We study the large scale behavior of a collection of hard core run and tumble particles on a one dimensional lattice with periodic boundary conditions. Each particle has persistent motion in one direction decided by an associated spin variable until the direction of spin is reversed. We map the run and tumble model to a mass transfer model with fluctuating directed bonds. We calculate the steady state single site mass distribution in the mass model within a mean field approximation for both large and small spin-flip rates and show that the Einstein relation is violated in both regimes. We also show how the non-gradient nature of the process can be taken into account in a systematic manner to calculate the hydrodynamic coefficients.

I. INTRODUCTION

Motion in natural contexts, such as bacterial movement, flocks of birds, etc., consists of units which achieve motility by converting their chemical energy to mechanical energy. The continuous supply of energy drives the system out of equilibrium and also results in some remarkable collective phenomena, such as clustering and pattern formation [1–4], and giant number fluctuations [5, 6]. These systems, widely known as active matter, have been studied through different simple non-equilibrium models. Examples include Vicsek models [7–9] with alignment interaction to study flocks of birds, active Brownian particles [10, 11] and run and tumble particles (RTPs) [12, 13] to describe the interacting microorganisms in a liquid medium, and active lattice gases [14–20]; for reviews see Refs. [21, 22]. Phenomenological active hydrodynamics has been developed to characterize flocking phenomena [23, 24] and to explore the motion of swarms of bacteria in a liquid medium [25]. There have also been attempts to formulate a thermodynamic structure for models of active matter by characterizing equilibrium-like intensive thermodynamic variables, such as temperature [26], chemical potential [27–29] or pressure [30]. However, a general theoretical understanding of large-scale behavior of the hydrodynamics and steady-states is still lacking. In this paper, with a view to understanding the unique features of active matter systems, we study the steady-state behaviour and calculate transport coefficients in a paradigmatic microscopic model of active matter, interacting RTPs on a one dimensional lattice, where the particles move with a constant average velocity, but with intermittent random changes of direction.

In the past decade, there have been many studies of the motion of RTPs as models for bacteria, and as interesting non-equilibrium models of interacting particles in their own right. Initial studies focused on a macroscopic approach by constructing a hydrodynamic theory for RTPs in one dimension. In Ref. [12], considering a density dependent mean run speed and a fixed tumble rate, it was argued that the system exhibits self-trapping, also known as the motility induced phase separation which happens in the absence of any attractive microscopic interaction, unlike a passive phase separation. Numerical simulation of hard core run RTPs showed that the particles cluster more for small tumble rates, though no true condensation occurs. By examining the absorption and evaporation of dimers, the scaling behavior of the steady state cluster distributions for small tumble rates could be obtained [31]. RTPs with multiple occupancy of lattice sites have also been studied numerically [32]. When the number of allowed particles on a site is larger than two, there is evidence of a condensation transition. A comparative study of RTPs with other models such as active Brownian particles and active Ornstein-Uhlenbeck particles can be found in Refs. [33, 34].

More recent approaches have focused on the behavior of systems with only one or two RTPs exactly. For a system of two RTPs, the steady state distribution of inter-particle distance has three contributions: a uniform contribution, an exponentially decaying correlation, and a ‘bound state’ in which two RTPs with opposite spins sat on adjacent sites of the lattice [17, 35]. This analysis was extended in Ref. [18] where the Markov matrix for the time evolution of one or two RTPs was diagonalised to show that the system undergoes a dynamical transition at certain values of the tumble rate. When additional thermal noise is added to the RTPs, then the steady state gap distribution becomes exponential [36]. For a single RTP, the large deviation function shows a first order dynamical transition where a ‘condensed’ phase for large displacements indicates that the large deviation function is dominated by a single run [37]. Studies of RTPs in bounded domains and confining potentials [38–40] have shown that the steady state distribution, under some conditions, shows an unusual structure with peaks away from the center of the domain. Similar results have been obtained in two dimensions [41]. The survival probability of two annihilating RTPs in one dimension can also be calculated exactly to define a ‘Milne length’ for
the correlations between the particles [42].

In this paper, we look at the case of many interacting RTPs on a one dimensional lattice, working in the frame of the gaps between particles, which allows the use of the framework of mass transport models. We go beyond previous studies by deriving the cluster and gap distributions for moderate and large tumble rates in the Independent Interval Approximation, and also in deducing the time-dependent behavior for small tumble rates. Other mass transport models have previous been studied in order to calculate various thermodynamic and hydrodynamic quantities, such as the chemical potential [43] and the transport coefficients [20, 44]. We show that the results from this model agree well with the simulations previously by deriving the cluster and gap distributions as shown in Fig. 1. The mass model has been found to be in excellent agreement with simulations. In addition, it is convenient to study the dynamics of the gaps between particles and define a corresponding mass transport model [47]. In this paper, we look at the case of many interacting RTPs on a one dimensional lattice, working in the frame of the gaps between particles, which allows the use of the framework of mass transport models. We go beyond previous studies by deriving the cluster and gap distributions for moderate and large tumble rates in the Independent Interval Approximation, and also in deducing the time-dependent behavior for small tumble rates. Other mass transport models have previous been studied in order to calculate various thermodynamic and hydrodynamic quantities, such as the chemical potential [43] and the transport coefficients [20, 44]. We shall see that for moderate tumble rates, these approaches give results which are well supported by numerical simulations. For very small tumble rates, we develop an alternate approach, also in the mass transport picture, based on a mapping to a diffusion-limited coalescence and fragmentation process [45, 46]. We show that the results from this model for the steady-state and the relaxation to the steady-state are in excellent agreement with simulations. In addition to the steady state gap distribution, we also calculate the diffusivity and conductivity for large tumble rates, and in the limit of very small tumble rates. We show that the Einstein relation is violated in both regimes.

The remainder of the paper is organized as follows. In Sec. II we define the model in the particle picture as well as the corresponding mass transport model in the gap picture. In Sec. III, we calculate the mass distribution within a mean field approximation and compare them to results from Monte Carlo simulation for moderate tumble rates, showing excellent agreement. In Sec. IV, we determine, for small tumble rates, the steady state mass distribution as well as relaxation to the steady state, by developing and analyzing a model of diffusion, fragmentation, and coalescence. In Secs. V and VI, we calculate hydrodynamic quantities such as the diffusion constant and conductivity for moderate and low tumble rates respectively, and compare the analytical results with results from Monte Carlo simulations. Section VII contains a summary of the paper and discussion of the results.

II. MODEL

Consider $N$ RTPs on a ring of $L$ sites, where each site can be occupied by at most one particle. Each particle is characterized by a spin $S$ that can take the values $+1$ (pointing right) or $-1$ (pointing left). A particle hops at rate 1 to the neighboring lattice site in the direction of its spin, provided the target site is empty. Thus, particles with $S = 1$ hop to the right and those with $S = -1$ hop to the left. In addition, each particle reverses the direction of its spin at rate $\eta$. Clearly, when $\eta \to \infty$, the value of the spin is random, and the model reduces to the well-studied symmetric exclusion process.

It is convenient to study the dynamics of the gaps between particles and define a corresponding mass transport model [47]. In this picture, the gaps between RTPs are mapped onto masses on a corresponding lattice, and the spins live on the bonds on this lattice. We now describe the mapping more precisely. Let $x_i$ be the position of the $i^{\text{th}}$ RTP on the original lattice, and let $S_i$ denote its spin as shown in Fig. 1(a). In the mass transport model, the $i^{\text{th}}$ site has a mass $m_i = x_{i+1} - x_i - 1$, the number of empty sites between the $i^{\text{th}}$ and $(i + 1)^{\text{th}}$ RTP, and the spins transform as $s_{i-1/2} = -S_i$. In the mass model, unit mass hops in the direction of the spins on the neighboring bonds. A particle hopping to the left (right) in the RTP model (shown by bent arrow in (a)) corresponds to a unit mass being transferred to the right (left) in the mass model (shown by bent arrow in (b)).

![Fig. 1. An example of the mapping between (a) the RTP model and (b) the mass transport model. In the mapping, mass at site $i$ equals the number of empty sites between the $i^{\text{th}}$ and $(i + 1)^{\text{th}}$ RTP, and the spins transform as $s_{i-1/2} = -S_i$. In the mass model, unit mass hops in the direction of the spins on the neighboring bonds. A particle hopping to the left (right) in the RTP model (shown by bent arrow in (a)) corresponds to a unit mass being transferred to the right (left) in the mass model (shown by bent arrow in (b)).](image)

The dynamics of the mass model can be derived as follows. Particle $(i + 1)$ moving one unit to the left in the RTP picture maps to a unit mass transfer from site $i$ to the right across the bond $i + 1/2$ (with $s_{i+1/2} = 1$) in the mass model, as shown in Fig. 1. Likewise, for a RTP moving to the right. The value of $s_{i+1/2}$ dictates the direction of mass transfer between sites $i$ and $i + 1$. If $s_{i+1/2} = +1$, mass from $i$ can move to site $i + 1$, but not from $i + 1$ to $i$. If $s_{i+1/2} = -1$, the reverse is the
Thus, the dynamics of the mass model may be summarized as follows. From a non-zero mass at site \( i \), unit mass is transferred with rate one to the right and rate one to the left, provided the spin on the bond that it crosses is in the direction of transfer. The spins \( s_{i+\frac{1}{2}} \) flip at rate \( \eta \) independently of the masses and the other spins.

### III. Steady-State Solution within a Mean Field Approximation

In this section, we derive the steady state mass distribution, or equivalently the distribution of gaps between particles in the RTP picture, within a mean field approximation. Let \( P(\{m_i\}, \{s_{i+\frac{1}{2}}\}, t) \) denote the probability of finding the system in a certain configuration of masses \( \{m_i\} \) and spins \( \{s_{i+\frac{1}{2}}\} \) at time \( t \). \( P(\{m_i\}, \{s_{i+\frac{1}{2}}\}, t) \) may be expressed as

\[
P(\{m_i\}, \{s_{i+\frac{1}{2}}\}, t) = P(\{m_i\}|\{s_{i+\frac{1}{2}}\}, t)P(\{s_{i+\frac{1}{2}}\}, t),
\]

where the notation \( P(x|y) \) denotes the conditional probability of \( x \) given \( y \). Equation (2) is exact, since it simply re-expresses joint probabilities in terms of conditional ones. Now, each spin flips independent of each other as well as independent of the configuration of masses, we immediately obtain that in the steady state

\[
P(\{s_{i+\frac{1}{2}}\}) = \prod_i P(s_{i+\frac{1}{2}}) = \frac{1}{2^N}.
\]

We will assume that the spins are initially chosen with this steady state probability so that the probabilities for spins are invariant in time.

