ABSTRACT

From the rate of hydrogen ionization and the gamma-ray flux, we derived the spectrum of relativistic and subrelativistic cosmic rays (CRs) nearby and inside the molecular cloud Sgr B2 near the Galactic Center. We studied two cases of CR propagation in molecular clouds: free propagation and scattering of particles by magnetic fluctuations excited by the neutral gas turbulence. We showed that in the latter case CR propagation inside the cloud can be described as diffusion with a coefficient of $\sim 3 \times 10^{22} \text{cm}^2 \text{s}^{-1}$. For the case of hydrogen ionization by subrelativistic protons, we showed that their spectrum outside the cloud is quite hard with a spectral index of $\delta > -1$. The energy density of subrelativistic protons ($\sim 50 \text{eV cm}^{-3}$) is one order of magnitude higher than that of relativistic CRs. These protons generate the 6.4 keV emission from Sgr B2, which was about 30% of the observed continuum from Sgr B2, and in principle, this X-ray component provided by electrons could be seen from the INTEGRAL data as a stationary high energy excess above the observed spectrum $E_x^{-2}$.

Key words: cosmic rays – Galaxy: center – ISM: clouds – X-rays: ISM

1. INTRODUCTION

One of the important but still unresolved problems of astrophysics is spatial distribution of cosmic rays (CRs) in the Galaxy. We still do not have a reliable understanding of how CRs are distributed in different parts of the Galaxy and what their spectrum is there. In principle, this can be estimated from the characteristics of nonthermal emission generated by CRs in a range of wavelengths. The density of relativistic protons in the Galactic Disk (GD) can be derived from the observed intensity of gamma-rays, which are believed to be produced by proton–proton (pp) collisions while the density of subrelativistic CRs can be estimated from the emission of nuclear de-excitation lines and IR absorption lines of ionized hydrogen (see, e.g., Ramaty et al. 1979; Berezinskii et al. 1990; Oka et al. 2005).

Several attempts were undertaken to derive the distribution of relativistic CRs in GD with energies above 1 GeV from the gamma-ray data. The distribution of CRs, derived from the COS-B (Bhat et al. 1986; Bloemen et al. 1986; Strong et al. 1988), EGRET (see, e.g., Strong & Mattax 1996) and Fermi-LAT (Abdo et al. 2010; Ackermann et al. 2011; Tibaldo & for the Fermi-LAT Collaboration 2013) measurements, showed that the density of CRs in the Galactic Center (GC) was higher than near-Earth but their spatial distribution in the GD was much flatter than the distribution of their potential Galactic sources: supernova remnants (SNRs; see Case & Bhatta-charya 1998; Green 2012) or pulsars (see, e.g., Lorimer 2004).

A natural explanation for this could be an effective spatial mixing of CRs by particle scattering on magnetic fluctuations in the Galaxy if the GD is surrounded by a giant halo in which CRs spend a significant part of their lifetime before escaping from the Galaxy (see Berezinskii et al. 1990). However, numerical calculations showed (see, e.g., Dogiel & Uryson 1988; Bloemen et al. 1993) that even in the most favorable case of a very extended halo this scattering (described as diffusion propagation) was unable to remove the signature of the source distribution. The CR distribution derived from the diffusion model was steeper than the distribution inferred from gamma-ray observations although it was flatter than the source distribution. One of the explanations was suggested by Strong et al. (2004) who showed that the problem can be solved by a variation in the $W_{\text{CO}}-N(\text{H}_2)$ (metallicity) scaling factor.

Another possible way to define the density of CRs at different galactocentric radii (and even at different altitudes above the GD) is the analysis of gamma-ray emission from molecular clouds whose total mass is known; see Digel et al. (1996), Hui et al. (2011), Yang et al. (2014a, 2014b), and Tibaldo et al. (2015) for the GeV energy range and Aharonian et al. (2006) for the TeV energy range. A special case is the circumnuclear disk of molecular gas in the Galactic plane whose position may coincide with the source J1745.6-2858 from the second and third Fermi-LAT source catalog (see...
Nolan et al. 2012; Abdo et al. 2015). This gamma-ray emission can be provided by CRs generated in the course of present or past activity of Sgr A* (see Chernyakova et al. 2011; Chernyshov et al. 2014; Malyshev et al. 2015). However, analysis of the radiation from source J1745.6–2858 is beyond the scope of the present work. We will analyze this emission elsewhere. We note that van Eldik (2015) provided an excellent review of the origin of gamma-ray emission from the GC.

