(Dated: September 10, 2020)

We develop a method to compute low-eccentricity initial data of black hole–neutron star binaries in the puncture framework extending previous work on other types of compact binaries. In addition to adjusting the orbital angular velocity of the binary, the approaching velocity of a neutron star is incorporated by modifying the helical Killing vector used to derive equations of the hydrostationary equilibrium. The approaching velocity of the black hole is then induced by requiring the vanishing of the total linear momentum of the system, differently from the case of binary black holes in the puncture framework where the linear momentum of each black hole is specified explicitly. We successfully reduce the orbital eccentricity to ≲ 0.001 by modifying the parameters iteratively using simulations of ≈ 3 orbits both for nonprecessing and precessing configurations. We find that empirical formulae for binary black holes derived in the excision framework do not reduce the orbital eccentricity to ≈ 0.001 for black hole–neutron star binaries in the puncture framework, although they work for binary neutron stars.

I. INTRODUCTION

One of the remaining and promising targets for ground-based gravitational-wave detectors is the coalescence of black hole–neutron star binaries (see Ref. 1 for reviews). Indeed, we have already been informed of possible black hole–neutron star binary coalescences in the LIGO-Virgo O3, including signals from inconclusive progenitors 2,3. If we would have detected these events with a high signal-to-noise ratio, we could infer finite-size properties of neutron stars such as the radius 4–8 and tidal deformability 9,10 as well as the mass and the spin of each component. Because the finite-size properties depend crucially on the underlying equation of state for supranuclear-density matter (see Refs. 11,12 for reviews), gravitational-wave observations of black hole–neutron star binaries will provide invaluable information not only to astrophysics but also to nuclear physics in a similar manner to the detections of binary neutron stars 13,14.

Reliable theoretical templates of gravitational waveforms are the prerequisite for accurate extraction of source properties 15,16. Accordingly, theoretical calculations of gravitational waveforms have been playing a central role in gravitational-wave astronomy. Particularly high accuracy is required to extract finite-size properties of neutron stars, namely the tidal deformability, in a reliable manner 17,19. Although the systematic errors associated with waveform models are smaller than the statistical errors for the first binary-neutron-star merger GW170817 14,20,21 and largely uninformative GW190425 2, improvement of the detector sensitivity by an order of magnitude 22 will make the systematic error discernible for GW170817-equivalent sources 23,24. Development of templates for black hole–neutron star binaries is generally premature 25,26 (see also Refs. 27,28 for recent progress). One reason is attributed to the small number of long-term and high-precision simulations of black hole–neutron star binaries in numerical relativity, which is the unique tool to investigate theoretically the late inspiral and merger phases and to derive gravitational waveforms. While a lot of insights on dynamical mass ejection and electromagnetic counterparts have been gained in the past years 29,30, we need to re-examine numerical-relativity simulations of the inspiral and merger phases to derive accurate gravitational waveforms 39,40.

Realistic initial data of black hole–neutron star binaries are necessary to compute realistic gravitational waves in numerical relativity. In particular, the orbital eccentricity has to be low enough, because the majority of astrophysical compact binaries are circularized nearly completely right before merger due to gravitational radiation reaction during its long inspiral 41,42. It has been pointed out that seemingly tiny eccentricity, say e ∼ 0.01, in theoretical templates can significantly degrade the accuracy with which we can measure the tidal deformability via gravitational-wave observation 18. Eccentricity reduction has already been performed for and routinely applied to initial data of black hole–neutron star binaries in the excision framework 43, in which the physical singularity inside the horizon is removed from the computational domain. However, the eccentricity reduction for initial data of black hole–neutron star binaries in the puncture framework 44,45, in which the singularity is handled in an analytic manner, has not yet been reported.
In this paper, we present a method to reduce the orbital eccentricity in initial data of black hole–neutron star binaries in the puncture framework. Specifically, we adjust the orbital angular velocity and incorporate the approaching velocity to obtain low-eccentricity initial data, where their values are determined iteratively by analyzing orbital evolution for a few orbits derived by dynamical simulations. Differently from initial data of binary black holes in the puncture framework, in which the approaching velocity of black holes is incorporated by actively choosing the values of the linear-momentum parameter, the transverse part of the metric cannot be specified freely in our formulation for black hole–neutron star binaries. In this work, we first incorporate an approaching velocity of the neutron star by modifying the hydrostationary equations in the same manner as in the case of binary neutron stars. Because the black hole is not subject to hydrodynamics, the approaching velocity of the black hole is passively induced by requiring the total linear momentum of the system to vanish. To control the approaching velocity of the binary as a whole, the velocity of the black hole is identified by the minus of the shift vector at the puncture.

The paper is organized as follows. The formulation is described in Sec. II. To demonstrate the validity of our method, we apply it to both nonprecessing and precessing systems. First, we decompose the conformal factor $\psi$, a weighted lapse function $\Phi := \alpha \psi$, and the conformally-weighted traceless part of the extrinsic curvature $\hat{A}_{ij}$ as

$$
\psi = 1 + \frac{M_p}{2r_{\text{BH}}} + \phi, \quad \Phi = 1 - \frac{M_k}{2r_{\text{BH}}} + \eta, \quad \hat{A}_{ij} = \hat{\nabla}_i W_j + \hat{\nabla}_j W_i - \frac{2}{3} f_{ij} \hat{\nabla}^k W_k + K_{ij}^\text{P},
$$