We implement a single-site mean field approximation where, for each mass, we keep track of only the spins neighboring it. Thus, we approximate the conditional mass distributional equation (2) as

\[
P(\{m_i\}|\{s_{i+\frac{1}{2}}\}) \approx \prod_i P(m_i|s_{i-\frac{1}{2}}, s_{i+\frac{1}{2}}).
\]

We, thus, have to determine four conditional distributions of \( P(m_i|s_{i-\frac{1}{2}}, s_{i+\frac{1}{2}}) \), which we denote as \( P_m^{++} \), \( P_m^{-+} \), \( P_m^{+-} \) and \( P_m^{-−} \). The first (second) superscript refers to the neighboring spin on the left (right) bond, with + referring to +1 (or rightward) and − referring to −1 (or leftward). Among these, only three are independent, since due to left-right symmetry

\[
P_m^{++} = P_m^{−−}, \quad m = 0, 1, 2, \ldots.
\]

This is because both probability distributions correspond to a site with one of its neighboring spins pointing inwards and the other outwards. Also, due to translational invariance, the probability distributions do not depend on the site index.

For ease of notation, we introduce symbols \( \alpha, \beta, \gamma, \delta \):

\[
\alpha = P_0^{++}, \quad \beta = P_0^{−+}, \quad \gamma = P_0^{+-}, \quad \delta = P_0^{−−}.
\]

as they will appear repeatedly in the calculations. These quantities will be determined in terms of the mass density \( \rho \) and spin flip rate \( \eta \). From Eq. (5), we see that in the steady state, \( \beta = \gamma \), and we will use the symbol \( \beta \) for both \( P_0^{++} \) and \( P_0^{−−} \) in this section. In Sec. V, in the presence of a field or a density gradient, we will see that this symmetry is broken.

First, let us consider the temporal evolution of \( P_m^{++} \). For this combination of neighboring spins, the site cannot receive mass, as both spins point away from it. The master equation for \( P_m^{++} \) is

\[
\frac{dP_m^{++}}{dt} = 2\eta(P_m^{++} - P_m^{−+}) + 2P_m^{−+} - 2(1 - \delta_{m,0})P_m^{−−},
\]

where the first term in the right hand side describe spin flips and the last two terms describe transfer of unit mass to neighboring sites. In the steady state, the time derivative may be set to zero and we obtain

\[
P_m^{−+} = -\eta(P_m^{++} - P_m^{−−}) + (1 - \delta_{m,0})P_m^{−−},
\]

Equation (8) can be solved using the generating function method. Let

\[
\tilde{P}^{++}(z) = \sum_{m=0}^{\infty} P_m^{++} z^m,
\]

with similar definitions for the other two distributions: \( \tilde{P}^{−+}(z) \) and \( \tilde{P}^{−−}(z) \). Multiplying Eq. (8) by \( z^m \) and summing over \( m \), we obtain

\[
\tilde{P}^{−+}(z) = \frac{(1 - z)\alpha - 2\eta \tilde{P}^{++}(z)}{1 - z(\eta + 1)},
\]

where \( \alpha \) is as defined in Eq. (6). Note that \( \tilde{P}^{−+}(z) \) depends upon the generating function \( \tilde{P}^{++}(z) \).

We now examine \( P_m^{−−} \). For this configuration of spins, the lattice site can only receive mass, as both the neighboring spins point inwards. \( P_m^{−−} \) evolves in time as

\[
\frac{dP_m^{−−}}{dt} = \sum_{m' = 1}^{\infty} \left( P_{m'}^{−−} + P_{m'}^{++} \right) \left[ P_{m+1}^{−+(1 - \delta_{m,0}) - P_{m+1}^{−−}} \right] + \eta \left( P_{m−−} + P_{m−+} - 2P_m^{−−} \right),
\]

where the \( \bullet \) in the superscript means that the spin could be either + or −. Clearly,

\[
P_m^{−−} = \frac{1}{2} P_m^{++} + \frac{1}{2} P_m^{−−}.
\]
We now examine $P^{++}(m)$. The spin configuration is such that the site can receive particles from the left neighbor but also loses particles to the right neighbor. Like the earlier cases, the time evolution equation for $P^{++}(m)$ may be written. In the steady state, we obtain

$$\frac{dP_{m+1}^{++}}{dt} = \frac{2 - \alpha - \beta}{2} \left[ P_{m+1}^{++} - P_{m-1}^{++} \right] - \eta \left( 2P_{m+1}^{++} - P_{m+1}^{+-} - P_{m-1}^{--} \right).$$

(17)

Multiplying by $z^m$ and summing over $m$, we obtain the generating function to be

$$\tilde{P}^{++}(z) = \frac{2(1 - z)\beta + 2\eta z \left[ \tilde{P}^{+-}(z) + \tilde{P}^{-+}(z) \right]}{2(1 - z) - z(1 - z)(2 - \alpha - \beta) - 4\eta z^2}.$$

(18)

Solving for the generating functions $\tilde{P}^{++}(z)$, $\tilde{P}^{+-}(z)$ and $\tilde{P}^{-+}(z)$ from Eqs. (10), (15) and (18), we finally obtain

$$\tilde{P}^{++}(z) = \frac{2[(\alpha + \beta - 2)(z - 1) + 2\eta \{ (\alpha + \beta)\eta z + \beta(z - 1) \}]}{h(z)},$$

$$\tilde{P}^{+-}(z) = \frac{2[(\alpha + \beta)\eta z + \beta(z - 1)]}{h(z)},$$

$$\tilde{P}^{-+}(z) = \frac{2\eta(z - 1) \left[ 3\alpha^2 z + \alpha((4\beta - 6)z + 2) + (\beta - 2)\beta z \right] + 4\eta^2 z(\alpha + \beta) + \alpha(z - 1)^2(\alpha + \beta - 2)\left[ z(\alpha + \beta - 2) + 2 \right]}{h(z)},$$

(19)

where the denominator $h(z)$ is given by

$$h(z) = [(\alpha + \beta - 2)(1 + \eta)z + 2 - \alpha - \beta + 2\eta] \times [(\alpha + \beta - 2)z^2 - (\alpha + \beta - 4\eta - 4)z - 2].$$

(20)

We note that the denominator $h(z)$ is common to all three generating functions, and $\alpha$ and $\beta$ remain undetermined.

The behavior of the probability distributions for large $m$ are determined by the poles of the generating functions, which in turn are determined by the three zeros of $h(z)$:

$$z_1 = \frac{2 - \alpha - \beta + 2\eta}{(\eta + 1)(2 - \alpha - \beta)},$$

$$z_2 = \frac{\alpha + \beta - 4\eta - 4 - \sqrt{(\alpha + \beta - 4\eta)^2 + 32\eta^2}}{2(\alpha + \beta - 2)},$$

$$z_3 = \frac{\alpha + \beta - 4\eta - 4 - \sqrt{(\alpha + \beta - 4\eta)^2 + 32\eta^2}}{2(\alpha + \beta - 2)}.$$

(21)

Among these, $z_1, z_2 > 1$ and $z_3 < 1$. A root whose magnitude is less than unity implies an exponentially diverging $P(m)$ for large $m$, which is unphysical. Hence, $z_3$ cannot be a valid pole. This can be true only if the numerator of all the three generating functions vanish at $z_3$, thus, removing the pole at $z_3$ [48, 49]. This leads to the constraint (for all three generating functions) that

$$\alpha = \frac{2\beta\sqrt{\beta + 2\eta + \eta^2 - \beta^2}}{\beta + 2\eta}.$$

(22)

leaving only $\beta$ to be determined.

To determine $\beta$, we use the fact the total mass is a conserved quantity. The generating function $\tilde{P}(z) = \sum_{m=0}^{\infty} P_m z^m$, where $P_m$ is the probability of a randomly chosen site having mass $m$, is given by

$$\tilde{P}(z) = \frac{1}{4} \tilde{P}^{+-}(z) + \frac{1}{4} \tilde{P}^{-+}(z) + \frac{1}{2} \tilde{P}^{++}(z).$$

(23)

The density $\rho$ is then given by

$$\rho = z \frac{dP(z)}{dz} \bigg|_{z=1},$$

$$= \frac{(\alpha + \beta)(3\alpha + \beta) + 8(2 - 2\alpha - \beta)}{8\eta(\alpha + \beta)} + \frac{2 - \alpha - \beta}{\alpha + \beta}.$$

(24)
Equations (22) and (24) may be solved to obtain $\alpha$ and $\beta$ in terms of $\rho$ and $\eta$. Thus, we obtain the full solution to the single site mass distribution within the mean field approximation.

Since, after the pole cancellation, there remain two poles of magnitude larger than one, the mass distribution $P(m)$ will be a sum of two exponentials. For large $m$, the pole closest to origin, which turns out to be $z_1$, will have the dominant contribution. Thus, for large masses, $P(m)$ will decrease to zero as (all the three conditional distributions will also have the same asymptotic behavior),

$$P(m) \sim e^{-m/m^*} \text{ for } m \gg 1,$$

where

$$m^* = \frac{1}{\ln z_1},$$

with $z_1$ as in Eq. (21). This completes the calculation of the single-site distributions within a mean-field framework.

For large $\eta$, the RTP model approaches a symmetric simple exclusion process, since the particle motion decouples from the spin fluctuations. For large $\eta$, the Eqs. (22) and (24) may be solved as a series expansion to give

$$\alpha = \frac{1}{1 + \rho} + \frac{\rho(2 + 3\rho)}{2(1 + \rho)^3\eta} + O(\eta^{-2}),$$

$$\beta = \frac{1}{1 + \rho} \frac{\rho^2}{2(1 + \rho)^3\eta} + O(\eta^{-2}),$$

$$\delta = \frac{1}{1 + \rho} - \frac{\rho(2 + \rho)}{2(1 + \rho)^3\eta} + O(\eta^{-2}),$$

$$\frac{1}{m^*} = -\ln \left(\frac{\rho}{1 + \rho}\right) - \frac{1}{2(1 + \rho)^3\eta} + O(\eta^{-2}).$$

Also, the probability of a site being empty $P(0) = \frac{1}{1 + \rho} + O(\eta^{-2})$. The leading terms, corresponding to $\eta = \infty$, are consistent with the results for the symmetric simple exclusion process.

For small $\eta$, the probabilities have the series expansion

$$\alpha = 1 - 8\rho(2\rho + 1)\eta^2 + O(\eta^3),$$

$$\beta = 1 - 8\rho\eta + 56\rho(\rho + 2\rho^2)\eta^2 + O(\eta^3),$$

$$\delta = \frac{1}{1 + 4\rho} + \frac{16\rho(\rho + 1)\eta}{(4\rho + 1)^2} + O(\eta^2),$$

$$\frac{1}{m^*} = \ln \left(\frac{1}{4\rho + 1}\right) + \frac{(8\rho + 5)\eta}{4\rho + 1} + O(\eta^2).$$

In the limit $\eta \rightarrow 0$, we see that $m^*$ tends to a finite number larger than zero, thus predicting an exponential decay. However, simulations show that the average number of particles per occupied site diverges as $\eta \rightarrow 0$, leading to clustering. We explain this deviation from mean field theory for small $\eta$ in Sec. IV.