Recent analysis of gamma-ray emission from a local molecular cloud near Earth and the cloud Sgr B2 in the GC provided by Yang et al. (2014a, 2014b) showed that the density of CRs was almost the same in these regions although the distance between them is about 8 kpc. However, these estimations of CR density inside the clouds depend on how freely energetic particles can penetrate into molecular clouds. Answering this question is one of the goals of this article.

The spectrum of CRs in the energy range below 1 GeV can also be estimated from the gamma-ray data. Dermer et al. (2013) derived the spectrum of the proton component of CRs in the local interstellar gas from the mid-latitude measurements of the Galactic gamma-ray emission (see Abdo et al. 2009). These investigations showed that there was a flattening in the proton spectrum below several GeV. A similar conclusion was obtained by Neronov et al. (2012) from an investigation of gamma-ray emission generated in local molecular clouds. However, due to the energy threshold of a pp reaction, the gamma-ray data that are useful for deriving the spectrum of CR protons are those with energies above one hundred MeV.

Bouchet et al. (2011) derived the spectrum of Galactic electrons in the range between 1 and 5 GeV from the intensity of diffuse hard X-ray emission measured by INTEGRAL. They showed that a significant fraction of the Ridge emission in the range above 50 keV is produced by the inverse Compton scattering of these electrons on background photons. Almost 40 years ago Ramaty et al. (1979) suggested measuring the flux of nuclear de-excitation lines with \( E_\gamma \sim 0.1–10 \text{ MeV} \) generated by subrelativistic CRs in order to estimate their density in the range between several MeV and hundreds of MeV. However, the sensitivity of gamma-ray telescopes was not (and still is not) high enough to detect these lines in the diffuse gamma-ray spectrum (see, e.g., Dogiel et al. 2009b; Benhabiles-Mezhoud et al. 2013).

Another very interesting result regarding the parameters of low energy CRs in the GC region was obtained by Nobukawa et al. (2015). They found an excess of the 6.4 keV line emission in the near east of the GC. They concluded that this excess is due to iron-atom bombardment by protons with energies 0.1–1000 MeV. The estimated energy density of these protons is about 80 eV cm\(^{-3}\), which is almost two orders of magnitude higher than the energy density of relativistic CRs near Earth.

In principle, the spectrum of low energy CRs in the range below 100 MeV can also be derived from the ionization rate of hydrogen in the interstellar medium. The point is that subrelativistic electrons and protons ionize hydrogen molecules effectively. The ionization rate can be derived from the \( H_2^+ \) IR absorption lines (see Oka et al. 2005 and Indriolo & McCall 2012; see also the review of Dalgarno 2006) which allows one to estimate the density of subrelativistic CRs inside molecular clouds and in the intercloud medium (see, e.g., Dogiel et al. 2002, 2013, 2014).

The average ionization rate in the 100 pc central region of the Galaxy, measured by Oka et al. (2005), is about \( (3–5) \times 10^{-15} \text{ s}^{-1} \), while this value for the cloud Sgr B2 is depleted and equals \( 4 \times 10^{-16} \text{ s}^{-1} \) (Van der Tak et al. 2006). This means that penetration of subrelativistic CRs into Sgr B2 is not complete, and the average density of these CRs in the intracloud region is higher than inside Sgr B2. A similar effect is observed for the clouds outside the GC where the ionization rate is about \( 3.5 \times 10^{-15} \text{ s}^{-1} \) in the diffuse clouds, while this value is \( 3 \times 10^{-17} \text{ s}^{-1} \) in dense molecular clouds (Indriolo & McCall 2012).

The spectrum of subrelativistic CRs inside molecular clouds depends on processes of particle propagation there. Several models are used in order to estimate CR density in the clouds. One of them is extrapolation of the model of CR propagation in the interstellar medium when charged particles are scattered by resonant MHD waves (see, e.g., Dogiel et al. 2002; Gabici et al. 2007; Protheroe et al. 2008). Alternatively, Padovani et al. (2009) derived the spectrum of subrelativistic CRs in the local interstellar medium from the rate of hydrogen ionization in the local molecular clouds assuming that they propagate freely (without scattering) inside the clouds although the effect of the large scale magnetic field may be essential in this case (see Padovani & Galli 2011). We discuss processes of CR penetration into the clouds and show that this process may differ strongly than supposed in previous publications. We also try to estimate the spectrum of CRs in the GC from the observed gamma-ray flux and the ionization rate of hydrogen in Sgr B2. Propagation of CRs in a partially ionized medium is a rather complicated process, which includes CR ionization of the medium, hydromagnetic waves generation and damping, density, and magnetic structures of the medium. We address the density structure and ionization state of Sgr B2 in Section 2. Section 3 discusses excitation of hydromagnetic waves by CRs, wave damping by ion-neutral collisions, and diffusion of CRs in the cloud, and Section 4 considers the magnetic structure of the cloud. Based on these, we calculate the CR spectrum for two models of the cloud in Section 5. Section 6 gives some consequences of the model. Section 7 discusses the possibility of ionization by electrons. Finally, in Section 8 we provide a summary.