Here, $r_{\text{BH}}$ is the coordinate distance from the puncture, $M_p$ and $M_k$ are constants of mass dimension, $\hat{\nabla}_i$ denotes the covariant derivative associated with $f_{ij}$. The singular part of the extrinsic curvature $K_{ij}^\text{P}$ is determined by two sets of covariantly-constant vectorial parameters, namely the linear momentum $P_k^\text{BH}$ and the bare spin angular momentum $S_k^\text{P}$ of the black hole, as

$$
K_{ij}^\text{P} := \frac{3}{2r_{\text{BH}}^2}[l_i F_j^\text{BH} + l_j F_i^\text{BH} - (f_{ij} - l_i l_j) l_k P_k^\text{BH}] + \frac{3}{r_{\text{BH}}^2} [\epsilon_{kil} S_i^k l_j + \epsilon_{ijk} S_i^k l_l],
$$

where $l_i := x_i^\text{BH}/r_{\text{BH}}$ is the unit radial vector, $l_i = f_{ij} l_j$, and $\epsilon_{ijk}$ is the Levi-Civita tensor associated with $f_{ij}$.

Finally, the regular parts of the geometric quantities $\phi$, $\eta$, $W_i$, and the shift vector $\beta^i$ are obtained by solving elliptic equations derived from a subset of the Einstein equation [see, e.g., Eqs. (16)–(19) of Ref. 50 for the explicit form]. In the puncture framework, we have no inner boundary at the horizon, and the outer boundary condition is derived from the asymptotic flatness condition.

One of the keys to obtain low-eccentricity initial data is the incorporation of the approaching velocity to the helical symmetry, which governs quasicircular initial data described in Ref. 46. In this work, numerical computations are performed using a public multidomain spectral method library, LORENE 59, and the details of the methods are presented in Ref. 50.

The puncture formulation for initial data of black hole–neutron star binaries is summarized as follows. First, conformal transformation is performed for the induced metric $\gamma_{ij}$ and the extrinsic curvature $K_{ij}$ as

$$
\gamma_{ij} = \psi^2 \hat{\gamma}_{ij}, \quad K_{ij} = \psi^{-2} \hat{A}_{ij} + \frac{1}{3} K \psi^4 \hat{\gamma}_{ij},
$$

where $K := \gamma^{ij} \hat{K}_{ij}$. In the puncture framework, the spatial conformal flatness and maximal slicing conditions,

$$
\hat{\gamma}_{ij} = f_{ij}, \quad K = 0,
$$

are imposed. We also require them to be preserved in time in the computation of initial data as usually done in the extended conformal-thin sandwich formulation (see also Refs. 60, 61).

Next, we decompose the conformal factor $\psi$, a weighted lapse function $\Phi := \alpha \psi$, and the conformally-weighted traceless part of the extrinsic curvature $\hat{A}_{ij}$ as

$$
\psi = 1 + \frac{M_p}{2r_{\text{BH}}} + \phi, \quad \Phi = 1 - \frac{M_k}{2r_{\text{BH}}} + \eta, \quad \hat{A}_{ij} = \hat{\nabla}_i W_j + \hat{\nabla}_j W_i - \frac{2}{3} f_{ij} \hat{\nabla}^k W_k + K_{ij}^\text{P}.
$$

Here, $r_{\text{BH}}$ is the coordinate distance from the puncture, $M_p$ and $M_k$ are constants of mass dimension, and $\hat{\nabla}_i$ denotes the covariant derivative associated with $f_{ij}$. The singular part of the extrinsic curvature $K_{ij}^\text{P}$ is determined by two sets of covariantly-constant vectorial parameters, namely the linear momentum $P_k^\text{BH}$ and the bare spin angular momentum $S_k^\text{P}$ of the black hole, as

$$
K_{ij}^\text{P} := \frac{3}{2r_{\text{BH}}^2}[l_i F_j^\text{BH} + l_j F_i^\text{BH} - (f_{ij} - l_i l_j) l_k P_k^\text{BH}] + \frac{3}{r_{\text{BH}}^2} [\epsilon_{kil} S_i^k l_j + \epsilon_{ijk} S_i^k l_l],
$$

where $l_i := x_i^\text{BH}/r_{\text{BH}}$ is the unit radial vector, $l_i = f_{ij} l_j$, and $\epsilon_{ijk}$ is the Levi-Civita tensor associated with $f_{ij}$.

Finally, the regular parts of the geometric quantities $\phi$, $\eta$, $W_i$, and the shift vector $\beta^i$ are obtained by solving elliptic equations derived from a subset of the Einstein equation [see, e.g., Eqs. (16)–(19) of Ref. 50 for the explicit form]. In the puncture framework, we have no inner boundary at the horizon, and the outer boundary condition is derived from the asymptotic flatness condition.

One of the keys to obtain low-eccentricity initial data is the incorporation of the approaching velocity to the helical symmetry, which governs quasicircular initial data.