Figures 2 and 3 compare the predictions of the mean-field single-site mass distributions with results from simulations for $\rho = 1$. It can be seen that for $\eta \geq 1$ there is excellent agreement with the simulation results, for all distributions $P^{++} = P^{--}$, $P^{-+}$, and $P^{+-}$ (see Fig. 2). For $\eta < 1$, we see that the distributions obtained from the simulations decay much more slowly at large $m$ than the mean-field prediction, showing that the mean-field approximation fails for small $\eta$.

We now determine the particle cluster distributions in the RTP picture within the mean field approximation for the mass model. The gaps in the RTP picture correspond to masses in the mass model, and conversely an empty...
site in the mass model corresponds to two neighboring particles in the RTP picture. Let \( p_{RTP}^\eta(n) \) denote the probability in the RTP picture that a given empty site has a cluster of exactly \( n \) particles to its right (\( n = 0 \) corresponds to there being no cluster immediately to the right of the site). In the mass model, this corresponds to the probability of a given non-empty site having \( n \) empty sites to its right, with the \((n+1)\)st site being non-empty. This probability, in the mean field approximation, may be written as a product of single site mass distributions at different sites. Recall that \( P(m_i|s_{i-\frac{1}{2}},s_{i+\frac{1}{2}}) \) is the probability of site \( i \) having mass \( m_i \), given the two neighboring spins [see Eq. (4)]. Let \( P(\bullet|s_{i-\frac{1}{2}},s_{i+\frac{1}{2}}) \) denote the probability that there is a non-zero mass at site \( i \). Then, \( p_{RTP}^\eta(n) \) can be written as

\[
p_{RTP}^\eta(n) = \frac{1}{2n+2} \sum_{s_{-\frac{1}{2}}}^{s_{n+\frac{1}{2}}} \prod_{k=1}^{n+1} P(0|s_{k-\frac{1}{2}},s_{k+\frac{1}{2}}) \cdot P(\bullet|s_{n+\frac{1}{2}},s_{n+\frac{1}{2}}). \tag{33}
\]

The sum over the spins are more easily evaluated using the transfer matrices

\[
T = \begin{pmatrix} P_{0+}^+ & P_{0-}^- \\ P_{0+}^- & P_{0-}^+ \end{pmatrix} = \begin{pmatrix} \alpha & \beta \\ \delta & \beta \end{pmatrix},
\]

and

\[
T' = \begin{pmatrix} 1 - \beta & \beta \\ 1 - \delta & \delta \end{pmatrix}, \tag{35}
\]

where \( \alpha, \beta \) and \( \delta \), defined in Eq. (6), are functions of \( \rho \) and \( \eta \). Eq. (33) then simplifies to

\[
p_{RTP}^\eta(n) = \frac{1}{2n+2} \sum_{i=1}^{2} \sum_{j=1}^{2} (T^nT')_{i,j}. \tag{36}
\]

We now check that in the limit \( \eta \to \infty \), we recover the results for the symmetric exclusion process. In this limit, from Eq. (27), we know that \( \alpha = \beta = \delta = (1 + \rho)^{-1} = \rho_{RTP} \), and hence \( T = \rho_{RTP} J \), while \( T' = (1 - \rho_{RTP})J \), where \( J \) is the \( 2 \times 2 \) matrix with all entries one. Clearly, \( J^n = 2^{n-1}J \). It is straightforward to simplify Eq. (36) to

\[
p_{RTP}^\eta(n) \xrightarrow{\eta \to \infty} \rho_{RTP}^n(1 - \rho_{RTP}), \tag{37}
\]

in agreement with results for the symmetric exclusion process on a ring which has a product measure in the steady-state.

The cluster distribution in the RTP picture, obtained from Monte Carlo simulations are compared with the mean field prediction in Eq. (36) in Fig. 4 for different values of \( \eta \). The distribution \( p_{RTP}^\eta(n) \) is exponential for large \( n \). We see that the mean field expression is able to describe the distribution accurately for larger \( \eta \). For values of \( \eta \) less than 1, the mean field result under predicts the probabilities, thus failing to capture tendencies towards clustering.

![FIG. 4. The probability of finding a cluster of size \( n \) in the RTP picture, \( p_{RTP}^\eta(n) \), for \( \eta = 0.1 \) and \( \rho = 1 \) or equivalently \( \rho_{RTP} = 0.5 \). The solid lines correspond to the results from mean field theory [see Eq. (36)]. The mean field predictions match with results from simulations for large \( \eta \). The data are for system size \( L = 500 \) in the mass model picture.](image)

We now estimate the regime of validity of the mean field approximation. Consider the RTP picture. The mean distance between two particles is \( \rho_{RTP}^{-1} \). If no spin flips occur, then the collision times are proportional to the inter-particle distance. For mean field theory to hold, there must be multiple spin flips during this time. Thus, we obtain the criteria for the validity of mean field theory to be \( \eta^{-1} \ll \rho_{RTP}^{-1} \), or effectively \( \eta \gg (1 + \rho)^{-1} \). The results from simulations [see Figs. 2, 3, and 4] are consistent with this criterion, where we find a good match between results from simulations and mean field predictions for \( \eta \gtrsim 1 \).

We now provide an alternative description of the mass model that is valid for small \( \eta \), based on a mapping to a single species birth and coalescence process.

## IV. COALESCENCE-FRAGMENTATION MODEL FOR \( \eta \ll 1 \)

In Sec. III, we showed that the numerical results for the mass distribution for \( \eta \gtrsim 1 \) are well described by the mean field results, while the mean field analysis fails for small values of \( \eta \). In this section, we provide an alternate description of the dynamics that allows us to capture the mass distribution for the case \( \eta \ll 1 \). We work, as above, in the mass transfer picture. At time \( t = 0 \), let the total mass be uniformly distributed on the lattice. For small \( \eta \), when no site contains large masses there is a separation of the time scales associated with spins and hopping. In this limit, we can treat the mass transfers in an adiabatic approximation, wherein we assume the spins to be fixed when the masses move.
A. Relaxation to the steady state

For simplicity, we assume that the initially the mass is distributed uniformly on the lattice. The system initially evolves to a state in which only sites whose neighboring spins on the left and right are + and − respectively (denoted as ++ sites) can have non-zero mass. These sites have both spins pointing into the site, and thus the mass at that site cannot move out. On the other hand, the masses at ++, −−, and −− sites hop out to neighboring sites. Each ++ site has a basin of attraction, which consists of all the sites that are connected to it by spins pointing towards the site. Thus, for \( \eta \ll 1 \), the initial stage of evolution, which is of very short duration \( \sim O(1) \) (the mean size of a basin of attraction is four), consists of masses moving to the +− sites and staying there.

We now look at the dynamics on time scales of \( O(\eta^{-1}) \) and larger. In the adiabatic approximation, the masses are assumed to move only between +− sites, considering occupancy of other sites as transient. A mass can only move out of a +− site only if one of its neighboring spins flips, leading to the mass being transferred to the nearest +− site in the direction of the spin that flipped. The typical time taken for this transfer is of the order of the typical mass-cluster size at that time. If this time is smaller than \( \eta^{-1} \) (the time for a spin flip), the spins involved in this transfer can be assumed to be fixed. Looking at sites with non-zero mass as units \( A \), this process can thus be modeled by the single-species coalescence reaction \( A + A \to A \) [45, 46, 50], with diffusion constant \( \eta (\langle \Delta d \rangle^2) \), where \( \Delta d \) is the average distance over which a mass cluster is transferred after a spin-flip event. From the known exact solution of \( A + A \to A \), we obtain that the mean density of sites with non-zero mass \( n_c(t) \), during this coalescence stage of evolution, decreases as

\[
n_c(t) \approx \frac{1}{\sqrt{2\pi\eta\langle\Delta d\rangle^2}t}, \quad t \ll \eta^{-2},
\]

where the regime of validity \( t \ll \eta^{-2} \) will be shown later in this section. This implies that the typical mass \( m(t) \) of an occupied site increases as \( m(t) \approx \sqrt{2\pi\eta\langle\Delta d\rangle^2}t \).

We now give an argument to calculate \( \langle\Delta d\rangle^2 \) in the coalescence regime. A mass transfer is initiated when one of the spins of a +− site flips, say the spin on the right. The mass is then transferred to the right from site to site until it encounters a − arrow. The probability of the first − arrow being a distance \( \Delta d \) to the right is

\[
P(\Delta d) = 2^{-\Delta d}, \quad \Delta d = 1, 2, \ldots,
\]

and thus

\[
\langle\Delta d\rangle^2 = 6.
\]

Hence

\[
n_c(t) \approx \frac{1}{\sqrt{12\pi\eta}t}, \quad t \ll \eta^{-2}.
\]

This result is valid for times \( t \gg \eta^{-1} \). In the case of the RTP in the mass transport picture, \( A \) sites are +− sites, which are an average distance 4 apart. For \( t \sim \eta^{-1} \), we find better agreement with the interpolation

\[
n_c(t) \approx \frac{b}{\sqrt{12\pi\eta(t + a\eta^{-1})}},
\]

where \( a \) and \( b \) are constants that do not depend on \( \eta \) (for \( \eta \ll 1 \)), i.e., when time is shifted to \( \tau = t + a\eta^{-1} \). The constants \( a \) and \( b \) are easily estimated by the observation that for \( t \ll \eta^{-1} \), all masses are present only on +− sites, and for initial densities larger than \( 1/4 \), all +− sites are occupied. This implies that \( n_c(t) \to 1/2 \) as \( t \to 0 \). We also know that \( n_c(t) \) should approach the form in Eq. (38) for \( t \gg \eta^{-1} \). Hence, we obtain \( b = 1 \) and \( a = 4(3\pi)^{-1} \).

![FIG. 5. The variation of the mean density of clusters \( n_c(t) \) with time \( t \) for three different values of \( \eta \ll 1 \). The data are for density \( \rho = 1 \), system size \( L = 1000 \) and have been averaged over 200 histories. The solid lines correspond to the analytical result in Eq. (41), with \( a \) and \( b \) as given in the text.](image-url)

In Fig. 5, we see that Eq. (41) describes the numerical data for \( n_c(t) \) well.

It is possible to keep track of the time dependent mass distribution by considering the coalescence process as constant-kernel aggregation reaction \( A_i + A_j \to A_{i+j} \) in one dimension. From the known solution of this problem [50–53], the mass distribution, during the coalescence stage of evolution, can be predicted to be

\[
P(m, t) \approx n_c(t)^2 g \left( mn_c(t) \right).
\]

For a uniform initial distribution of mass and the case where the diffusion is only to the nearest neighbour sites, the scaling function \( g(x) \) is known to be given by

\[
g(x) = \frac{\pi x}{2\rho^2} \exp \left( -\frac{\pi x^2}{4\rho^2} \right).
\]
where it is possible that the data has not reached the scaling limit. This shows that the adiabatic approximation is able to capture the approach to the steady state very well. It is seen that the curve of the scaling collapse deviates from the known scaling function \( g(x) \) (shown by solid line) in Eq. (43) with \( \rho = 1 \).

