Abstract:
Chronic recurrent multifocal osteomyelitis (CRMO) is an autoinflammatory bone disorder that generally occurs in children and predominantly affects the long bones with marginal sclerosis. We herein report two cases of adult-onset CRMO involving the tibial diaphysis bilaterally, accompanied by polyarthritis. Magnetic resonance imaging (MRI) showed both tibial osteomyelitis and high intensity of the extensive lower leg muscles. Anti-interleukin-6 therapy with tocilizumab (TCZ) effectively controlled symptoms and inflammatory markers in both patients. High intensity of the lower leg muscles detected by MRI also improved. These cases demonstrate that CRMO should be included in the differential diagnosis of adult patients with bone pain, inflammation, and high intensity of the muscles detected by MRI. TCZ may therefore be an effective therapy for muscle inflammation of CRMO.

Key words: osteomyelitis, polyarthritis, chronic recurrent multifocal osteitis (CRMO), myositis, SAPHO syndrome, tocilizumab

(DOI: 10.2169/internalmedicine.8473-16)

Introduction

Chronic recurrent multifocal osteomyelitis (CRMO) is an autoinflammatory bone disorder characterized by chronic nonbacterial osteomyelitis, multifocal bone lesions, and multiple recurrence (1-3). Generally, CRMO is a pediatric disease, with a mean age at onset of 10 years old and it is seen more frequently in girls (1, 3). The metaphyses of the long bones and clavicle are the most commonly affected sites, but the pelvis, vertebrae, and mandible are also frequently involved (1, 3, 4). Bone lesions with marginal sclerosis are one of the typical feature of CRMO (5). Several diseases have been reported to accompany CRMO, including palmar plantar pustulosis, psoriasis, Crohn’s disease, acne, and Sweet syndrome (1). In addition, CRMO has also been categorized as a juvenile form of SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteomyelitis) syndrome, implying that adult-onset CRMO should be included in the definition of SAPHO syndrome. The latter consists of several overlapping diseases, including pustulotic arthro-osteitis, sternocostoclavicular hyperostosis, and CRMO, and a high frequency of cutaneous manifestations (56-84%) (6). In the absence of skin lesions, the diagnosis of SAPHO syndrome, especially in patients with CRMO alone, is often difficult. Furthermore, because CRMO is mainly a pediatric disease, the diagnosis of adult-onset CRMO may be delayed. Indeed, there are only a few reports of adult patients with SAPHO syn-

drome in which the phenotype was CRMO without any skin manifestations. These cases were characterized by clavicular (7), vertebral, and sacroiliac (8) joint pain or involved the vertebrae and femoral neck (9).

We herein report the cases of two adult patients with CRMO without any typical skin lesions. The diaphyses of the long bones were involved and polyarthritis was present as well. In both patients, high intensity of muscles detected by magnetic resonance imaging (MRI), complicated the diagnosis. These cases demonstrate the importance of including adult-onset CRMO in the differential diagnosis of patients presenting with bone pain, inflammation and high intensity of muscles detected by MRI.

Case Reports

Case 1

A 48-year-old man was admitted to our hospital because of right lower leg pain. From the age of 17, he had been experiencing right lower leg pain of one week’s duration that recurrently occurred 2-3 times per year. These episodes were not accompanied by fever. At age 38, he was admitted to a local hospital for swelling and redness of his right lower leg. His C-reactive protein (CRP) level was 3.56 mg/dL and his white blood cell (WBC) count 8,500/μL. A biopsy of the right tibia showed no malignant cells and non-bacterial osteomyelitis was therefore tentatively diagnosed. Although no treatment was started, his right lower leg pain gradually improved, but did not resolve entirely. At age 41, he was admitted to another hospital because of fever, polyarthritis bilaterally involving his shoulders, and his right elbow and right wrist. His body temperature was 38-39°C and his right elbow, right wrist, and left ankle were swollen. His CRP was 10 mg/dL; his rheumatoid factor (RF), anti-cyclic citrullinated peptide (CCP), and anti-nuclear antibody were all negative. His matrix metalloproteinase-3 (MMP-3) level was normal (104.0 ng/mL) as well. An MRI scan showed enhancement of the fascia of his anterior right lower leg, suggesting fasciitis. The bone marrow was of slightly heterogeneous intensity, but was not enhanced, consistent with his previous osteomyelitis. Reactive arthritis was considered, and he was started on prednisolone (PSL) at 5 mg/day and salazosulfapyridine (SSZ) therapy. Treatment reduced the polyarthritis, but the abnormal CRP level (1-3 mg/dL) and pain in his right lower leg persisted. After moving to the city where our hospital is located, the patient began treatment under our supervision. Since autoinflammatory disease was suspected, he was started on 0.5 mg colchicine/day, but it was not effective. He was therefore treated with methotrexate (MTX) and minodronate and his PSL dose was increased to 10 mg/day, but his right lower leg pain and elevated CRP continued. Loxoprofen was therefore prescribed for pain relief.