---

1 Following our previous work [49], we refer to initial data obtained by assuming helical symmetry by “quasicircular,” and those with the approaching velocity by “low-eccentricity.”
of binaries. Following Ref.\[46\], we adopt a symmetry vector equipped with the approaching velocity $v_{\text{app,NS}}^i$ of the form

$$\xi^\mu = (\partial_t)^\mu + \Omega (\partial_\phi)^\mu + v_{\text{app,NS}}^i (\partial_i)^\mu$$

(8)

around the neutron star. In our computation, the rotational axis is taken to be the $z$ axis, and both the black hole and the neutron star are chosen to be located on the $xz$ plane. That is, we have $x_{\text{NS}}^i = (x_{\text{NS}}, 0, z_{\text{NS}})$ and $x_{\text{BH}}^i = (x_{\text{BH}}, 0, z_{\text{BH}})$. We always choose $z_{\text{NS}} = 0$ without loss of generality. For nonprecessing configurations, we also set $z_{\text{BH}} = 0$ and thus both members of the binary are located on the $x$ axis. Our symmetry vector with a translational approaching motion is slightly different from the uniform contraction usually adopted in other eccentricity reduction methods \[43, 63, 64\], and no significant difference has been found for binary neutron stars \[46\].

**B. Choice of free parameters**

Free parameters in the formulation must be determined by physical requirements. In this subsection, we describe our method for determining them. A concise summary is presented in Table\[1\].

The bare mass, $M_p$, and the bare spin parameter, $S_p$, are determined to obtain desired values of the mass and spin of the black hole. The mass and spin magnitude of the black hole are computed in the isolated-horizon framework (see Ref.\[65\] for reviews) with an approximate rotational Killing vector obtained by minimizing its shear on the horizon \[66\]. In our computation, we restrict the spin parameter to have only $x$ and $z$ components and define the inclination angle $\iota$ as the angle between the coordinate components of the orbital angular momentum and the spin angular momentum in a gauge-dependent manner \[68\]. The linear momentum of the black hole, $p_{\text{BH}}^i$, is determined by requiring the total linear momentum of the system vanishes. This means that we cannot choose values of $p_{\text{BH}}^i$ to control the approaching velocity of the black hole. This is the chief difference from the eccentricity reduction of binary black holes in the puncture framework \[47, 67, 68\] and is the reason that we need to develop a method suitable for black hole–neutron star binaries. A constant value of the first integral of the Euler equation is determined by requiring the baryon rest mass of the neutron star to take a desired value.

The mass parameter in the weighted lapse function, $M_\Phi$, is determined by the condition that the Arnowitt-Deser-Misner and Komar masses are equal, which holds for stationary and asymptotically-flat spacetimes \[39, 70\]. This condition also holds for quasicircular initial data computed in our formulation \[71, 72\], and thus requiring this condition is fully justified. However, this does not hold rigorously for low-eccentricity initial data with an approaching velocity. Despite this caveat, we still determine the value of $M_\Phi$ by the equality of the two masses even if the approaching velocity is turned on. We expect that this condition is not very problematic, because we observe for initial data of binary neutron stars \[46\] that the differences between the Arnowitt-Deser-Misner and Komar masses are of the same order for both quasi-circular and low-eccentricity cases. This situation is also reported in black hole–neutron star initial data computed in the excision framework \[33\]. When more accurate numerical computations become necessary, the condition for determining $M_\Phi$ should be elaborated.

As we will discuss in the next section, we would like to control the orbital angular velocity $\Omega$ and approaching velocity of the binary $v_{\text{app}}$ to obtain low-eccentricity initial data\[4\]. On one hand, the orbital angular velocity, $\Omega$, appears explicitly in our symmetry vector, Eq.\[8\]. On the other hand, the approaching velocity of the binary is controlled implicitly via that of the neutron star, $v_{\text{app,NS}}^i$; in our formulation. The approaching velocity vector of the black hole, $v_{\text{app,BH}}^i$, in the initial data is identified as the minus of the $x$ and $z$ components (see below for the $y$ component) of the shift vector at the puncture as

$$v_{\text{app,BH}}^i = (-\beta^x, 0, -\beta^z)|_{\text{BH}}.$$  

(9)

Then, we adjust the value of $|v_{\text{app,NS}}^i|$, where the usual Euclidean norm is assumed, so that $|v_{\text{app,NS}}^i| + |v_{\text{app,BH}}^i|$ agrees with the desired value of $|v_{\text{app}}|$. Because we always require the vanishing of the total linear momentum of the system, the approaching velocity of the neutron star automatically induces that of the black hole.

When we compute quasicircular initial data for a given separation along the $x$ axis, $d^x$, the value of $\Omega$ is determined by requiring the force balance at the neutron-star center \[65\],

$$\frac{\partial h}{\partial x} |_{\text{NS}} = 0.$$  

(10)

The approaching velocity is set to be zero by choosing $v_{\text{app,NS}}^i = 0$. This results in $v_{\text{app,BH}}^i = 0$ within the numerical error.

When we compute low-eccentricity initial data for a given value of $d^x$, we prescribe desired values of $\Omega$ and $v_{\text{app}}$ according to the estimates from dynamical simulations (see Sec.\[2\]). The value of $\Omega$ in Eq.\[8\] is fixed to this prescribed value for each computation of initial data. For the approaching velocity vector of the neutron star, $v_{\text{app,NS}}^i$; in Eq.\[8\], we need to determine the magnitude and the direction. The magnitude is determined so that $|v_{\text{app,NS}}^i| + |v_{\text{app,BH}}^i|$ take the prescribed value, $|v_{\text{app}}|$. The direction is set to point toward the black hole. For nonprecessing binaries, $v_{\text{app,NS}}^i$ has only the $x$ component

2 The parameter, $v_{\text{app}}$, is denoted by $2v$ in Ref.\[49\] for equal-mass binary neutron stars.
and $v^i_{\text{app,BH}}$ points exactly opposite to $v^i_{\text{app,NS}}$. For precessing binaries, we find that the induced approaching velocity of the black hole, $v^i_{\text{app,BH}}$, does not point exactly toward the neutron star in our coordinates, but the deviation is smaller than 0.1° for the case studied here. Because the direction is inherently gauge dependent, we regard this deviation as acceptable.

