes up to $>3 \times 10^{-11}$ erg cm$^{-2}$ s$^{-1}$, and variations in $N_H$, from $8 \times 10^{22}$ up to $15 \times 10^{22}$ cm$^{-2}$. The rapid variations and variable $N_H$ suggested accretion from a clumpy wind, rather than an accretion disk. Heinke et al. (2009) also identified a bright near-infrared (NIR) counterpart (2MASS J17444541-2950446) within the 2" XMM error circle. Heinke et al. (2009) calculated the probability of a star of this brightness appearing in the X-ray error circle as only 2%, indicating that it is almost certainly the true counterpart. This star appears highly obscured and shows infrared colors typical of late-type stars, which Heinke et al. suggested indicates that XMMU J174445.5-295044 is a symbiotic star or symbiotic X-ray binary.

The INTEGRAL Galactic bulge monitoring program Kuulkers et al. (2007) reported an X-ray transient detected

2 Bahramian et al.

by the JEM-X monitor on March 23, 2012 (Chenevez et al. 2012), at 17:44:48, -29:51:00, with an uncertainty of 1.3′ at 95% confidence, consistent with XMMU J174445.5-295044. The 10-25 keV flux of 1.5±0.3 × 10\(^{-10}\) erg cm\(^{-2}\) s\(^{-1}\) is larger than previously reported for XMMU J174445.5-295044, but the high estimated \(N_H\) (not specified, but the JEM-X source was undetected below 10 keV, indicating \(N_H > 10^{23}\) cm\(^{-2}\)) suggests that this is likely the same source, as it is known to exhibit similarly large intrinsic extinction (Heinke et al. 2004). In March 2013, the INTEGRAL IBIS telescope detected a hard transient at 9.3 ± 1.4 × 10\(^{-11}\) erg cm\(^{-2}\) s\(^{-1}\) (17-60 keV), at position 17:44:41.76, -29:48:18.0, uncertainty 4.2′ (Krivonos et al. 2013). Krivonos et al. note that this position is consistent with XMMU J174445.5-295044, but suggest that follow-up observations are needed to verify whether it is the same source.

In this paper, we present Gemini NIFS spectroscopy of 2MASS J17444541-2950446, and conclude that its spectral type indicates a M2 III giant. We also describe a Swift/XRT observation permitting the confident identification of the 2013 INTEGRAL/IBIS transient (Krivonos et al. 2013) with XMMU J174445.5-295044. We combine these results to infer a peak \(L_X > 4 \times 10^{32}\) erg s\(^{-1}\). These results together allow us to confidently identify XMMU J174445.5-295044 as a symbiotic X-ray binary containing a neutron star or black hole accretor, rather than a white dwarf.

2 DATA AND ANALYSIS

2.1 Swift/XRT

We observed XMMU J174445.5-295044 with Swift/XRT on March 30th, 2013 (two days after the INTEGRAL/IBIS detection of Krivonos et al. (2013) in photon-counting mode. The observation was interrupted after an on-source exposure of ~150 seconds due to a Gamma-ray burst alert. We detect a single source in the 23.6′ diameter field, showing 7 counts. Using FTOOLS xrtcentroid we determine the position to be \(\text{RA} = 17:44:46.26\) and \(\text{DEC} = -29:50:56.08\) with positional uncertainty of 9′, consistent within <2′ with the position of XMMU J174445.5-295044. Given the lack of other X-ray sources nearby (see figure 4 of Heinke et al. 2009), the Swift/XRT source is thus certainly the same as XMMU J174445.5-295044.

We reprocessed the Swift/XRT data (using HEASOFT 6.14), extracted a spectrum with XSELECT, and created an effective area file with xrtmkarf. We fit the Swift/XRT spectrum with an absorbed power-law using cstat statistics (Cash 1979) in XSPEC 12.8.1, fixing the photon index to 1.18 (as found in the deepest and most-constrained observation of Heinke et al. 2009). We measure \(N_H = 4.5^{+7.2}_{-3.5} \times 10^{22}\) cm\(^{-2}\) and an unabsorbed 2-10 keV flux of \(8.5^{+10.3}_{-5.0} \times 10^{-12}\) erg s\(^{-1}\) cm\(^{-2}\), the second-highest 2-10 keV flux recorded from XMMU J174445.5-295044.