At 48 years of age, he was admitted to our hospital. He did not have fever (36.6°C), but he complained of pain in his right lower leg and right upper arm. His CRP level was 4.14 mg/dL and his WBC count was 10,700/μL. His creatinine kinase (CK) level was low (29 U/L) and he had no elevations in the levels of anti-myeloperoxidase, and proteinase 3 antineutrophil cytoplasmic antibodies. On X-rays, bilateral osteosclerosis of the tibias was observed (right>left) (Fig. 1). On the MRI scan of his lower legs, the tibial bone marrow and muscles enhanced bilaterally (Fig. 2a, b). On 99mTc-hydroxymethylene diphosphonate (HMDP) bone scintigraphy there was an uptake from the proximal metaphysis to the diaphysis of the tibias bilaterally and at the right humeral diaphysis (Fig. 3). His serum interleukin (IL)-6 and tumor necrosis factor (TNF)-α levels were elevated: 57.2 pg/mL (normal range: 0-33 pg/mL) and 6.5 pg/mL (normal range: 0.6-2.8), respectively; his serum IL-1β level was <10 pg/mL, and his serum IL-10 level was negative (<2 pg/mL). Chronic recurrent non-bacterial osteomyelitis was therefore suspected and he was started on tocilizumab (TCZ, 8 mg/kg) as an in-
Case 1

A 74-year-old man was admitted to our hospital because of bilateral lower leg pain and polyarthralgia. He had been diagnosed with diabetes mellitus and hypertension when he was 55 years old. At 63 years of age, he developed polyarthritis of the third and fourth metacarpophalangeal (MP) joints bilaterally, the right fourth proximal interphalangeal (PIP) joint, and his elbows bilaterally. He did not have fever. His CRP level was 3.5 mg/dL, but his RF, anti-CCP and anti-nuclear antibody levels were negative. The MRI scan of his right hand revealed synovitis and bone marrow edema of the fourth and fifth travenous drip over 4 weeks. The CRP level was 5.04 mg/dL just before the second administration of TCZ, but it decreased to 0.31 mg/dL just before the third administration. Loxoprofen could be stopped because his symptoms of pain in his right lower leg and right upper arm improved. After the fourth administration of TCZ, the CRP levels stayed negative and the PSL dose was tapered. The high intensity of lower leg muscles detected in MRI also diminished over eight months. However, the higher linear enhanced intensity in the tibial diaphysis remained and chronic or old osteomyelitis was considered (Fig. 2c, d).

Case 2

A 26-year-old man was admitted to our hospital because of bilateral lower leg pain and polyarthralgia. He had been taking levetiracetam and valproic acid because of epilepsy, which had been diagnosed when he was 13 years old. At 23 years of age, he developed polyarthritis of the third and fourth metacarpophalangeal (MP) joints bilaterally, the right fourth proximal interphalangeal (PIP) joint, and his elbows bilaterally. The pain in his right upper arm was presented. He did not have fever. His CRP level was 4.41 mg/dL, but his RF, anti-CCP and anti-nuclear antibody levels were negative. The MRI scan of his right hand revealed synovitis and bone marrow edema of the fourth and fifth

Figure 2. a: Magnetic resonance imaging (MRI) (T2WI) shows higher enhanced intensity of the muscles. b: A higher linear enhanced intensity in the tibial diaphyses bilaterally, indicating osteomyelitis (T2WI). c and d: a higher enhanced intensity of the muscles decreased, but a higher linear enhanced intensity in the tibial diaphysis remained (T2WI).