We have to determine the location of the rotational axis, or the positions of black hole and neutron star relative to the rotational axis, in our computations. In the excision framework, this location is fixed by the condition that the total linear momentum of the system vanishes

$$
\int \rho \gamma d^3x = 0.
$$

(12)

This states that the puncture moves along the symmetry vector, Eq. (3), and is consistent with our definition of $v^i_{\text{app,BH}}$, where the unused $y$ component of the shift vector is interpreted as the orbital velocity.

We also have to determine the separation between the black hole and the neutron star along the rotational axis, $d^z$, when we compute precessing configurations. It is determined by requiring the force-balance condition like Eq. (10) but along the $z$ direction

$$
\frac{\partial h}{\partial z}_{\text{NS}} = 0.
$$

(13)

The position of the neutron star is fixed to $z_{\text{NS}} = 0$ throughout.

### C. Iterative correction

We seek the optimal choice of $\Omega$ and $v^i_{\text{app}}$ for a given value of the separation along the $x$ axis, $d^x$, via iterative corrections estimated from the orbital evolution derived by dynamical simulations. This strategy is originally developed for binary-black-hole initial data [63], and later applied successfully to black hole–neutron star binaries in the excision framework [43] and to binary neutron stars [46, 77, 78]. Our dynamical simulations are performed with an adaptive-mesh-refinement code, SACRA [79], and the formulation adopted in the current version is explained in Ref. [46]. We do not use the MPI-parallelized version of SACRA [80], because the eccentricity reduction does not require orbital evolution with a very high precision.

The position and velocity of the neutron star are identified with the integration over the fluid as

$$
x^i_{\text{NS}} = \frac{\int \rho u^i x^3 d^3x}{\int \rho u^3 d^3x},
$$

(13)

$$
\dot{x}^i_{\text{NS}} = \frac{\int \rho u^i \dot{x}^3 d^3x}{\int \rho u^3 d^3x},
$$

(14)

where $\rho_* := \rho_0 u^t \sqrt{\gamma}$ and $\dot{x}^i := u^i / u^t$, with $\rho$ and $u^\mu$ being the rest-mass density and the four velocity of the fluid, respectively. The velocity of the black hole is identified as the minus of the shift vector at the puncture in a similar manner to Eq. (9) as

$$
\dot{x}^i_{\text{BH}} = -\beta^i_{\text{BH}},
$$

(15)

and the position is obtained by integrating this in time. In SACRA, the shift vector at the puncture is determined
by trilinear interpolation from surrounding eight grid points, and this limits the accuracy with which we can determine the orbital evolution for given data of gravitational fields. The orbital angular velocity of the binary is computed from the Euclidean outer product of \( x^t := x^t_{NS} - x^t_{BH} \) and \( \dot{x}^t := \dot{x}^t_{NS} - \dot{x}^t_{BH} \) as [64] [81]

\[
\Omega = \frac{x \times \dot{x}}{|x|^3}.
\]  

We estimate appropriate values of the correction to \( \Omega \) and \( v_{\text{app}} \) by fitting the time evolution of orbital angular velocity, \( \tilde{\Omega}(t) \), by a function [63 [64] [82]]

\[
\tilde{\Omega}(t) = A_0 + A_1 t + B \cos(\omega t + \phi_0),
\]  

where \( \{A_0, A_1, B, \omega, \phi_0\} \) are parameters determined by the fitting. We average numerical data over \( \sim 100 \) time steps in deriving \( \tilde{\Omega}(t) \) to remove high-frequency noise [46]. The fitting is performed using \( \tilde{\Omega}(t) \) during \( 0.5P_0 < t < 3P_0 \), where \( P_0 \) is the initial orbital period of the binary. Aiming at removing the modulation term, \( B \cos(\omega t + \phi_0) \), we modify \( \Omega \) and \( v_{\text{app}} \) in the initial-data computation by

\[
\delta\Omega = -\frac{B \omega \sin \phi_0}{4\Omega^2},
\]

\[
\delta v_{\text{app}} = \frac{B d \cos \phi_0}{2\Omega},
\]

according to Newtonian expressions [46] [63] [64]. Here, \( d = \sqrt{(\delta x)^2 + (\delta y)^2} = |x(t = 0)| \) is the initial orbital separation. We also estimate the orbital eccentricity by

\[
e \approx \frac{|B|}{2\omega \Omega}.
\]  

in this fitting procedure. Exceptionally when \( e < 0.001 \), we find that the beginning of the fitting interval has to be delayed until \( t = 0.75P_0 \) to obtain meaningful estimates of the residual eccentricity.

### III. Demonstration

We present results of our eccentricity reduction for a few models of black hole–neutron star binaries. Key quantities of the initial data constructed in this work are summarized in Table 1. The neutron stars are modeled by a piecewise polytropic approximation [83] of the APR4 equation of state [84] with the gravitational mass in isolation of \( M_{NS} = 1.35M_\odot \). The APR4 equation of state is consistent with GW170817 [13] [14] [81], and gives the dimensionless tidal deformability of 323 for this 1.35\( M_\odot \) neutron star. The gravitational mass in isolation of the black hole is fixed to be \( M_{BH} = 4.05M_\odot \), giving the mass ratio \( Q := M_{BH}/M_{NS} = 3 \). Accordingly, the total mass at infinite separation \( m_0 := M_{BH} + M_{NS} = 5.4M_\odot \).