If the INTEGRAL/IBIS measurement is extrapolated (using the spectrum above) to the 2-10 keV band, the Swift/XRT flux measurement is 1/3 of the INTEGRAL measurement. Such a high flux from XMMU J174445.5-295044 only two days after the INTEGRAL/IBIS detection, combined with the lack of other detections within the 4.2′ INTEGRAL/IBIS error circle, indicates that XMMU J174445.5-295044 was the origin of the INTEGRAL/IBIS detection.

The 2012 INTEGRAL/JEM-X detection (Chenevez et al. 2012), with a smaller error circle of 1.3′, can also be confidently assigned to XMMU J174445.5-295044.

We created long term X-ray lightcurves of XMMU J174445.5-295044, calculating X-ray luminosities in the 2-10 keV band using our calculated 3.1 kpc distance (see below). In Figure 2 we show the published detections of XMMU J174445.5-295044 (including our Swift measurement, and associating the two INTEGRAL detections, extrapolating their flux down to 2-10 keV).

2.2 Infrared data

2.2.1 Data and reduction

We observed XMMU J174445.5-295044 with Near-infrared Integral Field Spectrograph (NIFS, McGregor et al. 2002) mounted on the Fredrick C. Gillett telescope at Gemini-North observatory. The observation was done in queue mode on July 9th, 2012 under program ID GN-2012A-Q-114 (PI: C. O. Heinke). NIFS provides spectroscopy with resolving power \(R \sim 5000\) over a 3.0′×3.0′ field of view in the Z through K-band (9500 to 24000 Å). We performed the observation in K-band with standard methods for near-infrared, with a series of observations pointing on-source and blank sky. Blank sky observations were done in order to subtract sky emission from on-source observations. In order to remove telluric features in the spectrum of our target, we observed the A0V star HIP 88566 at similar airmass. For wavelength calibration, an exposure of Argon/Xenon arc lamps was taken. Also for spatial removal and calibration, exposures with a Ronchi mask were taken.

We reduced and reprocessed the data using Gemini IRAF package V1.12 beta 2 included in IRAF for three stages of data reduction (baseline calibration, telluric data and science data) in “nifsexamples” in baseline calibration we made flat field and had pixel map, performed wavelength calibration and determined the spectral curvature and spectral distortion in the Ronchi flat.

The spectra of A0V stars in the K band only show one significant feature, at Brγ (21661 Å). We removed this stellar feature from our reference spectrum to obtain a pure telluric spectrum. After extracting the one-dimensional spectrum of the telluric star, we divided the spectrum with a blackbody spectrum and included a Voigt profile fit to the Brγ feature (following Barbosa et al. 2008) to mimic the A0V spectrum of our calibration source. This spectrum was created using mkidspec in ardata package. We assumed a temperature of ~9800 K for the blackbody continuum of the A0V telluric star (Adelman 2004) and determined the Voigt profile parameters by fitting with the task splot. We then eliminated telluric features in the science spectrum using the achieved pure telluric spectrum with the task nftelluric. The final

\(^{1}\) IRAF is distributed by the National Optical Astronomy Observatory, which is operated by the Association of Universities for Research in Astronomy (AURA) under cooperative agreement with the National Science Foundation.

\(^{3}\) http://www.gemini.edu/sciops/instruments/nifs/?q=node/10356
A new symbiotic X-ray binary

output of the reduction stage is calibrated telluric-corrected data in the form of a three-dimensional data cube with two spatial dimensions, each 62 pixels wide, and one spectral (wavelength) dimension of 2040 pixels. We extracted a one-dimensional spectrum by merging spatial dimensions inside a circular region with radius of 7 pixels centred on the source using DS9.