B. Characterization of the steady state

The adiabatic approximation of treating the spins being fixed during mass transfer breaks down when typical masses become large and there is no longer a clear separation between the spin flip rates and mass transfer rates. Then, the evolution can no longer be modeled as a pure coalescence process. An example of interrupted mass transfer is when a second spin flips while mass transfer is going on.

Consider a ++ site. Suppose one of the neighboring spins flips so that the mass at the site starts transferring in the direction of the spin one by one. If, now the other neighboring spin flips before the total mass is transferred, then the mass at the site gets transferred to both its neighbors. This leads the reaction \( 0A \rightarrow A0A \), where 0 denotes a vacancy. If, on the other hand, the other neighboring spin does not flip, we have a diffusion move \( A0 \rightarrow 0A \). At large times \( t \gg \eta^{-2} \), there is a balance between diffusion, coalescence and breaking up, and the system reaches a steady-state. We now determine the steady-state value of \( n_c \) by considering the coalescence and fragmentation rates. We assume below that in addition to \( \eta \ll 1 \), the number of clusters \( n_c \ll 1 \), and only consider terms to leading order in \( n_c \).

We first calculate the coalescence rate. For the purposes of this section, we assume that sites are independently occupied or empty with probability \( n_c \) and \( (1-n_c) \) respectively, except for the necessary caveat that two occupied sites cannot be next to each other. To leading order in \( n_c \), this is consistent with the more detailed calculation of the steady-state using empty interval probabilities, given in the Appendix.

Then, to leading order in \( n_c \), the probability that two sites on a lattice separated by a distance \( n \) are both occupied is \( n_c^2(1+\epsilon(n)) \), where \( \epsilon(n) = O(n_c) \). Now, consider the two occupied ++ sites separated by a distance \( n \). The sites will coalesce into one if (a) the − arrow on the site on the left or the + arrow on the site on the right flip, which happens at rate \( 2\eta \), and (b) all the arrows on the (empty) sites in between the two sites are pointing the right, in the former case, and to the left in the latter case. If the sites are separated by a distance \( n \), there are \( n-2 \) arrows in between, this probability is then \( 2^{-n+1} \). Hence, the total rate of coalescence is

\[
\eta_c = 2\eta n_c^2 \sum_{n=2}^{\infty} 2^{-n+2} (1+\epsilon(n)) = 4\eta n_c^2 + O(\eta n_c) \tag{44}
\]

Now, we calculate the fragmentation probability. A fragmentation occurs when, during the course of a mass transfer, a spin between the original site and the target site flips, thus interrupting the transfer. Now, consider an initial flip of the right spin of an occupied ++ site, leading to a transfer to a site a distance \( k \) to the right. This requires that the arrows at all intervening sites be pointed to the right, and the \( k^{th} \) arrow be pointed to the left, to stop the mass transfer. The rate of this process is

\[
\eta \times n_c \times 2^{-k} \tag{45}
\]

Now, consider the case where the \((k-1)^{th}\) spin from the original site flips. For \( k = 1 \) this means the − spin on the original site flips back from + to −. Then all the mass simply ends up at a new site a distance \( k - 1 \) from the original, since the original target site is no longer ++ but is −− now, and thus cannot hold mass. In this case fragmentation does not occur.

However, if any of the \( k - 1 \) sites between the original and the target spin during the transfer, the mass will end up at two sites. If the left spin on the original site flips during the transfer, some of the mass will start getting transferred to the left, and in this case too, the mass will end up at two sites. A mass transfer over \( k \) sites takes a time \( m^* + \delta(k) \), where \( m^* \) is the average mass on an occupied site, and \( \delta(k) \) is a correction of \( O(1) \). The probability that one of \( k \) spins flips during this time is, to first order,

\[
\eta \times k \times (m^* + \delta(k)) \tag{46}
\]

And hence, the total fragmentation rate is (the factor of 2 in front signifies that the case of the mass transfer
being initiated by the + spin on the original site flipping can be treated in exactly the same fashion)
\[ r_f = 2\eta^2 n_c(m^* + \delta(k)) \sum_{k=1} 2^{-k} k, \]
\[ = 4\eta^2 n_c m^* + O(\eta^2 n_c m^*). \quad (47) \]

A steady-state is reached when the coalescence rate is equal to the fragmentation rate, \( r_c = r_f \), which gives
\[ n_c = \eta m^*. \quad (48) \]

We also use the equality \( n_c m^* = \rho \), the average density, to eliminate \( m^* \) from the above equation. Thus, we finally obtain
\[ n_c = \sqrt{\rho \eta}, \quad (49) \]
\[ m^* = \sqrt{\frac{\rho}{\eta}}, \quad (50) \]
to leading order.

We now compare the predictions from the effective aggregation-fragmentation model discussed above with results from simulations of the mass model. Fig. 7 shows the variation of the steady state mean \( n_c \) with different densities \( \rho \) and spin flip rates \( \eta \). The data for different densities collapse onto a curve when \( n_c \) is scaled by \( \sqrt{\rho} \), as predicted by Eq. (49). From the figure, it is clear that the dependence on \( \eta \) is as predicted by Eq. (49), right up to the constants.

In Fig. 8, we compare the predictions for \( m^* \) with estimates from simulations for small \( \eta \). To obtain \( m^* \) from simulations, we first measure the mass distribution \( P(m) \). For each \( m \), we obtain \( m^*(m) \) as
\[ \frac{1}{m^*(m)} = \frac{1}{2} \ln \frac{P(m-1)}{P(m+1)}. \quad (51) \]

\( m^*(m) \) converges to \( m^* \) for large \( m \). The variation of \( m^*(m) \) with \( m \) is shown in Fig. 8 for three values of \( \eta \). It is clear that for small \( \eta \), we find an excellent match between the theoretical prediction in Eq. (50) and numerical results.

Knowing the initial temporal decay \( n(t) \approx \frac{1}{\sqrt{12\pi \rho \eta t}} \) [see Eq. (40)], and the steady state value \( n(t) \approx \sqrt{\rho \eta} \), we can develop a scaling form for the behavior of \( n(t) \). The crossover time is obtained by equating the early and late time behaviors to give \( t^* \approx 1/(\rho \eta^2) \). Thus, we can write
\[ n_c(t) = \sqrt{\rho \eta} f(t \rho \eta^2), \quad t \to \infty, \ \eta \to 0, \quad (52) \]
where the scaling function \( f(x) \approx 1 \) for \( x \to \infty \), and \( f(x) \approx 1/\sqrt{12\pi x} \) for \( x \to 0 \). Fig. 9 shows the variation of the mean density of clusters \( n_c(t) \) with time \( t \) for four different values of \( \eta \ll 1 \). As \( \eta \) decreases the extent of the coarsening regime increases, and the final number of clusters in the steady-state decreases, as expected from Eq. (49). The inset in Fig. 9 shows that the data for different times collapse onto a single curve when the different variables are scaled as in Eq. (52), confirming the scaling hypothesis. In addition, the numerical data are consistent with the predictions for the asymptotic behavior of the scaling function.

We conclude that the aggregation-fragmentation model complements the mean field approximation in providing an accurate description of the mass model for small values of the spin flip rate \( \eta \).

V. HYDRODYNAMICS FOR LARGE \( \eta \); MEAN FIELD APPROXIMATION

In this section, we derive hydrodynamic equations along the line of recently developed macroscopic fluctu-
The hydrodynamic coefficients depend on the rate of density gradient and the field strength $F$. In the presence of field, these distributions become site dependent. We introduce the following notation. Let the conditional probability of finding a mass $m$ on site $i$, given the site has a $-$ bond to the left and a $+$ bond to the right, be denoted as $P^{-+}_{m,i}$. Similar definitions hold for $P_{m,i}^{++}$, $P_{m,i}^{-+}$, and $P_{m,i}^{+-}$. These distributions are, in the presence of a field, different from the distributions $P^{++}$, $P^{+-}$, and $P^{-+}$ defined in Sec. III for the homogeneous case. We also note that the symmetry $P^{++}_{m,i} = P^{+-}_{m,i}$ is no longer valid in the presence of a field or density gradient.

The mean current between sites $i$ and $(i + 1)$ has contributions from particles hopping from $i$ to $i + 1$ (denoted by $\langle J_{i,i+1}^+ \rangle$) and particles hopping from $i + 1$ to $i$ (denoted by $\langle J_{i,i+1}^- \rangle$). Clearly,

$$\langle J_{i,i+1}^+ \rangle = \frac{1 + F}{4} \left[ \sum_{m=1}^{\infty} P^{++}_{m,i} + \sum_{m=1}^{\infty} P^{-+}_{m,i} \right].$$

Similarly,

$$\langle J_{i,i+1}^- \rangle = -\frac{1 - F}{4} \left( 2 - P^{-+}_{0,i+1} - P^{++}_{0,i+1} \right).$$

The average current across the bond is the sum of the two currents:

$$\langle J_{i,i+1} \rangle = \frac{P^{++}_{0,i+1} + P^{-+}_{0,i+1} - P^{++}_{0,i} - P^{++}_{0,i+1}}{4} + \frac{4 - P^{++}_{0,i+1} - P^{-+}_{0,i+1} - P^{-+}_{0,i} - P^{++}_{0,i}}{4}.$$

The current depends on the site dependent values of $P^{-+}_{0,i}$, $P^{++}_{0,i}$, and $P^{+-}_{0,i}$. The mass model is not a pure mass transfer process, but has other degrees of freedom, the spins on the bonds that do not relax infinitely fast. It is not surprising that even a small density gradient or field will modify the steady-state probabilities. Thus, to calculate the current in the presence of a field or gradient, we also need to calculate the modified steady-state mass distributions.

The different probability distributions evolve in time according to

$$\frac{1}{\sigma^2(\rho)} = \frac{D(\rho)}{\chi(\rho)},$$

where $\sigma^2(\rho)$ is the single-site mass fluctuations. To derive the hydrodynamic equations for the mass model, we consider the current across a bond in presence of a small density gradient $\partial \rho / \partial x$, and in presence of a small field of strength $F \ll 1$, that couples to the mass [20, 44, 54]. In the presence of a field, particles hop to the right with rate $1 + F$ and to the left with rate $1 - F$. The average current across a bond $\langle J \rangle$ is then expressed in terms of the hydrodynamic coefficients $D(\rho)$ and $\chi(\rho)$ as

$$\langle J \rangle = -D(\rho) \frac{\partial \rho}{\partial x} + F \chi(\rho).$$
the kind

\[ \frac{\partial P_{m,i}}{\partial t} = \eta \left[ P_{m,i}^+ - P_{m,i}^- - 2P_{m,i}^+ + 2P_{m+1,i}^- - 2(1 - \delta_{m,0})P_{m,i}^+ \right], \]

\[ \frac{\partial P_{m,i}^-}{\partial t} = \eta \left[ P_{m,i}^+ + P_{m,i}^- - 2P_{m,i}^+ + P_{m-1,i}^+ (1 - \delta_{m,0}) - P_{m,i}^- \right] \left[ 1 + F \right] \frac{2 - P_{0,i-1}^+ - P_{0,i-1}^-}{2} + (1 - F) \frac{2 - P_{0,i+1}^+ - P_{0,i+1}^-}{2}. \]  

(58)

In the following we solve for the probabilities \( P_{m,i} \) as a series expansion in the density gradient \( \rho'(x) = \partial \rho / \partial x \) in Sec. V A and field \( F \) in Sec. V B.