We have checked that our eccentricity reduction method works similarly for other equations of state and/or binary

parameters (see Ref. [46] for binary neutron stars). We plan to present results of systematic long-term simulations of low-eccentricity black hole–neutron star binary coalescences elsewhere.

All the simulations are performed with computational domains consisting of five boxes fixed around an approximate center of mass and four pairs of boxes comoving with each binary component. The edge length of the largest computational domain is \( \approx 2500 \) km and the grid resolution at the finest domain is \( \approx 240 \) m. The grid resolution is intentionally kept moderate for demonstrating that the eccentricity reduction can be performed with a reasonable computational cost. We checked for selected models, both before and after the eccentricity reduction, that the eccentricity does not depend on the grid resolution of the dynamical simulations.

### A. Nonprecessing case

First, we apply the eccentricity reduction described in Sec. II to two nonprecessing binaries. One is the ZS (zero spin) model, for which the black hole is nonspinning. The other is the AS (aligned spin) model, for which the black hole is spinning in a prograde sense with respect to the orbital angular momentum with its magnitude being \( \chi = 0.75 \). (See IS for the next subsection.) The orbital modulation is induced only by the residual eccentricity and possible gauge artifacts (see, e.g., Refs. [46] [67]) for these models. Thus, the eccentricity reduction should be straightforward.

#### 1. Time evolution

Figure 1 shows the time evolution of the orbital separation for selected models in the sequence of eccentricity reduction. The orbital eccentricity is reduced from \( 0.04 \) to \( < 0.001 \) (see Table 1) by several iterative corrections. To achieve this eccentricity with current models, for which \( m_0 \Omega \approx 0.25 \), we need to modify the orbital angular velocity by \( \approx 1.5\% – 1.7\% \) and to add the approaching velocity of \( \approx 0.17\% \) of the speed of light. While the required approaching velocity is similar to the value found for binary neutron stars considered in Ref. [46], the fractional amount of the required correction to the orbital angular velocity, \( \delta\Omega/\Omega \), is larger by a factor of \( \approx 4 \). This is consistent with the degree of the residual eccentricity, which is also higher by a factor of \( \approx 4 \) than that of binary neutron stars, \( e \approx 0.01 \), for quasicircular initial data considered in Ref. [46], because Eqs. (18) and (20) indicate that these quantities are approximately proportional to each other. The approaching velocity may play a subdominant role for determining the residual eccentricity.

The number of required iterations is typically larger than that for binary neutron stars with our method [46]. Changes of the relevant parameters during the eccentricity reduction are presented graphically in Fig. 2, which
TABLE II. Key quantities of the models of black hole–neutron star binaries constructed in this work. Names of models represent the spin configuration and the stage of eccentricity reduction. Specifically, QC and IterX stand for quasicircular and the Xth iteration, respectively. The total mass of the binary at infinite separation, $m_0$, is $5.4M_\odot$ for all the models. The normalized orbital angular velocity $\nu_0\Omega$ and approaching velocity $v_{\text{app}}$ of the binary characterize the initial data. The Arnowitt–Deser–Misner mass is denoted by $M_0$, where we show it as the gravitational binding energy, $|M_0 - m_0|$. The magnitude of the orbital angular momentum of the system is given by $L_0$, which does not include the spin angular momentum of the black hole. The eccentricity $e$ is estimated by fitting the time derivative of the orbital angular velocity obtained in dynamical simulations. The initial orbital period, gravitational-wave frequency, and wavelength are $\approx 6.7\text{ ms}$, $\approx 300\text{ Hz}$, and $\approx 1000\text{ km}$, respectively.

| Model | $m_0\Omega$ | $v_{\text{app}}$ | $|M_0 - m_0|/M_\odot$ | $L_0/M_\odot^2$ | $e$ |

FIG. 1. Time evolution of the orbital separation for the ZS (left) and AS (right) families during initial $\approx 3$ orbital cycles. The eccentricity-induced modulation has a longer period than the orbital period due to the periastron advance. Differently from Ref. [86], we do not need to perform Bezier smoothing to eliminate high-frequency noises, because the location of the neutron star is defined not by the maximum density on discrete grid points but by the integral, Eq. [13]. Dips seen during the first 2–3 ms reflect initial gauge transition.
should be compared with Fig. 1 of Ref. [46]. This difference means that the eccentricity reduction is cumbersome for black hole–neutron star binaries, which are highly asymmetric and involve singularities associated with the puncture. The necessity of many iterations is partly ascribed to larger eccentricities in quasicircular initial data of black hole–neutron star binaries in the puncture framework described above. Another reason may be that our current correction formulae, Eqs. (18) and (19), are not efficient at \( \epsilon \lesssim 0.2\%–0.3\% \). The situation is visualized as wandering of points beyond Iter3 in Fig. 2. This low efficiency may be ascribed to the fact that initial transition of the gauge condition in the simulations (see Fig. 1) limits the accuracy with which we can extrapolate results of the fitting to \( t = 0 \) [67]. Our results also suggest that the presence of a black-hole spin increases the computational cost for the eccentricity reduction, and indeed our experience supports this observation.