2. HYDROGEN PARAMETERS OF SGR B2 AND ENERGY LOSSES OF CRS

Parameters of CR propagation depends on the medium parameters. The strength of magnetic field in Sgr B2 was estimated from the Zeeman splitting and was about 0.5 mG (see, e.g., Crutcher et al. 1996). The cloud Sgr B2 is a very massive complex. Aharonian et al. (2006) estimated its total mass as \( (6–15) \times 10^6 \text{ M}_\odot \) for a \( 0.5 \times 0.5 \text{ (75} \times 75 \text{ pc}^2) \) region surrounding Sgr B2. The gas distribution in the cloud Sgr B2 is highly uncertain.

Lis & Goldsmith (1989, 1990, 1991) and Goldsmith et al. (1990) derived a two-component density distribution: an envelope with a constant \( H_2 \) density of about 1800–3500 cm\(^{-3}\) extending to the outer radius of about 22.5 pc and a central core with a central density of \( (4–9) \times 10^4 \text{ cm}^{-3} \). According to their analysis the density distribution can be approximated as

\[
n_{H_2}(r) = \begin{cases} 
n_1 + n_2, & \text{if } r \leq r_0, \\
(n_1/r)^{\alpha} + n_2, & \text{if } R \geq r > r_0,
\end{cases}
\]

where \( n_1, n_2, r_0, R \) are constants.
with \( r_0 = 1.25 \) pc, \( R = 22.5 \) pc, \( n_l = 5.5 \times 10^4 \text{ cm}^{-3} \), \( n_2 = 2.2 \times 10^5 \text{ cm}^{-3} \), and \( \alpha = 2 \). The H$_2$ column density at the center is \( N(H_2) = 2.6 \times 10^{24} \text{ cm}^{-2} \), and they took the total mass of Sgr B2 to be \( 6.3 \times 10^6 \text{ M}_\odot \).

Protheroe et al. (2008) expressed the gas distribution in Sgr B2 in the form

\[
n_{H_2} = \frac{M_{H_2}}{2m_H} \left( \frac{1}{2\pi^3} \right) \exp\left(-r^2/2\sigma^2\right),
\]

where \( M_{H_2} \) is the total mass of Sgr B2 and \( \sigma = 2.75 \) pc. The density is about \( 10^4 \text{ cm}^{-3} \) at the center of the Sgr B2 complex, and decreases to \( 10 \text{ cm}^{-3} \) at a radius of \( \sim 12 \) pc, which they considered to be its outer radius. The central column density is about \( 2.5 \times 10^{24} \text{ cm}^{-2} \) and the estimated mass of Sgr B2 is about \( M_{H_2} \approx 2 \times 10^5 \text{ M}_\odot \) (see Protheroe et al. 2008).

Below we analyze processes of hydrogen ionization and gamma-ray emission for these two extreme distributions of hydrogen in Sgr B2.

CRs effectively lose their energy inside the dense molecular clouds. In the non-relativistic energy range the rate of losses is determined by ionization (see Hayakawa 1964; Ginzburg 1989)

\[
\left( \frac{dE}{dt} \right)_I = -\frac{2\pi e^4 n_i}{m_e c} \ln \left( \frac{m_e^2 c^2 W_{\text{max}}}{4\pi e^2 \hbar^2 n} \right),
\]

where \( n_i \) is the density of background gas, \( m_e \) is electron mass, \( W_{\text{max}} \) is the highest energy transmitted to an ambient electron, and \( \beta(E) = u/c \), where \( u \) is the particle velocity in units of light speed \( c \). The characteristic time of the losses is

\[
\tau_i = \int_E \frac{dE}{(dE/dt)_I}.
\]

In the relativistic energy range protons lose their energy through collisions with the ambient gas (pp collisions). The characteristic time of the process is

\[
\tau_{pp} = c n_H \sigma_{pp},
\]

where the cross-section of a pp reaction can be found in, e.g., Kamae et al. (2006).