Figure 3. ⁹⁹mTc-HMDP bone scintigraphy shows the uptake from the proximal metaphysis to the diaphysis of the tibias bilaterally and at the right humeral diaphysis. HMDP: hydroxy-methylene diphosphonate
Figure 4. a: MRI (T1WI) of the right hand reveals synovitis and bone marrow edema of the fourth and fifth metacarpophalangeal joint. b: MRI (T2WI) shows enhanced bone marrow in the right tibial diaphysis associated with cortical bone hypertrophy. The right lower leg muscle was also enhanced, suggesting myositis. c: MRI (T2WI) reveals an enhancement of the right triceps brachii muscle.

Figure 6. Pathological findings of a biopsy specimen obtained from a subcutaneous nodule in the left upper arm. Necrotizing vasculitis of a subfascial small artery was diagnosed pathologically.

MP joints (Fig. 4a), suggestive of rheumatoid arthritis (RA). He was started on MTX, which improved his arthritis slightly, but his CRP level remained elevated. At 24 years of age, he experienced bilateral lower leg pain. The MRI showed enhanced bone marrow of the right tibial diaphysis associated with cortical bone hypertrophy suggesting chronic osteomyelitis (Fig. 4b). The muscles of his right lower leg (Fig. 4b) and the right triceps brachii muscle (Fig. 4c) were also enhanced, suggesting myositis. The X-ray and CT images showed hypertrophy of the cortical bone of the tibia bilaterally (Fig. 5). $^{67}$Ga scintigraphy showed slightly increased uptake in the middle of both lower legs. His CRP level was high (6.35 mg/dL), but his CK (87 IU/L), WBC count (6,730/μL), acetylcholinesterase (11.6 U/L), and soluble IL-2 receptor (279 U/mL) levels were all within the normal range. Anti-Jo-1 antibody was negative (<5.0 index). His electromyogram was normal and a muscle biopsy was not performed. Dermatomyositis, polymyositis, sarcoidosis, and lymphoproliferative syndrome were excluded. A subcutaneous nodule in the left upper arm was palpable and a biopsy was performed. Necrotizing vasculitis of a subfascial small artery was diagnosed pathologically (Fig. 6). Since rheumatoid vasculitis was suspected at that time, he was therefore started on PSL (10 mg/day), with the dose later increased to 20 mg/day. He was also treated with MTX (12 mg/week). At 26 years of age, he was taking 13 mg PSL/day and 12
Both of the patients presented herein had adult-onset non-bacterial CRMO of the diaphysis, high intensity of muscles detected by MRI, and polyarthritis. One patient also had cutaneous nodules of necrotizing vasculitis. TCZ was effective for controlling the disease in both cases.

After the first administration of TCZ, bilateral lower leg pain improved and the CRP level decreased to normal levels. The PSL dose could be tapered and his left knee swelling decreased after three months. The high intensity of the lower leg muscles detected in MRI also decreased after 10 months (Fig. 7c). The high intensity of bone marrow was still slightly higher than normal intensity, which was suggestive of chronic or old osteomyelitis (Fig. 7c).

**Discussion**

Both of the patients presented herein had adult-onset non-bacterial CRMO of the diaphysis, high intensity of muscles detected by MRI, and polyarthritis. One patient also had cutaneous nodules of necrotizing vasculitis. TCZ was effective for controlling the disease in both cases.

Generally, the bone pain of CRMO is multifocal, typically involving the femoral and tibial metaphyses, the pelvis, clavicles, and vertebrae (1, 4, 10-12); however, as in our patients, the diaphyses of the long bones may also be involved (11). Arthritis is associated with CRMO in 11-38%...
of the cases (1, 13). In our patients, synovitis was detected on MRI, but no joint destruction, which was seen in patients with RA, was observed.

CRMO is mainly seen in children, with only a few reports of patients with adult-onset CRMO (7, 8). SAPHO syndrome covers a broad spectrum of findings (6) and it is diagnosed when a patient has as few as one of the four following nonspecific features: joint lesions accompanying severe acne; joint lesions accompanying palmoplantar pustulosis; osteohypertrophy of the extremities, spine, or sternoclavicular joints; and CRMO (9, 14). Since CRMO is one of the criteria for SAPHO syndrome, regardless of the presence or absence of skin lesions, our patients with CRMO could also have been diagnosed with SAPHO syndrome. However, skin manifestations are a major feature of SAPHO syndrome and CRMO without skin lesions complicates its diagnosis. Thus, CRMO in adults should be distinguished diagnostically from SAPHO syndrome.