We recall that the orbital eccentricity of quasicircular initial data, i.e., those without the approaching velocity, can be reduced by a factor of 2–3 compared to the QC data adopted in this study simply by changing the condition to determine the location of the rotational axis [3] [50]. We compare orbital evolution derived with various quasicircular initial data as well as low-eccentricity ones for ZS models in Fig. 3. Here, the PN-J model refers to quasicircular initial data in which the location of the rotational axis is determined by requiring that the total angular momentum of the system agrees with post-Newtonian predictions [30] [41] while the QC model is derived using Eq. (11). No iterative eccentricity reduction is applied to either initial data. This figure shows that the PN-J data are superior to the QC data but cannot be a substitute for low-eccentricity initial data, ZS-Iter5. At the same time, this figure suggests that the eccentricity reduction described in this work may further be improved by modifying the method to determine the location of the rotational axis. In addition, the number of required iterations may be reduced by changing the method appropriately. We leave this topic as a future task.

We also find that phenomenological formulae for \( \Omega \) and \( v_{\text{app}} \) derived by simulations of binary-black hole mergers in the excision framework [80] do not reduce the orbital eccentricity of black–neutron star binaries in the puncture framework to \( \lesssim 0.001 \), although they work successfully for binary neutron stars [80] [87] [89]. The orbital evolution is shown in Fig. 3 as ZS-MP. The eccentricity of this model is only smaller by a factor of \( \lesssim 2 \) than that of ZS-QC. This inefficiency may be ascribed to different approaches for handling black holes, i.e., the puncture or excision. Actually, it has been shown in the study of quasiequilibrium sequences that the puncture initial data are characterized by insufficient orbital angular momenta compared to the excision initial data and

---

4 Many of our previous numerical simulations have been performed using these PN-J data (e.g., Refs. [30] [33]) because of their moderately low eccentricity.
post-Newtonian predictions \cite{50}. Thus, it is naturally expected that the parameters to achieve low eccentricity depend significantly on the framework to handle the black hole.

To demonstrate that the successful reduction of the eccentricity is not a gauge artifact, we also show the time evolution of the mode amplitude of a Weyl scalar \( \Psi_4 \) as a gauge-invariant quantity in Fig. \( \PageIndex{7} \). The time coordinate is taken to be a retarded time defined by

\[
t_{\text{ext}} := t - D - 2m_0 \ln(D/m_0),
\]

\[
D := r_{\text{ext}} \left( 1 + \frac{m_0}{2r_{\text{ext}}} \right)^2,
\]

where \( r_{\text{ext}} = 800M_\odot = 1181 \text{ km} \) is the extraction radius. The suppression of the modulation in \( \Psi_4 \) confirms that the reduced orbital modulation shown in Fig. \( \PageIndex{7} \) is a physical outcome caused by the reduced eccentricity. This figure also shows that the modulation is eliminated irrespective of the harmonic modes. This is particularly important for asymmetric systems like black hole–neutron star binaries, for which higher multipole modes are prominent in the actual gravitational-wave signals \cite{3,90}.

2. Properties of initial data

We briefly comment on notable features of initial data. The eccentricity reduction decreases the absolute value of the binding energy and increases the orbital angular momentum of the binary. Although it is not as good as in the case of binary neutron stars \cite{16}, the agreement of the angular momentum between our numerical initial data and post-Newtonian approximations is improved by a factor of \( \approx 3 \) by the eccentricity reduction. Quantitatively, for \( \chi = 0 \) associated with the ZS model, 4th post-Newtonian approximations give \( |M_0 - m_0| = 0.0394M_\odot \) and \( L_0 = 21.59M_\odot^2 \) for \( m_0\Omega = 0.025\Omega \) \cite{61}, where the tidal effect does not significantly affect these values \cite{22}. For an updated value of \( m_0\Omega = 0.0253657 \) corresponding to ZS-Iter5, post-Newtonian approximations give \( |M_0 - m_0| = 0.0397M_\odot \) and \( L_0 = 21.52M_\odot^2 \).

The increase of the angular momentum for low-eccentricity initial data is consistent with our previous finding that the eccentricity in quasicircular initial data can be reduced by enhancing the angular momentum via the condition to determine the location of the rotational axis \cite{5,50}. However, the binding energy for low-eccentricity initial data tends to deviate more from the post-Newtonian predictions than that for quasicircular initial data. The less binding of the low-eccentricity initial data is consistent with our previous work \cite{50} and may reflect an inherent limitation of initial data for black hole–neutron star binaries in the puncture framework.

We find that junk radiation may account for a significant fraction of the differences in the binding energy and the orbital angular momentum. Specifically, the junk radiation\(^\text{5}\) is found to carry away the energy \( \Delta E \approx 4.5 \times 10^{-4}M_\odot \) and the angular momentum \( \Delta L \approx 5.6 \times 10^{-2}M_\odot^2 \) irrespective of the residual eccentricity for the ZS family. They correspond to \( \approx 30\%–40\% \) for the binding energy and \( \approx 50\%–60\% \) for the orbital angular momentum of the differences between ZS-Iter5 and the post-Newtonian predictions. For ZC-QC, taking into account the junk radiation only increases the differences.

The agreement of the angular momentum is improved only moderately for spinning black hole–neutron star binaries. For \( \chi = 0.75 \) associated with the AS model and \( m_0\Omega = 0.025 \), the post-Newtonian prediction gives \( |M_0 - m_0| = 0.0413M_\odot \) and \( L_0 = 20.63M_\odot^2 \), where the spin effect is included up to 3.5th order \cite{91,93}. These values change to \( |M_0 - m_0| = 0.0417M_\odot \) and \( L_0 = 20.54M_\odot^2 \) for \( m_0\Omega = 0.0254245 \) corresponding to AS-Iter9. In addition, the binding energy of quasicircular initial data appears closer to the post-Newtonian prediction than that of low-eccentricity initial data is. Still, our results indicate that the key to reduce the eccentricity is to enhance the orbital angular momentum and the binding energy from quasicircular initial data derived with the helical symmetry.