One of the key point for the problem of CR penetration into dense molecular clouds is how they propagate through the gas. This problem is discussed in the next section.

3. CR DIFFUSION INSIDE MOLECULAR CLOUDS

In the standard model of CR propagation through the interstellar medium (see, e.g., Berezinskii et al. 1990) the spatial diffusion coefficient can be presented in the form

\[
D \sim \frac{u^2}{\nu(E)},
\]

where \( \nu(E) \) is the frequency of particle scattering by resonant MHD waves:

\[
\nu \sim \omega_H \frac{\delta H(k)^2}{H_0^2}.
\]

Here \( \delta H(k) \) is the strength of a magnetic fluctuation with the wave number \( k \), \( H_0 \) is the large scale magnetic field, \( \omega_H = eH_0/m_e c \gamma \), and \( \gamma \) and \( m \) are the gamma factor and the mass of a scattered particle, respectively. The wave–particle interaction is resonant. A particle with energy \( E \) is scattered by waves whose wavelength is about the particle Larmor radius, \( \lambda = 2\pi/k \sim \eta_i(E) \). The amplitude of magnetic fluctuations, \( \delta H \), is supposed to be much smaller than the strength of the large scale magnetic field \( H_0 \) in the interstellar medium,

\[
\delta H(k) \ll H_0.
\]

For the wave spectrum of fluctuations \( W(k) \propto k^{-\kappa} \), where \( \delta H(k)^2 = kW(k) \), the spatial diffusion coefficient \( D \) of relativistic CRs is energy dependent as (see Berezinskii et al. 1990)

\[
D(E) \propto E^{2-\kappa}.
\]

This model of CR diffusion in the interstellar medium is often extrapolated to the case of CR propagation inside molecular clouds. However, the process of particle propagation nearby and inside the almost neutral and dense gas of molecular clouds is quite different in comparison with the standard process of CR diffusion in the interstellar medium. There are several specific mechanisms that determine this process.

1. Dense molecular clouds absorb CRs with energies whose lifetime \( \tau_i(E) \) (determined by Equations (4) or (5)) is smaller than the time of particle propagation through the cloud, \( \tau_{pp} \). For ballistic propagation in the cloud

\[
\tau_{pp} = \frac{R}{u} \text{ and for diffusion propagation } \tau_{pp} = \frac{R^2}{D_c}.
\]

Here \( R \) is a cloud radius, \( u \) is the particle velocity, and \( D_c \) is the characteristic time of particle diffusion in the cloud.

For energies determined by the condition

\[
\tau_i(E) < \tau_{pp} \text{ (E)},
\]

a flux of CRs toward the cloud arises because of the gradient generated by CR absorption in the cloud. This CR flux generates MHD waves with the increment (see Kulsrud & Pearce 1969)

\[
\gamma(k, r) = \frac{\pi^2 e^2 v_A}{c^2} \int_p dpu \left( 1 - \mu^2 \right) \delta \left( \mu k \left| \left| \frac{k}{c} \right| \right| + \frac{v_A}{c} \mu \frac{\partial \delta}{\partial \mu} \right).
\]

Here \( H \) is the magnetic field strength near the cloud, \( v_A = H/(4\pi \rho_i) \) is the Alfvén velocity, \( \rho_i \) is the density of ionized gas, \( f(p, r, \mu) \) is the CR particle distribution function, \( p \) is the particle momentum, \( \mu \) is the particle pitch angle, \( k \) is the wave number of a magnetic fluctuation excited by CRs, and \( k \| = H \cdot k \| H \| \).

2. On the other hand, ion-neutral friction in the dense low ionized molecular clouds damps MHD waves with frequencies \( \omega = kv_A < \mu \nu_{in} \), where \( v_A = H/(4\pi \rho_i) \) is the Alfvénic velocity, \( \rho_i \) is the density of the ionized component (see, e.g., Kulsrud & Pearce 1969), and the decrement of wave absorption is

\[
\nu_{in} \sim \frac{m_n}{(m_i + m_n)} \sigma_{in} v_H \langle \sigma v \rangle.
\]

Here \( \sigma_{in} \) is the cross-section of ion-neutral collisions, \( m_n \) is the mass of neutral particles, \( m_i \) is the mass of ionized particles, and \( \langle \sigma v \rangle \) is the thermal velocity of hydrogen. For the condition of molecular clouds \( \langle \sigma v \rangle = 2 \times 10^{-9} \text{ cm}^3 \text{ s}^{-1} \) (see Pinto et al. 2008).