2.2.2 Spectral analysis

We measured the radial velocity of the source, using the 

```plaintext
rvidlines
``` task in IRAF RV package to achieve a red/blue shift-corrected spectrum. In order to do this we first needed to identify a small number of prominent lines in the spectrum of this source. These include Al I (21170 Å), Si I (21360 Å), Ti (21789 Å, 21903 Å), Na I (22090 Å) and Ca I (22614 Å). 

`rvidlines` provided us with a velocity correction of -12 ± 3 km s⁻¹, which was applied to the full spectrum. This corrected spectrum can be seen in Figure 2.

We used various available spectral libraries for late-type stars [Kleinmann & Hall 1986; Wallace & Hinkle 1997; Ramirez et al. 1997] to identify spectral features present in the spectrum. To obtain accurate identification and vacuum wavelength values we compared these identifications with data available in National Institute of Standards and Technology Atomic Spectra Database (NIST-ASD, Krivonos et al. 2013). Figure 2 shows the rest-frame spectrum of XMMU J174445.5-295044 with all identified features. These features are tabulated in Table 1.

For two-dimensional stellar classification (spectral and luminosity) of the source we followed the method discussed by Ramirez et al. (1997); Ivanov et al. (2004); Comerón et al. (2004). This method consists of comparing the strength of a feature which is temperature-dependent with a feature which is temperature- and surface gravity-dependent. Following the method outlined in Comerón et al. (2004), we selected wavelength regions encompassing significant temperature-dependent features (Na I, Ca I), and one region representing a temperature- and surface gravity-dependent feature (¹²CO). For each feature, we use two nearby, featureless continuum regions to approximate the expected continuum level within the feature by linear interpolation. We used nearly the same feature and continuum definitions as Comerón et al. (2004) (Table 2). We made a small modification to the range of the blue continuum region for the Ca I feature given by Comerón et al. (2004), shortening it by 4 Å to avoid including the relatively strong nearby Ti I (22450 Å) line. This modification has an effect of < 0.2% on the equivalent width measurement. These features and continua are represented in Figure 3. Finally we calculated an equivalent width for each feature, and compared these values to the values reported in Comerón et al. (2004).

To estimate errors, we divided the continuum regions into halves, and computed the equivalent widths using either half alone. We took the largest variation from our reported values as an estimate of the error in each measurement.

---

Figure 1. Long term X-ray light curve of XMMU J174445.5-295044, calculating X-ray luminosities in the 2-10 keV band using our calculated 3.1 kpc distance (§ 3.2). Errorbars do not include the distance uncertainty, so that intrinsic variations can be more clearly seen. Chandra (black circles & upper limits), XMM-Newton (blue squares & upper limits) and Suzaku (red diamonds) fluxes from Heinke et al. (2009). INTEGRAL 2-10 keV fluxes (green stars) are extrapolated from the fluxes reported by Chenevez et al. (2012, JEM-X, 10-25 keV) and Krivonos et al. (2013, IBIS/ISGRI, 17-60 keV). Our Swift/XRT observation (magenta pentagon) is reported in § 2.1. The final XMM-Newton datapoint has statistical errorbars smaller than the marker size.
3 RESULTS AND DISCUSSION

3.1 Two-dimensional spectral classification

Comerón et al. (2003) demonstrate that the 12CO feature for supergiants always shows an equivalent width (EW) of > 25 Å (see their figures 8-13). We obtained EW(12CO) = 19.4 ± 0.1 Å, which is typical for giants or dwarfs (Comerón et al. 2004). Thus we can rule out the possibility of a supergiant.

Ramírez et al. (1997) and Ivanov et al. (2004) show that log(EW(CO)/(EW(Ca I)+EW(Na I))) can be used to separate giants from dwarfs. Ramírez et al. (1997) show that this quantity should be between -0.22 and 0.06 for dwarfs, vs. between 0.27 and 0.61 for giants. We found this quantity to be 0.67 ± 0.06 for our source, in agreement with the estimated range for giants. Presence of fairly strong 12CO bands in our spectrum is another indicator for a giant, as these features are invisible in a dwarf.