**A. Current in the presence of a density gradient**

In this section, we solve for the steady state mass distribution in the presence of a non-zero density gradient \( \rho' \), but field \( F = 0 \). We look for perturbative solutions of the kind

\[ \mathcal{P}^{ab}_{m,i} = \mathcal{P}^{ab}_{m}(\rho_i) + \rho' \mathcal{Q}^{ab}_{m,i} + O(\rho^2), \quad a, b = +, -, \]  

(62)

where \( \mathcal{P}^{ij}_{m} \) is the steady state solution in the absence of a field, as obtained in Sec. III, and \( \mathcal{Q}^{ab}_{m,i} \) is the first order correction.

Some of the \( \mathcal{Q}^{ab}_{m,i} \) may be determined from symmetry considerations. If the sign of \( \rho' \) is reversed, it is clear that \( \mathcal{P}^{++}_{m,i} (\rho') = \mathcal{P}^{--}_{m,i} (-\rho') \). In addition, \( \mathcal{P}^{−+}_{m,i} (\rho') = \mathcal{P}^{++}_{m,i} (-\rho') \), and \( \mathcal{P}^{+-}_{m,i} (\rho') = \mathcal{P}^{--}_{m,i} (-\rho') \). This implies that

\[ Q^{−+}_{m,i} = Q^{++}_{m,i}, \]

\[ Q^{+-}_{m,i} = Q^{−−}_{m,i}. \]  

(63)

(64)

For convenience, we also introduce the notation \( \beta_{1,i} = Q^{++}_{0,i} \), such that

\[ \mathcal{P}^{+}_{0,i} (\rho') = \beta(\rho_i) + \rho' \beta_{1,i}, \]  

(65)

consistent with the notation in Eq. (6). Note that the leading order term depends on the site \( i \) through the site-dependent density. For notational convenience, henceforth, we will not explicitly denote the dependence.

To determine \( \beta_{1,i} \), we consider Eq. (60) for \( \mathcal{P}^{+}_{m,i} \). Expanding the different quantities to order \( \rho' \) and using Eq. (64), it is straightforward to show that the term proportional to \( \rho' \) satisfies

\[ 0 = Q^{++}_{m+1,i} - Q^{++}_{m,i} \left[ 2\eta + 1 - \delta_{m,0} + \frac{2 - \alpha - \beta}{2} \right] + \frac{2 - \alpha - \beta}{2} (1 - \delta_{m,0}) Q^{++}_{m-1,i} \]

\[ + \frac{1}{2} \left[ \frac{\partial \beta(\alpha + \beta)}{\partial \rho} - \beta_1 \right] \left[ P^{+}_{m-1}(1 - \delta_{m,0}) - P^{++}_{m} \right]. \]  

(66)

Consider the generating function

\[ \tilde{Q}^{++}_{1}(z) = \sum_{m=0}^{\infty} Q^{++}_{m,i} z^m, \]  

(67)

with \( \tilde{P}^{++}(z) = \sum_{m=0}^{\infty} P^{++}_{m} z^m \) as defined earlier in Eq. (9). Multiplying Eq. (66) by \( z^m \) and summing over \( m \), we obtain

\[ \tilde{Q}^{++}_{1}(z) = \frac{z(1 - z) \left[ \frac{\partial \beta(\alpha + \beta)}{\partial \rho} - \beta_1 \right] \tilde{P}^{++}(z) + 2(1 - z)\beta_1}{(2 - \alpha - \beta) z^2 - (4 - \alpha - \beta + 4\eta) z + 2}. \]  

(68)

Here, \( \beta_1 \) is still undetermined. We determine it using the root cancellation method that was used in the mean field approximation. Equation (68) has two poles. Of these, the pole

\[ z_c = \frac{4 + 4\eta - \alpha - \beta - \sqrt{(4 + 4\eta - \alpha - \beta)^2 - 8(2 - \alpha - \beta)}}{2(2 - \alpha - \beta)} \]  

(69)

is less than 1. This pole will contribute to an exponentially diverging probability unless \( z_c \) is a zero of the numerator. This implies that

\[ \beta_1 = \frac{z_c \tilde{P}^{++}(z_c) \frac{d}{d\rho} (\alpha + \beta)}{z_c \tilde{P}^{++}(z_c) - 2 \left\{ \frac{d}{d\rho} (\alpha + \beta) \right\} \rho'}. \]  

(70)

In Fig. 10, we show the variation of \( \beta_1 \) with density \( \rho/(1 + \rho) = 1 - \rho_{RTP} \) for different spin flip rate \( q \). It can be seen that for most values of \( \rho \), the correction is \( O(1) \), and hence not negligible. It is also seen that \( |\beta_1| \) decreases with \( \eta \) for fixed density. This is reasonable since in the \( \eta \rightarrow \infty \) limit the RTP approaches a simple exclusion process, for which \( \beta_1 = 0 \). \( |\beta_1| \) is also smaller for larger \( \rho \), as the probability of a site being empty reduces in this limit, therefore both \( \beta_1 \) and \( \beta \) decrease.

We can now calculate the current in Eq. (57) when the field \( F = 0 \). Expanding to order \( \rho' \), we obtain

\[ \langle J \rangle = \frac{1}{4} \left[ \frac{d}{d\rho} (\alpha + \beta) - 2\beta_1 \right] \rho'. \]  

(71)
Comparing with Eq. (54), we immediately read out the diffusion constant to be

$$D(\rho) = -\frac{1}{4} \left[ \frac{d}{d\rho} (\alpha + \beta) - 2 \beta_1 \right].$$

(72)

Note that $D(\rho)$ depends on the correction $\beta_1$ to the steady state due to the presence of a non-zero density gradient. Substituting for $\beta_1$ from Eq. (70), we obtain

$$D(\rho) = \frac{1}{4} \left[ \frac{z_c \rho_0 P_0^{cz}(z_c) + 2}{z_c \rho_0 P_0^{cz}(z_c) - 2} \right] \frac{d}{d\rho} (\alpha + \beta).$$

(73)

In simulations, we test the above prediction for $D(\rho)$ by measuring the spreading of an initial small density inhomogeneity,

$$\rho(x) = \rho_0 + \rho_1 \exp \left( \frac{-x^2}{2\Delta^2} \right).$$

(74)

The initial width is chosen to be $\Delta = 10$, and the spread of the fluctuation averaged over many realizations in the Monte Carlo simulations. The analytical prediction is obtained by numerically integrating Eqs. (54) and (73) using the Euler method. In Fig. 11, we compare the numerical results for the spreading of an initial density profile with those from analytically calculated $D(\rho)$ for two different values of $\eta$. As can be seen from the figure, the two are in excellent agreement. We stress that the term proportional to $\beta_1$ turns out to be essential for reproducing the numerical, and comparing with the naive prediction for $D(\rho)$ does not produce similar agreement (plots not shown).

FIG. 10. The variation of $\beta_1$, the correction to the steady state due to the presence of a density gradient [see Eq. (65) for definition] with density $\rho/(1+\rho) = 1 - \rho RT \omega$ for (from top to bottom) $\eta = 1, 2$ and $5$. We see that the contribution of $\beta_1$ to $D(\rho)$ is significant for moderate $\eta$ and low $\rho$, but decreases with increasing $\eta$ and $\rho$.

FIG. 11. Numerical results for the spreading of an initial Gaussian density perturbation, as described in Eq. (74), with time $\tau$ is compared with the results from the analytical mean-field expression for $D(\rho)$ [see Eq. (73)] for (a) $\eta = 1$ and (b) $\eta = 2$.

**B. Current in the presence of a field**

We now consider the case of a non-zero field $F$ but in the absence of a density gradient, i.e., $\rho = 0$. Since the system on a ring is translationally invariant, it is easy to see that $P_{m,i} = P_{m}^{ab}$ is independent of the index $i$. We expand the probabilities to first order in $F$:

$$P_{m}^{ab} = P_{m}^{ab} + FR_{m}^{ab} + O(F^2), \quad a, b = +, -,$$

(75)

where $P_{m}^{ab}$ is the steady state mean field solution obtained in Sec. III for the homogeneous case, and $R_{m}^{ab}$ denotes the first order correction.

For non-zero $F$, the system has certain symmetries. For sites with one spin pointing inwards and one spin pointing outwards, the probabilities are invariant under $F \rightarrow -F$, $s \rightarrow -s$. This implies that $P_{m}^{ab} = P_{m}^{ab}(-F)$. For sites with both spins pointing inwards or both pointing outwards, the probabilities are invariant under $F \rightarrow -F$. This implies that $P_{m}^{+}(-F) = P_{m}^{+}(-F)$, and $P_{m}^{-}(F) = P_{m}^{-}(-F)$, i.e, they are even functions of
Consider Eq. (60) with \( \rho' = 0 \) in the steady state. Using the symmetries in Eqs. (76) and (77), the \( \mathcal{O}(F) \) term in Eq. (60), after simplification, satisfies

\[
R_{m+1}^{++} [1 - \delta_{m,0}] [2 - \alpha - \beta] - R_m^{++} [4 + 4\eta - \alpha - \beta - 2\delta_{m,0}] + 2R_{m+1}^{++} + P_{m+1}^{++} - P_m^{++} [4 - \alpha - \beta - 2\delta_{m,0} - \beta_1^F] + P_{m-1}^{++} (1 - \delta_{m,0}) [2 - \alpha - \beta - \beta_1^F] = 0. \tag{79}
\]

Equation (79) can be solved by the method of generating functions. Let \( \tilde{R}^{++}(z) = \sum_{m=0} R_m^{++} z^m \). Multiplying Eq. (79) by \( z^m \) and summing over \( m \), we obtain

\[
\frac{\tilde{R}^{++}(z)}{1 - z} = \frac{2(\beta + \beta_1^F) + \tilde{P}^{++}(z) [2 - \alpha - \beta]z - 2z\beta_1^F]}{(2 - \alpha - \beta)z^2 - (4 - \alpha - \beta + 4\eta)z + 2}. \tag{80}
\]

\( \tilde{R}^{++}(z) \) has two poles, one of which is less than zero. This pole equals \( z_c \), as given in Eq. (69). At this value of \( z_c \), the numerator should also vanish, allowing \( \beta_1^F \) to be determined:

\[
\beta_1^F = \frac{[2 - (2 - \alpha - \beta)z_c] \tilde{P}^{++}(z_c) - 2\beta}{2 - z_c \tilde{P}^{++}(z_c)}. \tag{81}
\]

Knowing \( \beta_1^F \), we can now calculate the drift coefficient \( \chi(\rho) \). From Eqs. (54) and (57), we obtain

\[
\chi(\rho) = \frac{2 - \alpha - \beta - \beta_1^F}{2}. \tag{82}
\]

We see that the non-gradient nature of the process also affects \( \chi(\rho) \) through the presence of \( \beta_1^F \).