Again, junk radiation may account for a significant fraction of the difference between AS-Iter9 and the post-Newtonian predictions. In particular, the energy carried away by the junk radiation is \( \Delta E \approx 2 \times 10^{-3}M_\odot \) and agrees approximately with the difference in the binding energy. On another front, the angular momentum carried away by the junk radiation is \( \Delta L \approx 5.6 \times 10^{-2}M_\odot^2 \), approximately coinciding with the value for the AS family. This account for \( \approx 30\% \) of the difference.

Finally, as we do not have a direct control of \( v_i^{\gamma,\text{app,BH}} \), it is worthwhile to check whether the approaching velocity of the binary in the initial data is reasonably distributed to the black hole and the neutron star with the ratio around an expected value of \( Q = 3 \). Figure \( \PageIndex{9} \) shows the ratio of the \( x \) components of the velocity as well as the \( x \) coordinates for ZS and AS families. This figure indicates that the reasonable distribution is automatically achieved. Because both the velocity and the position are gauge-dependent quantities, we believe that the deviation of \( 1\%–2\% \) from \( Q = 3 \) found here as acceptable.

B. Precessing case

Next, we perform precessing binaries, for which the black hole spin angular momentum is inclined with respect to the orbital angular momentum of the binary. The spin-orbit, spin-spin, and quadrupole-monopole couplings induce orbital precessions for inclined spins \cite{94,96}, and precession-induced

\(^{5}\) We estimate quantities of junk radiation at \( r_{\text{ext}} = 200M_\odot \) to account for the short wavelength.
FIG. 4. Time evolution of the mode amplitude of $\Psi_4$ normalized by $Dm_0$ for the ZS (left) and AS (right) families. The top, middle, and bottom rows show the $l = m = 2$, 3, and 4 modes, respectively. The initial $\approx 1$ ms suffers from junk radiation in the initial data. Wiggles observed in our previous work $^{[46]}$ are not significant for the $l = m = 2$ mode, because the extraction radii are larger by a factor of $\approx 4$ here. Still, they are discernible in higher harmonics.
FIG. 5. Ratio of the velocity (circle) and position (cross) between the neutron star and the black hole for the ZS (left) and AS (right) families. The horizontal axis denote the stage of iterative corrections with 0 being the QC data. The dotted lines denote $Q = 3$. 
modulation appears in the orbital evolution and gravitational waves [34]. This feature could make the eccentricity reduction more complicated than in the cases of nonprecessing binaries.

We specifically consider the IS (inclined spin) model, for which the black-hole spin of $\chi = 0.75$ is inclined toward the neutron star by $\approx 92^\circ$ from the initial orbital angular momentum in the initial data [34]. This model is expected to exhibit precession of the orbital plane with the period $\approx 130$ ms, which decreases during the orbital evolution. Following Ref. [33], the $z$ axis of the dynamical simulation is taken to be the direction of the total angular momentum, which is approximately fixed throughout the evolution.

### 1. Time evolution

Figure 6 shows the time evolution of the orbital separation for the IS family. This indicates that the performance of our eccentricity reduction is similar to that for the ZS family. The orbital evolution itself is also similar to that of the ZS model, because the black-hole spin is approximately confined in the orbital plane so that the inspiral is not decelerated or accelerated by the spin-orbit interaction [34]. Because we aim only at reducing the orbital eccentricity to a moderately low value of $\lesssim 0.001$, the precession-induced modulation does not appear even in our low-eccentricity evolution. We have checked that we did not incorrectly subtract the precession-induced modulation during the iterative eccentricity reduction.

Specifically, frequency of the precession-induced modulation is expected to be twice the orbital frequency. Because the eccentricity-induced modulation should have frequency lower than the orbital frequency, it is straightforward to distinguish these two modulation effects.

Required corrections to the orbital parameters are presented in Fig. 7. They also exhibit similarity with those for the ZS family shown in Fig. 2. The situation should change, however, if we further reduce the eccentricity to, say, $e \lesssim 10^{-4}$, where precession-induced modulation is likely to play a role [34].

To monitor the eccentricity using $\Psi_4$, the mode mixing due to the precession has to be removed appropriately. Because our simulations adopt the direction of the total angular momentum as the $z$ axis, the precession-induced modulation is likely minimal but definitely nonnegligible [35, 36]. In this paper, we transform $\Psi_4$ obtained in our simulations to components in the coprecessing frame defined according to Refs. [35, 100, 101] restricting ourselves only to $l = 2$ modes. To the knowledge of the authors, this is the first application of the radiation axis defined in Ref. [35] to black hole–neutron star binaries in numerical relativity (see also Ref. [102] for another choice of the radiation axis [103]).

Time evolution of the $l = |m| = 2$ mode amplitude of $\Psi_4$ is shown in Fig. 5. Specifically, we average $m = 2$ and $m = -2$ modes to remove reflection-asymmetric components [104, 105]. Overall, we confirm that the reduction of eccentricity is not a gauge artifact. Although the evolution appears similar to that of the ZS model as expected from the approximate absence of the spin component along the orbital angular momentum, definite comparisons are difficult because of the presence of additional structures in $\Psi_4$ of the IS model. In particular, modulation with approximately twice the orbital frequency, which is consistent with the precession-induced one, ap-

$^6$ The angle between the rotational axis and the spin angular momentum is taken to be $90^\circ$.
pears to be present in our coprecessing-frame data. We defer detailed investigations of this feature as a future task.