To estimate the temperature of this source, we used the first-order relationship between effective temperature ($T_{eff}$) and EW(12CO) (in angstroms) for giants proposed by Ramírez et al. (1997):

$$T_{eff} = (5019 ± 79) - (68 ± 4) \times EW[12CO]$$

(1)

Considering the uncertainty in EW(12CO), we found $T_{eff} = 3700 ± 160$ K. According to van Belle et al. (1999), $T_{eff} = 3700$ K indicates M2 giant; using Richichi et al. (1994) suggests M1.5 while the relation in Ramírez et al. (1997) gives an M1.7 giant. Thus, adopting either the van Belle or Richichi calibration, the resulting spectral type is M2 III, with a reasonable range from M0 to M3. If we used the less detailed calibration from Ramírez et al. 1997, we obtain a similar result of M1.7 (M0 to M3). Thus, we adopt M2 III as our spectral type, with a possible range from M0 to M3 III.

There is no evidence for a feature at Brγ in our spectrum, either before or after our telluric subtraction. Nespoli et al. (2010) see Brγ emission from two symbiotic X-ray binaries. However, the similar P-Cygni shape of the Brγ feature in both stars, and also in the supergiant X-ray binary IGR J16493-4348 studied by them with the same method, lend support to their hypothesis that this feature is a residual artifact of their telluric removal procedure (which is more complex than ours, involving using a G star as a second telluric reference).

3.2 Extinction, distance, and nature of the accretor

We use our identification of the spectral type, with the 2MASS photometry (Skrutskie et al. 2006) reported by Heinke et al. (2009), to estimate the extinction, and thus the distance, to XMMU J174445.5-295044, in a similar way as Kaplan et al. (2007), but explicitly accounting for the difference between the $K_S$ and $K$ bands. Although the 2MASS colors were measured at a different time from the NIFS spectroscopy reported here, we do not expect large variations in the temperature or observed extinction of the giant, as the stars most affected by this are of later (> M5) spectral types (Habing 1996).

M2 III stars have an absolute magnitude of $M_J = -3.92$ and intrinsic $J-K_S$ colors of 1.12 (Covey et al. 2007). Heinke et al. (2009) report a 2MASS magnitude of $m_J = 14.89$ in $J$ for our object, and an observed $J-K_S = 4.72$.

We use $A_J/A_V = 0.282$ (Cardelli et al. 1989), and $A_J/A_{K_s} = 2.5±0.2$ (Indebetouw et al. 2005). Thus we infer $A_V = \frac{(J-K_S)_{obs} - (J-K_S)_{int}}{(A_J/A_V) - (A_J/A_K_s)} = 21.3^{+1.9}_{-1.1}$, and $A_J = 6.0^{+0.5}_{-0.3}$. The extinction measurement converts (using $N_H$ (cm$^{-2}$) = (2.21± 0.09) $\times 10^{21}$ $A_V$, Güver & Özel 2009), to $N_H = (4.7± 0.5) \times 10^{22}$ cm$^{-2}$, which is below the X-ray measured values (measurements of $8.6± 0.4 \times 10^{22}$ cm$^{-2}$, and $16^{+5}_{-2} \times 10^{22}$ cm$^{-2}$, from different observations) in Heinke et al. (2009). This is consistent with expectations for a wind-accreting system, where much of the $N_H$ is expected to be local to the compact object, and with the evidence for variation in $N_H$ between different observations shown by Heinke et al. (2009).

Using this $A_J$ estimate, the expected $M_J$ for a M2 III star, and the observed $J$ magnitude, we can thus estimate $d = 3.1$ kpc as the most likely distance to our object. The largest uncertainty in our distance estimate is our estimate of the absolute magnitude of the companion star. Allowing for a conservative 1-magnitude uncertainty on the absolute magnitude (estimated from Breddels et al. 2010, this is probably more precise than $1\sigma$), we find $d = 3.1^{+1.8}_{-1.1}$ kpc. This distance is consistent with our (small) radial velocity.
A new symbiotic X-ray binary

Figure 2. K-band spectrum of XMMU 174445.5-295044. Identified line profiles are listed in Table 1. Features identified using spectral libraries (Kleinmann & Hall 1986; Ramirez et al. 1997) are marked with solid lines while features identified using NIST/ASD are marked with dashed lines. Ambiguous and uncertain identifications are labeled with “?”.