The variation of \( \beta_1^F \) with density \( \rho/(1 + \rho) = 1 - \rho_{RTP} \) for different values of \( \eta \) is shown in Fig. 12. It is clear that, in the regime \( \eta > 1 \), where we expect the mean-field theory to be valid, \( \beta_1^F \) gives only a small contribution to \( \chi(\rho) \). In addition, \( |\beta_1^F| \) decreases with increasing \( \eta \), consistent with the fact that it equals zero for \( \eta = \infty \).

We now compare the predictions for \( \chi(\rho) \) with results from simulations. We measured the conductivity \( \chi(\rho) \) in simulations of the system on a periodic ring, with a field \( F \) biasing the mass transfers. The current was measured for various values of \( \eta \) and \( \rho \), and the \( J/F \) for \( F = 1, 2, 3 \) was extrapolated to \( F = 0 \) to find the linear conductivity. In Fig. 13, we compare the theoretical result for \( \chi(\rho) \) with simulation data for different values of \( \eta \) and \( \rho \). It is clear that the mean field hydrodynamic theory is in excellent agreement with simulations.

**C. Mass fluctuations**

To test the Einstein relation [see Eq. (53)], we need to calculate the mass fluctuations \( \sigma^2 \) defined as

\[
\sigma^2 = \frac{\langle m_\ell^2 \rangle - \langle m_\ell \rangle^2}{\ell}, \quad \ell \to \infty, \tag{83}
\]

where \( m_\ell \) denotes the total mass in a subsystem of \( \ell \) sites. Although we work in the mean-field approximation, we cannot treat the masses as completely independent, as different sites are correlated by the interconnecting spins. If \( P(m_1, m_2, \ldots, m_\ell) \) denotes the joint probability distribution function of \( \ell \) consecutive sites numbered
1, 2, …, ℓ, then
\[ P(m_1, \ldots, m_\ell) = \frac{1}{2^{\ell+1}} \sum_{k,n} \left[ \prod_{i=1}^{\ell} \left( \frac{P_{i,n}^{+} \frac{1}{P_{i,m}^{-} - P_{i,n}^{-}}}{P_{i,m}^{+} - P_{i,n}^{-}} \right) \right] \] \hspace{1cm} (84)

Now consider the generating function \( P(\ell)(z) \) for the total mass of the subsystem
\[ P(\ell)(z) = \langle z^{m_1 + m_2 + \cdots + m_\ell} \rangle. \] \hspace{1cm} (85)

Multiplying Eq. (84) by \( z^{m_1 + \cdots + m_\ell} \) and summing over the masses, we obtain
\[ P(\ell)(z) = \frac{1}{2^{\ell+1}} \sum_{i,j} \left[ \left( \frac{P_{i,j}^{+} \frac{1}{P_{i,j}^{-}}}{P_{i,j}^{+} - P_{i,j}^{-}} \right) \right]. \] \hspace{1cm} (86)

For large subsystem sizes \( \ell \), the generating function \( P(\ell)(z) \) is dominated by the larger eigenvalue, \( \Lambda(z) \), of the matrix on the right hand side of Eq. (86). Diagonising, we obtain
\[ \Lambda(z) = P^{+}(z) + \sqrt{P^{-}(z)P^{+}(z)}. \] \hspace{1cm} (87)

Then,
\[ \frac{\ln P(\ell)(z)}{\ell} = \ln \Lambda(z) - \ln 2 + O\left(\frac{1}{\ell}\right). \] \hspace{1cm} (88)

The mass fluctuations are then given by
\[ \sigma^2 = \left( z \frac{d}{dz} \right)^2 \frac{\ln P(\ell)(z)}{\ell}. \] \hspace{1cm} (89)

In Fig. 14, we compare the theoretical result for the subsystem fluctuations with simulations for different \( \eta \) and \( \rho \). In the simulations, we measure single site mass fluctuations. They are in excellent agreement, further confirming the validity of mean-field theory for moderate and large \( \eta \).

Knowing the subsystem mass fluctuations, \( \sigma^2(\rho) \), we can proceed to test the Einstein relation.

D. Einstein relation

In this subsection, we test the Einstein relation \( \frac{1}{\sigma^2(\rho)} \frac{D(\rho)}{\chi(\rho)} \) given in Eq. (53). To do so, we note that our analytic expressions for the transport coefficients reproduce the numerical results quite accurately, see Figs. 11, 13 and 14. Hence, we check for the Einstein relation using these analytic expressions. Fig. 15 shows the variation of \( \frac{D(\rho)}{\chi(\rho)} \sigma^2(\rho) \) with \( \rho \) for various values of \( \eta \). If the Einstein relation is valid, this ratio should equal one. It is clear that the Einstein relation is not valid for moderate to large \( \eta \). However, the ratio \( \frac{D(\rho)}{\chi(\rho)} \sigma^2(\rho) \) tends to one as \( \eta \to \infty \).

We see that the Einstein relation fails for all finite \( \eta \), even in the regime where the mean-field approximation shows excellent agreement with simulations. There are two reasons for this. First, since the current in the mass transfer process depends on the spin configuration, the process is no longer a gradient process, and second, the persistence of the spin configuration over a time \( \eta^{-1} \) means that the noise in the macroscopic current at two different times is no longer uncorrelated, and hence the conductivity \( \chi(\rho) \) no longer represents the strength of the fluctuating part of the current. Thus, care has to be taken when writing a fluctuating hydrodynamics for the RTP, and in analyzing its relation to the conductivity. In the next section, we shall see that these problems are even more severe for small \( \eta \), since the persistence times get longer.
VI. HYDRODYNAMICS FOR THE COALESCENCE MODEL

We showed in Sec. IV that in the limit of \( \eta \ll 1 \), the steady state mean density of clusters as well as the approach to the steady state is well approximated by an effective aggregation-fragmentation model. We now calculate the hydrodynamic coefficients \( D(\rho) \) and \( \chi(\rho) \) [see Eq. (54) for a definition] by determining the rates of mass transfers across a given bond in the presence of a density gradient \( \rho' = \partial \rho / \partial x \) and a field \( F \). In the presence of a field, the rate of mass transfer towards the right is increased by a factor \((1 + F)\) and the rate towards the left is decreased by a factor \((1 - F)\).

We show in Appendix B using the empty interval method that, unlike in the previous section, the presence of a field or density gradient does not change the steady-state measure. This implies that we can use the equilibrium formulae for \( n_c(\rho) \) and \( m^*(\rho) \) in calculating the current under a small density gradient or field.

A. Calculation of current: preliminaries

To derive the hydrodynamic coefficients \( D(\rho) \) and \( \chi(\rho) \), we now calculate the mass current across the bond \((-1,0)\) to first order in \( F \) and \( \rho' \). As a preliminary observation, we note that the mass current across a given bond might originate in a spin slip at a site far away from the bond, if all the intervening arrows between the site and the bond point towards the bond. We will first consider mass transfers across \((-1,0)\) to the right, initiated by the flip of one of the spins around the site \(-k\). We will use symmetry to calculate the current to the left across \((-1,0)\) from mass transfer from site \( k-1 \) and finally summing over \( k \) to calculate the total current.

Now, if the site \(-k\) is occupied, then \( s_{-k+1} = -1 \) and \( s_{-k-1} = 1 \), since we assume that only \(++\) sites are occupied. The probability that a given site is occupied is \( n_c(\rho) \). Now, if \( s_{-k+1} \) flips to 1, which happens at rate \( \eta \), then mass transfer is initiated to the right. Suppose the nearest \(-1\) spin is a distance \( j \) away. If no other spin flips during the time period under consideration, then the mass at site \(-k\) will end up at site \(-k+j\). This implies all the intervening spins are \(+1\). The probability of the nearest \(-1\) spin to the right being a distance \( j \) away is thus

\[
p(j) = 2^{-j}.
\]

Similarly we denote the probability that the nearest \(-1\) spin to the right being a distance \( \ge j \) away as

\[
p_{\ge}(j) = 2^{-j+1} = 2p(j).
\]

The time for a mass transfer over a distance \( j \sim O(1) \) is, \( m^* + O(1) \) on average, since \( m^*(\rho) \) is the average mass on a site, since the rate of mass transfer over each bond is 1. In the presence of a field, the mass transfer time to the right is \((1 - F)m^* \), and to the left is \((1 + F)m^* \), to leading order.

B. Current in a constant density gradient

We consider the current across the bond \((-1,0)\) due to a mass at site \(-k\), in the presence of a small, constant density gradient \( \rho' \). The average density at site \( j \) is then \( \rho_j = \rho_0 + j\rho' \). Our aim is to calculate the leading order term in the diffusion constant. For this purpose, it is sufficient to consider processes where only one single spin flip has occurred.

Consider the mass transfer from site \(-k\) across the bond \((-1,0)\) through a process of a single spin flip. The probability that site \(-k\) is occupied is given by \( n_c(\rho-k) \), since \( n_c \) depends on position only through the local density. If site \(-k\) is occupied, it is of type \(+\), and hence the spin \( s_{-k+1} = -1 \). Mass transfer to the right is initiated by the flipping of the spin \( s_{-k+1} \). If all the spins between \(-k+2\) and 0 are pointing to the right, the mass is transferred across \((-1,0)\) to the right. Since spin flips happen at rate \( \eta \), the current due to site \(-k\) is

\[
J_{-k}^+ = \eta n_c(\rho-k)m^*(\rho-k)p(k).
\]

The current to the left across \((-1,0)\) due to site \( k-1 \) is similarly

\[
J_{k-1}^- = \eta n_c(\rho_{k-1})m^*(\rho_{k-1})p(k).
\]

Summing over \( k \), the total current is

\[
J = \sum_{k=1}^{\infty} J_{-k}^+ - J_{k-1}^- = \eta \sum_{k=1}^{\infty} p(k)(\rho_{-k} - \rho_{k-1}),
\]

which gives, to leading order,

\[
D(\rho) = 6\eta.
\]

In Eq. (96) we used

\[
\sum_{k=1}^{\infty} p_k = 2, \quad \sum_{k=1}^{\infty} kp_k = 4.
\]

The calculation of the next-to-leading-order term is beyond the scope of our calculations, as it requires careful consideration of empty interval method that, unlike in the previous section, the presence of a field or density gradient does not change the steady-state measure. This implies that we can use the equilibrium formulae for \( n_c(\rho) \) and \( m^*(\rho) \) in calculating the current under a small density gradient or field.

\[
\rho_j = \rho_0 + j\rho', \quad D(\rho) = 6\eta.
\]
allows us to obtain an excellent fit. This is because for the values of \( \rho \) and \( \eta \) we study, the subleading correction is important for the initial stages of the spread. Our simulations are consistent with the above form, and an excellent fit is obtained with \( d = 3 \), as shown in Fig. 16.