Since bacterial osteomyelitis and malignancy are most important for making a differential diagnosis of CRMO, many patients with CRMO undergo bone biopsies. Jansson et al. proposed a clinical score system for nonbacterial osteitis to avoid unnecessary bone biopsies (5). Wipff et al. used this score system in patients with CRMO, considered to be the most severe form of nonbacterial osteitis (1). The clinical score was based on seven factors, each of which was assigned a score: normal blood cell count (score: 13), symmetric lesions (10), lesions with marginal sclerosis (10), normal body temperature (9), vertebral, clavicular, or sternal lesions (8), radiologically proven lesions ≥2 (7), and CRP ≥1 mg/dL (6). A score ≥39 (out of a maximum of 63) is considered to be diagnostic of nonbacterial osteitis. In our patients, both patients had scores of 55, corresponding to 6 out of 7 risk factors (except vertebral, sternal, or clavicular lesions) (Table). Thus, both of our patients were diagnosed with CRMO.

The high intensity of muscles detected on MRI, suggested the presence of myositis in both patients, but the CK levels were normal and muscle weakness was absent. There have been several reports of patients with CRMO and myositis. Whole-body MRI was performed in nine pediatric patients with CRMO and in one patient with myositis of the tibias.
In children with CRMO, non-steroidal anti-inflammatory drugs (NSAIDs) are the first-line treatment and they are effective in 73% of cases (1). Naproxen results in a symptom-free status in 6 months in 43% of treated patients (13). Pamidronate also dramatically improves symptoms in patients with CRMO (23). The authors of the latter study suggested that pamidronate changes the relative proportions of cytokines (23). In addition to NSAIDs and pamidronate, patients with refractory CRMO have been treated with glucocorticoids, MTX, sulfasalazine, and anti-TNF therapy (1, 3, 13, 24). Wipff et al. performed a cluster analysis of a CRMO cohort; all of the patients with the severe phenotype were male and 97% of them had multifocal disease (1). These severe phenotype patients also had the worst prognosis, with a remission rate of 22%, despite a higher rate of treatment with bisphosphonate and/or anti-TNF antibodies (33%) (1). Both of our patients were male and they had multifocal lesions; their symptoms and inflammation had continued for many years, even after treatment with NSAIDs, PSL, and MTX. Thus, male patients with adult-onset CRMO characterized by multifocal lesions might develop more severe forms of predominantly pediatric CRMO. Despite many reports in which autoinflammatory diseases were successfully treated using TCZ (25-27), ours is the first report of the successful use of TCZ for the treatment of CRMO. Our decision to use TCZ was based on the high serum IL-6 levels in our patients and previous reports of lower remission rates with anti-TNF antibodies in severe phenotype patients. The reductions in both the symptoms and inflammatory parameters indicate that TCZ may be effective for treating severe forms of CRMO.

The high intensity of the lower leg muscles detected by MRI significantly improved by TCZ therapy, but otherwise the high intensity of the bone marrow did not change in our patients.

In Case 2, the bone marrow enhancement in MRI prior to TCZ therapy (Fig. 7a) had already improved by PSL and MTX therapy, as shown in Fig. 4b. In Case 1, the bone marrow showed a slightly heterogeneous intensity without any treatment at 41 years of age, although a biopsy of the right tibia showed non-bacterial osteomyelitis at 38 years of age. MRI at 48 years of age showed a slightly higher intensity of bone marrow with PSL, and MTX therapy and TCZ did not improve the intensity. In our cases, adding TCZ to PSL and MTX did not significantly improve osteomyelitis according to the MRI findings. However, PSL could be tapered without an exacerbation of osteomyelitis and TCZ was therefore thought to have successfully controlled osteomyelitis in our patients.

In summary, we herein described the cases of two patients with adult-onset CRMO involving the diaphyses of the long bones and accompanied by high intensity of muscles on MRI and polyarthritis. Necrotizing vasculitis in one patient was also evident, based on a biopsy of a cutaneous nodule. In adult-onset CRMO, anti-IL-6 therapy should therefore be considered in patients with muscle inflammation not re-
sponding to NSAIDs, MTX and PSL.

The authors state that they have no Conflict of Interest (COI).