Table 2. Definition of spectral features, chosen continuum intervals and measured equivalent width. We used definitions in Comerón et al. (2004) with a small modification to Ca I blue continuum (§2.2.2).

| Feature | Band              | Blue continuum Center(Å) | δλ | Red continuum Center(Å) | δλ | Equivalent width (Å) |
|---------|-------------------|--------------------------|----|--------------------------|----|-----------------------|
| Na I    |                   | 22075                    | 70 | 21940                    | 60 | 22150                 | 40 | 2.23±0.14             |
| Ca I    |                   | 22635                    | 110| 22507                    | 53 | 22710                 | 20 | 1.93±0.40             |
| 12CO    |                   | 22955                    | 130| 22500                    | 160| 22875                 | 70 | 19.36±0.13            |

Figure 3. Chosen features and continua intervals used to obtain the spectral classification of the companion in this system. Left to right: Na I, Ca I, 12CO(2,0). Light shaded regions show chosen regions for features and dark shaded regions represent chosen continua regions. These regions are tabulated in Table 2. The dashed lines represent interpolated continuum level in each case.
estimate, which would be typical of a disk star observed at a very small Galactic latitude ($l = 359.1^\circ$), and with our measurement of the relative strengths of the CO and Na lines, the ratio of which is more consistent with disk giants than with giants in the bulge (Figueredo et al. 2004). From this distance estimate, we can infer the X-ray luminosities of XMMU J174445.5-295044, as plotted in Figure 1 (errors there do not include the distance uncertainties). The majority of the X-ray detections are between 10$^{33}$ and 10$^{34}$ erg s$^{-1}$, but the INTEGRAL/JEM-X detection in March 2012 (Chenevez et al. 2012) gives a (2-10 keV) X-ray luminosity of (1.1±0.2)$\times$10$^{33}$ erg s$^{-1}$ for $d = 3.1$ kpc; even at the lower limit on the distance ($d = 2.0$ kpc), the luminosity exceeds 4 $\times$ 10$^{34}$ erg s$^{-1}$ (Similarly, the March 2013 INTEGRAL/IBIS detection gives a (2-10 keV) $L_X = 2.5 \times 10^{34}$ erg s$^{-1}$ for 3.1 kpc, or 1.1 $\times$ 10$^{34}$ erg s$^{-1}$ for the 2.0 kpc lower distance limit, which further confirms the high X-ray luminosity of XMMU J174445.5-295044). Combining this high peak X-ray luminosity (four times the maximum seen for any accreting white dwarf (Stacey et al. 2011) with the hard X-ray spectrum inferred from the later Integral/IBIS detection above 17 keV (Krivonos et al. 2013), we can confidently rule out a white dwarf nature for the accretor. Thus, we securely identify XMMU J174445.5-295044 as a symbiotic X-ray binary, with a neutron star (or, less likely, black hole) accreting from the wind of an M2 giant star.

XMMU J174445.5-295044 stands out from other symbiotic X-ray binaries only in not showing detectable X-ray pulsations (Heinke et al. 2000). The complete absence of NIR spectroscopic evidence of accretion in our NIFS spectrum is typical of other symbiotic X-ray binaries with relatively low accretion rates. The lack of detected pulsations also means that the accretor could be a black hole, though black hole symbiotic X-ray binaries should be less common.

The increasing number of symbiotic binaries without detected emission lines in high-quality spectra being detected recently (van den Berg et al. 2006, 2012; Hynes et al. 2014) strongly suggests that there should be many more symbiotic stars (with white dwarf accretors) which also do not show optical/NIR spectroscopic evidence of accretion (van den Berg et al. 2006). Symbiotic systems may make up an important portion of the faint Galactic X-ray source population.