**C. Current in a small field \( F \)**

We now assume that the field \( F \) is nonzero, but density gradient is absent. Since the system is on a ring, there will still be translational invariance. As before, we consider the current across the bond \((-1, 0)\), in a time \( T \). The probability that a given bond flips during this time is \( \eta T \). The probability that \( j \) given bonds flip is \( (\eta T)^j \) while the probability that \( j \) given bonds do not flip is to leading order, \( 1 - j \eta T \). The probe time scale \( T \) is chosen so that it is greater than the time scale of mass transfer \( m^* \), but \( T \ll \eta^{-1} \), allowing for an expansion in numbers of bonds flipped during the transfer.

There are five processes which contribute to mass transfer across the bond \((-1, 0)\) from the site \(-k\), with \( k > 0 \).

1. \( s_{-k+\frac{1}{2}} \) flips initially and no other spin flips. This leads to a mass \( m^* \) being transferred across \((-1, 0)\) if all of the intervening spins are pointing to the right. If the mass ends up at site 1 or beyond, no spins between \((-k + 1)\) and 0 should flip during the mass transfer. If the mass ends up at site 0, the spin \( s_{-\frac{1}{2}} \) should not flip during the probe time-scale \( T \), as this will lead to a mass less than \( m^* \) being transferred across \((-1, 0)\) at the end of the probe time period. The current due to process (1) is

\[
J^+_1 = n_c \eta m^* \left[ p_\geq (k + 1)(1 - (k + 1)\eta m^*(1 - F)) + p(k)(1 - \eta m^*(1 - F) - \eta T) \right],
\]

(100)

where the first term is the contribution to current from mass transfer to sites 1 and beyond, and the second describes the contribution to mass to transfer to site 0.

2. \( s_{-k+\frac{1}{2}} \) flips initially followed by \( s_{-k-\frac{1}{2}} \) flipping during transfer. This leads to some mass being transferred to the left of site \(-k\). On average, the spin \( s_{-k+\frac{1}{2}} \) flips halfway through the transfer, thus the remaining mass is \( m^*/2 \). Of this remaining mass, due to the field \( F \), a fraction \( (1 + F)/2 \) ends up on the right and \( (1 - F)/2 \) on the left of site \(-k\). If the spins between \(-k \) and 0 point to the right, the mass transferred across \((-1, 0)\) is \( m^*/2 + m^*(1 + F)/4 \). The current is

\[
J^+_2 = n_c \eta \left( \frac{3}{4} m^* + \frac{1}{4} m^* F \right) \left( \eta m^*(1 - F) p_\geq (k) \right)
\]

(101)

3. \( s_{-k-\frac{1}{2}} \) flips initially followed by \( s_{-k+\frac{1}{2}} \) flipping during transfer. The initial mass transfer is to the left of \(-k\) (and against the field), but during the transfer the flipping of \( s_{-k+\frac{1}{2}} \) leads to some mass being transferred across \((-1, 0)\). Since the transfer is in the direction of the field, the average mass transferred to the right is \( m^*(1 + F)/4 \). Therefore,

\[
J^+_3 = n_c \eta \frac{1}{4} m^*(1 + F) (\eta m^*(1 + F)) p_\geq (k).
\]

(102)

4. \( s_{-k+\frac{1}{2}} \) flips initially followed by a spin between \(-k \) and 0 flipping from right to left during the mass transfer. Such a flip interrupts the transfer and on average leads to only mass \( m^*/2 \) being transferred across \((-1, 0)\). However, as in (1) above, we have to distinguish between the cases where the transfer is to site 1 or beyond, and the transfer ending at site 0. In the latter case, flipping of any spin between \(-k \) and \(-1 \) interrupts the transfer as before, but flipping of spin \( s_{-\frac{1}{2}} \) will lead to the whole mass ending up at site \(-1 \) and no mass transferred across \((-1, 0)\) at the end of the probe period \( T \). Hence,

\[
J^+_4 = n_c \eta m^* \left[ p_\geq (k + 1)k \eta m^*(1 - F) + p(k) \left( (k - 1) \eta m^*(1 - F) + \eta m^*(1 + F) \right) \right] \]

(103)

5. \( s_{-k+\frac{1}{2}} \) flips initially followed by a spin between \(-k \) and 0 flipping from left to right during the mass transfer.
The fifth type of process is in a way the inverse of (4) above: say the initial closest $-1$ spin was $s_{-i+\frac{1}{2}}$, with $0 < i < k$, but that spin flips during the time $T$. If the next nearest $-1$ spin is beyond site 0, then mass will end up across $(-1,0)$. Taking the mass transfer time into account, if this flip happens in $[0,T-m^*(1-F)]$, the whole mass $m^*$ ends up across $(-1,0)$. If it happens in $[T-m^*(1-F),T]$, on average only half the mass ends up across $(-1,0)$ after time $T$. Note that the probability that the nearest spin is at $-i+\frac{1}{2}$ and the next nearest beyond 0 is $p(k-i)p_{\geq}(i) = p_{\geq}(k)$. The site $i$ can be in one of $(k-1)$ positions. If site $i$ was initially occupied, which happens with probability $n_c$, an additional mass $m^*$ will be transferred across $(-1,0)$. However, if $i = k-1$, the site $i$ cannot occur, since two occupied sites cannot be directly adjacent. Hence when $i$ is in one of the other $(k-2)$ places, $2m^*$ is transferred across $(-1,0)$. Thus, the current is

\[
J_5^+ = n_c\eta p_{\geq}(k)(k-1)[m^*\eta(T-m^*(1-F)) + \frac{m^*}{2}\eta m^*(1-F)] + m^*\eta p_{\geq}(k)(k-2)[m^*\eta(T-m^*(1-F)) + \frac{m^*}{2}\eta m^*(1-F)] \Theta(k-2). \tag{104}
\]

where the Heaviside Theta function accounts for the fact that the contribution of the second type when $k = 1$ is zero.

Summing up the contributions to the current from the above five processes, we obtain the total current from left to right across the bond $(-1,0)$. To calculate the conductivity $\chi(\rho)$, we need only consider only those terms of $J^+$ that are proportional to $F$. In the absence of a density gradient, the other terms of the current will cancel each other. We denote the part of the current $J$ proportional to $F$ as $J_F$. Using $p_{\geq}(k) = 2p_{\geq}(k+1) = 2p(k)$, we obtain

\[
J_F^+ = F(\eta p)^{3/2} \sum_{k=1}^{\infty} p(k) \left( \frac{5k}{2} + \frac{1}{2} \right),
\]

\[
= \frac{11}{2} F(\eta p)^{3/2}. \tag{105}
\]

Similarly, the $F$-dependent term of $J_F^-$ is

\[
J_F^- = \frac{11}{2} F(\eta p)^{3/2}. \tag{106}
\]

Thus, we obtain

\[
\chi(\rho) = 11(\eta p)^{3/2}, \quad \eta \ll 1. \tag{107}
\]

In Fig. 17, we show the variation of $\chi$ with $\eta$ for two values of density $\rho$. The data for the two densities collapse onto one curve when $\chi$ is plotted against $\eta p$, consistent with Eq. (107). For small $\eta p$, the data is consistent with a power law with exponent $3/2$ as in Eq. (107). However, the curve deviates from the power law for larger $\eta p$. In the inset, we account for these correction terms in order to measure the prefactor of the power law more accurately to be $\approx 11.01$, consistent with the theoretical prediction $11(\eta p)^{3/2}$ (solid line), as given in Eq. (107). Inset: The coefficient of the power law is obtained by plotting $\chi(\eta p)^{3/2}$ against $\sqrt{\eta p}$. The best fit, shown by dotted line, is $11.01 = 20.02\sqrt{\eta p} - 68.18\eta p$.

**D. Transport coefficients and Einstein relation**

So far we have not considered the distribution of mass on an occupied site in the low $\eta$ regime. To test the Einstein relation, we need to estimate the mass fluctuations in a subsystem. We will see that the Einstein relation is not obeyed in the low $\eta$ regime, and the discrepancy is of the order of $\eta^{-1}$ and thus not simply a matter of getting the numerical factors correct. But to proceed with the estimate, we postulate that the mass distribution on occupied sites is $D_{occ}(m) \sim e^{-\sqrt{m}}$. Since the density of occupied sites is $n_c = \sqrt{\eta p}$, we have (after normalization)

\[
P(m) = \begin{cases} 
\frac{1}{\eta} e^{-\sqrt{m}} & \text{for } m = 0, \\
\eta e^{-\sqrt{m}} & \text{for } m > 0.
\end{cases} \tag{109}
\]

If we assume the masses at different sites are independent, this gives

\[
\sigma^2(\rho) = \langle m^2 \rangle - \langle m \rangle^2 = 2\rho^{3/2} \sqrt{\eta} + O(1), \quad \tag{110}
\]

Comparing with

\[
\frac{D(\rho)}{\chi(\rho)} = \frac{6}{\eta^{1/2} \rho^{3/2}} + O(1), \quad \tag{111}
\]
we see that the Einstein relation, given in Eq. (53), is not satisfied for the dynamics in the coalescence picture, i.e., for $\eta \ll 1$. The physical reason for this is that mass transfers in the low $\eta$ regime are correlated over a time $\eta^{-1}$, which can be very large. The Einstein relation assumes that $\chi(\rho)$ is also the coefficient of a delta-correlated noise term in the current without a field, considered as a random variable. However, the long-time correlations make this assumption false, and hence the Einstein relation is not expected to hold.

VII. CONCLUSION

In this paper, we studied a system of hard core run and tumble particles on a one dimensional lattice. A particle moves persistently in the direction of its spin, till the spin flips direction. We study the properties of the gaps between particles by mapping the model to a mass transport model across fluctuating directed bonds that are persistent for a time $\eta^{-1}$. We solve for the mass distribution using a mean field approximation which reproduces well the distribution for moderate and large spin flip rates $\eta$, but fails for small $\eta$. For small $\eta$, we develop an equivalent aggregation fragmentation model to analytically characterize both the approach to the steady state as well as the steady state, both in excellent agreement with results from simulations. For both large and small $\eta$, we also derived the hydrodynamic coefficients of diffusivity and conductivity by calculating the current across a bond in the presence of a small density gradient and a small biasing field respectively. In the moderate and large $\eta$ case, we see that the steady-state changes upon introduction of a small gradient or biasing field, and such a change in the steady-state contributes significantly to the hydrodynamic coefficients. This is due to the fact that crowding occurs differently behind particles parallel to and anti parallel to the field or gradient, and the direction of particle motion is persistent for a time $\eta^{-1}$. For small $\eta$, we calculate the hydrodynamic coefficients exactly to leading order.

The Einstein relation between the hydrodynamic coefficients and the subsystem mass fluctuations is not obeyed for $\eta \neq \infty$. This is, again, because of persistence of the motion of individual particles. In particular, unlike in usual lattice gases, the conductivity does not equal the amplitude of the current fluctuations in the steady-state, because the current fluctuations are correlated over a time $\eta^{-1}$. It is the balance between the diffusivity and the current fluctuations in the steady-state that dictates the subsystem mass fluctuations, and not the balance between the diffusivity and the conductivity. Thus, the discrepancy in the Einstein relation in both regimes is proportional to $\eta^{-1}$.