2. Properties of initial data

The binding energy and the orbital angular momentum of the IS family are shown in Table II. They again behave similarly to those of the ZS family. Post-Newtonian predictions are $|M_0 - m_0| = 0.0393M_\odot$ and $L_0 = 21.63M_\odot^2$ for $m_0\Omega = 0.025$, and they change to $|M_0 - m_0| = 0.0397M_\odot$ and $L_0 = 21.56M_\odot^2$ for $m_0\Omega = 0.025383$ corresponding to IS-Iter5. The level of agreement and its improvement is similar to those for the ZS model.

The amount of junk radiation is different between the ZS and IS models. The junk radiation carries away the energy $\Delta E \sim 2 \times 10^{-3}M_\odot$ and the angular momentum $\Delta L \sim 5.6 \times 10^{-2}M_\odot^2$ for the IS model. These values are closer to those for the AS model than for the ZS model, because the property of junk radiation is influenced strongly by the magnitude of the black-hole spin. While $\Delta E$ corresponds to $\sim 14\%$ of the difference of the binding energy between IS-Iter5 and the post-Newtonian prediction, $\Delta L$ approximately coincides with the difference of the orbital angular momentum. What is common among all the models considered in this study is that a significant fraction of the difference between low-eccentricity initial data and the post-Newtonian prediction may be ascribed to the junk radiation.

We also plot the ratio of the approaching velocity and the $x$ coordinate of the black hole and the neutron star in Fig. 9. They are reasonably close to the expected values of $Q = 3$. To sum up, our initial-data computations including the eccentricity reduction perform similarly for both nonprecessing and precessing configurations.

IV. SUMMARY

We demonstrated that the orbital eccentricity in black hole–neutron star binaries prepared in the puncture framework can be reduced to $\varepsilon \lesssim 0.001$ irrespective of the spin configuration. Following previous work [40, 63, 64], we iteratively modify parameters specifying the initial data, namely the orbital angular velocity and the approaching velocity of the binary, by analyzing orbital evolution derived by dynamical simulations for a few orbits. Because the linear momentum of the black hole cannot be specified freely in our puncture-based formulation for initial data of black hole–neutron star binaries, we cannot adopt methods developed for binary black holes in a straightforward manner [17, 67, 68, 106, 1]. In this work, we instead control the approaching velocity of the neutron star by modifying the helical Killing vector required to integrate Euler’s equation [45] (see also Ref. [17]). The approaching velocity of the black hole is induced automatically by the requirement that the total linear momentum of the system vanishes. To control the approaching velocity of the binary, the velocity of the black hole is defined by the minus of the shift vector at the puncture. Accordingly, we also determine the location of the rotational axis by requiring that the puncture moves in the azimuthal direction with the orbital angular velocity [19].

Our work completes, at least as a first serious attempt, the eccentricity reduction for initial data of

\[ \varepsilon \lesssim 0.001 \]
compacting black hole–neutron star binaries required for fully exploiting ground-based gravitational-wave detectors [16]. For binary neutron stars, an essentially common formulation has been adopted by various authors to reduce the orbital eccentricity [40, 77, 78]. Although the eccentricity reduction of binary black holes has long been performed both in the excision [63] and puncture [67] frameworks, it has performed only in the former for black hole–neutron star binaries [43]. Taking the robustness of the moving-puncture simulations into account, our formulation may potentially be advantageous for systematic exploration of a wide parameter space of black hole–neutron star binaries (see Refs. [6, 7] for our early effort).

Unsatisfactory aspects of our eccentricity reduction indicate future directions for the improvement. The required number of iterative corrections are generally larger than that for binary neutron stars, particularly for the case that the black-hole spin is high. In addition, previous studies on binary black holes in the puncture framework suggest that the gauge dynamics could degrade the accuracy in fitting the orbital motion at $e \lesssim 0.001$ [67]. Although the initial transition of the gauge condition could remain to be an obstacle, these features may be improved by adopting a sophisticated fitting procedure [64, 68]. Differently from the case of binary neutron stars [40], fitting formulae derived from binary-black-hole simulations in the excision framework [80] do not reduce the orbital eccentricity to a satisfactory level of $e \approx 0.001$. It would be helpful to develop phenomenological formulæ tailored to black hole–neutron star binaries in the puncture framework after performing systematic eccentricity reduction. Regarding the low-eccentricity initial data themselves, global quantities like the binding energy and the orbital angular momentum do not agree very well with post-Newtonian predictions. Our investigation suggests that a significant fraction of the deviation may be ascribed to junk radiation, and formulation that suppresses it will improve the accuracy of initial data and dynamical simulations (see also Refs. [43, 107] for issues related to the high spin).

Detections of gravitational waves from black hole–neutron star binaries are now becoming realistic. It is probable that we will detect their coalescences with measurable matter effects, possibly associated with electromagnetic counterparts (see, e.g., Refs. [31, 34]), in the foreseeable future. We are now systematically performing long-term simulations of inspiraling black hole–neutron star binaries, extending our previous work on binary neutron stars [80, 89], to develop reliable gravitational-wave templates. We plan to report results derived by these simulations elsewhere.