Our calculations explicitly demonstrate the unusual effects of persistence on the hydrodynamics of RTPs, namely the effect of the change in the steady-state in a field, and the mismatch between the conductivity and current fluctuations. They would be useful starting points for constructing more accurate hydrodynamic theories of persistent walkers.

Although a system of RTPs in higher dimensions cannot be expressed in a gap picture, the mass transport model with directed fluctuating bonds studied here can be easily generalized to higher dimensions. In the low-$\eta$ regime, especially if one introduces interactions between the directed bonds, one expects to find interesting clustered and patterned phases. The single-particle mean-field developed here for the moderate and large $\eta$ regime can also be usefully applied to other one dimensional systems of RTPs, for example the case of RTPs in continuum, or the model of RTPs on a lattice with multiple occupancy.

VIII. ACKNOWLEDGMENTS

We thank Punyabrata Pradhan for helpful discussions.

Appendix A: The empty interval approximation for small $\eta$

Let $E_n$ be the probability that a given set of $n$ contiguous sites is empty. Then probability that a set of $n$ contiguous sites is empty and has an occupied site on the immediately right is $E_n - E_{n+1} \equiv Q_n$. We now study the time evolution of the probability $E_n$ for $n \gg 1$. There are two contributions: complete mass transfers labeled as (1) and incomplete mass transfers due to fragmentation labeled as (2).

(1) Consider the contribution from complete transfers. An empty cluster of length $n$ is destroyed if there is a transfer over a distance $k$ or greater from an occupied site at the end of an empty cluster of length $n + k - 1$. The rate of this happening is given by \( \eta p_s(k) Q_{n+k-1} \), where $p_s(k)$ is the probability of mass being transferred to distances larger than $k$.

A cluster of length $n$ is created if there is a cluster of length $n - k$, followed by an occupied site, followed by an empty cluster of length $k - 1$, and there is an event which transfers the mass at the occupied site by a distance $\geq k$. The probability of this event can be approximated as \( \eta p_s(k) Q_{n-k} Q_{k-1}/n_c \), where $n_c$ is the density of occupied sites in the steady state. Collecting together the creation and destruction processes, we obtain

\[
\left. \frac{dE_n}{dt} \right|_{(1)} = 2\eta \sum_k p_s(k) \left( Q_{n+k-1} - Q_{n-k} \frac{Q_{k-1}}{n_c} \right),
\]

where the subscript (1) denotes the contribution from complete mass transfers.

Since we have assumed $n \gg 1$, we can approximate the
above by a continuum description,

\[ \frac{dE_n}{dt} \bigg|_{(1)} \approx 2\eta \sum_k p_{>}(k) \left[ (2k-1) \frac{dQ_n}{dn} + Q_{n-k} \left( 1 - \frac{Q_{k-1}}{n_c} \right) \right]. \]  

(A2)

We note that the quantity \( Q_{k-1} \) is of the order of \( n_c \) times the probability of finding an interval of length \( k \), and hence \( 1 - Q_{k-1}/n_c \) is of \( O(n_c) \). We have assumed that we are in the limit \( n_c \ll 1 \). Now, for large \( n \), \( Q_n \sim n_c e^{-n_c n}, \) \( Q'_n \) is \( O(n_c^2) \), and thus the two terms are of comparable order, and hence we cannot neglect the second term.

In order to evaluate the second term in Eq. (A2), we approximate \( Q_j \) as follows: \( Q_0 = Q_1 = n_c \), since the density of occupied sites is \( n_c \) and an occupied site is always followed by an empty site, since two \( +\) sites cannot be contiguous. And for \( k > 1 \), we assume \( Q_j \approx n_c(1 - n_c)^{j-1} \). With this assumption, we can calculate the second term to be

\[ 2\eta \sum_k p_{>}(k) Q_{n-k} \left( 1 - \frac{Q_{k-1}}{n_c} \right) \approx 2\eta \sum_k p_{>}(k) Q_{n-k}(k-2)n_c \approx 2\eta n_c Q_n, \]  

(A3)

where we used \( Q_{n-k} \approx Q_n - kQ'_n = Q_n + O(n_c^2) \).

(2) We now consider the contributions to the empty interval probabilities due to incomplete mass transfers. Consider a mass transfer event initiated at a \( +\) site due to the flipping of the \( - \) spin, and the nearest \( - \) spin to the right is at a distance \( k \). If, during this transfer, a spin a distance \( i \) \( k - 1 \) to the right flips, the mass ends up at two sites, \( i \) and \( k \). (If the spin at \( k - 1 \) flips, the whole mass ends up at \( k - 1 \) instead of \( k \).) The probability of this event for a given \( i \) is \( \eta \)\( m \) to leading order. This happens also in case the \( + \) spin on the original \( + \) site flips as well, where now some of the mass ends up on the right of the original site and some on the left. Note that since some mass does end up a distance \( k \) away, the destruction of empty clusters to the right happens whether there is a splitting or not. However, the creation of new empty clusters might not happen.

Consider the change in the creation term due to splitting events. If during a mass transfer over a distance \( > k \) from an occupied site inside the cluster, one of the intervening \( k \) spins flips \( (k-1) \) in case of a transfer over exactly \( k \) sites), the creation is interrupted. This could also happen in case the spin on the other side of the occupied site also flips. Thus,

\[ \frac{dE_n}{dt} \bigg|_{(2)} = 2\eta^2 \sum_k m^* [kp(k) + (k + 1)p_{>}(k + 1)] \frac{Q_{n-k}Q_{k-1}}{n_c} = 10\eta^2 m^*(Q_n + O(n_c^2)). \]  

(A4)

Collecting together the contributions from Eqs. (A2), (A3) and (A4), we obtain, to leading order,

\[ \frac{dE_n}{dt} = 12\eta \frac{dQ_n}{dn} + (2\eta n_c + 10\eta^2 m^*)Q_n. \]  

(A5)

Thus, in the steady state,

\[ -1 \frac{dQ_n}{Q_n} = \frac{1}{6}(n_c + 5\eta m^*). \]  

(A6)

Since the density of clusters is \( n_c \), the average distance between clusters is \( n_c^{-1} \), and hence, for large \( n \), we can write \( Q_n \approx C e^{-n_c n} \) to leading order. \( C \) is a constant that might depend on \( n_c \) and other factors. We use the equality \( n_c m^* = \rho \), the average density, to eliminate \( m^* \) from the above equation. Thus, we finally obtain

\[ n_c = \sqrt{T \eta}, \]  

(A7)

\[ m^* = \frac{\sqrt{\rho}}{\eta}, \]  

(A8)

to leading order.

**Appendix B: Invariance of the low \( \eta \) steady state to first order in \( \rho' \) and \( F \)**

In this appendix, we show that, for small \( \eta \), the empty interval probabilities are invariant up to order \( \eta \) in the presence of a field \( F \). Consider the equations [see (A2) and (A4)] for the empty interval probabilities \( E_n \), the probability of finding a void of length \( n \). Consider the terms in Eqs. (A2) and (A4), but written in the general form

\[ \frac{dE_n}{dt} = \sum_i f_i F_i(E_{k_1}, E_{k_2}, \ldots), \]  

(B1)

where we have written only the equation for the creation and destruction terms at the right boundary of \( E_n \). The \( f_i \) denote the rates for the various jump processes, which depend on the spin configurations and rates for spin flips, and the \( F_i \) are functions of the void probabilities \( E_k \). Now, in the presence of a constant density gradient, the rates \( f_i \) remain unchanged, but the \( E_k \) depend on position due to their dependence on the density field \( \rho(x) \). It is convenient to specify the position of a void of size \( n \) by the position of its midpoint, say at \( x \), and denote the probability of this cluster of sites being empty as \( E_{n,x} \). In the presence of a density gradient,

\[ E_{n,x} = E_{n,0} + \rho'(x) \frac{E_n}{d\rho} + O((\rho')^2). \]  

(B2)

Now, the equation for the rate of change of void probabilities \( E_n \) in the presence of a density gradient, due to transfer of particles through its right boundary becomes

\[ \frac{dE_n}{dt} \bigg|_{\text{right}} = \sum f_i F_i(E_{k_1,x_1}, E_{k_2,x_2}, \ldots), \]  

(B3)
where for convenience we have taken the original void to be centered at \( x = 0 \), and the void which contribute to \( F_i \) to be centered at \( x_1, x_2 \), and so on. To first order, this equals

\[
\frac{dE_{n,0}}{dt} \bigg| \text{right} = \sum_i f_i F_i(E_{k_1,0}, E_{k_2,0}, \ldots) + \sum_i f_i \rho'(x) \sum_j x_j \frac{dF_i}{dE_k} \frac{dE_k}{d\rho} + O(\rho'^2).
\]

By symmetry, the equation for the rate of change of \( E_{n,0} \) due to flows across its left boundary is

\[
\frac{dE_{n,0}}{dt} \bigg| \text{left} = \sum_i f_i F_i(E_{k_1,-x_1}, E_{k_2,-x_2}, \ldots) = \sum_i f_i F_i(E_{k_1,0}, E_{k_2,0}, \ldots) - \sum_i f_i \rho'(x) \sum_j x_j \frac{dF_i}{dE_k} \frac{dE_k}{d\rho} + O(\rho'^2).
\]

Hence, the equation for the rate of change of \( E_{n,0} \) in the presence of a density gradient is

\[
\frac{dE_{n,0}}{dt} = 2 \sum_i f_i F_i(E_{k_1,0}, E_{k_2,0}, \ldots) + O(\rho'^2), \tag{B4}
\]

which proves that the steady state does not change in the presence of a density gradient, to first order in \( \rho'(x) \).

Now, in the presence of a constant field \( F \), assuming the system is on a ring, the probabilities \( E_n \) do not depend on position. However, the jump rates to the right and left become functions of \( F \). If a jump to the right occurs at rate \( p(F) \), the same jump to the left occurs against the field, and hence at a rate \( p(-F) \). To first order in \( F \), \( p(F) + p(-F) = 2p(0) \). Now, the rate of change of \( E_n \) due to a left jump across the right boundary has its corresponding process on the left boundary as a right jump. Hence, denoting the functional dependence of the jump rates \( f_i \),

\[
\frac{dE_{n}}{dt} = \sum_i f_i(F) F_i(E_{k_1}, E_{k_2}, \ldots) + \sum_i f_i(-F) F_i(E_{k_1}, E_{k_2}, \ldots) = 2 \sum_i f_i(0) F_i(E_{k_1,0}, E_{k_2,0}, \ldots) + O(F^2). \tag{B5}
\]

Hence, the steady state also does not, under a constant field \( F \), change to first order in \( F \). Thus we can also conclude that \( m^*, P(m) \) and \( n_c \) remain unchanged from their steady-state values to first order in \( F \) and \( \rho' \).