Dogiel & Sharov (1985) provided detailed analysis of
CR propagation near molecular clouds and showed that MHD waves are excited far away from the clouds, but they are completely damped inside the clouds. This means that CRs should freely propagate inside the clouds without scattering (but with energy loss). We also note that a similar analysis of CR propagation and MHD wave excitation near the clouds was provided later by Everett & Zweibel (2011) and Morlino & Gabici (2015).

3. However, as observations showed, the neutral gas in the clouds is highly turbulent (see the review of Hennebelle & Falgarone 2012). This turbulence of neutral gas excites forced magnetic fluctuations through interaction with the ionized component (Dogiel et al. 1987). These fluctuations prevent free particle propagation in the clouds. This process is discussed in the next section.

4. MAGNETIC FIELD STRUCTURE INSIDE MOLECULAR CLOUDS

Detailed analysis of magnetic field structure in turbulent molecular clouds was provided by Istomin & Kiselev (2013). Below we present a brief review of their analysis and apply its results to the case of Sgr B2. For a homogeneous and isotropic medium they considered the correlation function of the velocity field \( \langle v_i(x, t)\rangle \) as delta-correlated in time,

\[
\langle v_i(x, t) v_j(x + r, \tilde{t}) \rangle = v_j(r) \delta(t - \tilde{t}),
\]

where \( \tau \) is the characteristic time of hydrodynamic turbulence of the neutral gas.

From the conditions of the tensor symmetry and for the incompressible liquid (\( \nabla \cdot \mathbf{v} = 0 \)) the correlation tensor \( v_{ij}(r) \) can be presented in the form

\[
v_{ij}(r) = 2 V(r) \delta_{ij} + r \frac{dV(r)}{dr} \left( \delta_{ij} - \frac{r_i r_j}{r^2} \right),
\]

where \( V(r) \) is an unknown function, which will be derived below from the observed spectrum of turbulence in molecular clouds.

In this medium the correlation tensor of magnetic fluctuations \( b_{ij} \) is the velocity correlation tensor, but the average is taken at the same time moments,

\[
b_{ij}(r, t) = \langle b_i(x, t) b_j(x + r, t) \rangle = 2Q \delta_{ij} + r \frac{dQ}{dr} \left( \delta_{ij} - \frac{r_i r_j}{r^2} \right),
\]

where the function \( Q \) is a function of \( r \) and \( t \) in the general case. The amplitude of magnetic fluctuations \( b_0 \) is defined as \( b_0^2 = \langle b_i(x) b_i(x) \rangle \).

If there is a large scale magnetic field \( H_0 \) in the medium, then the equation for the correlation function \( Q \) can be derived from the MHD equations (see Istomin & Kiselev 2013)

\[
\frac{1}{2\tau_c} \frac{\partial Q(r)}{\partial t} = [V(0) - V(r)]
+ \frac{1}{\pi \rho_i \mu_{in} \tau_c} \left( Q(0) + \frac{H_0^2}{6} \right) \left( \frac{d^2 Q}{dr^2} + \frac{4 dQ}{r dr} \right)
- \frac{dV}{dr} \frac{dQ}{dr} - \frac{1}{r} \left( \frac{4 dV}{dr} + \frac{r^2 V}{dr^2} \right) \left( Q + \frac{H_0^2}{6} \right),
\]

where \( \rho_i \) is the density of ionized component of the gas.

The spectrum of turbulent velocities in molecular clouds was derived from measurements of the CO and NH\(_3\) line Doppler broadening. The turbulence has a power-law Kolmogorov-like spectrum in a very broad range of scales from supersonic (Larson 1981) to subsonic (Myers 1983) regions (see also the review of Hennebelle & Falgarone 2012):

\[
v(L) = 1.1 \ L^\alpha \text{pc km s}^{-1} \text{ where } \alpha \simeq 0.3 - 0.5,
\]

where \( v \) is the velocity of turbulent motions and \( L \) is its scale \((0.01 < L < 300 \text{ pc})\). Then from Equation (16) the correlation function of velocity \( V \) can be derived. With the known \( V \) we can define the correlation function of magnetic fluctuations \( Q \) from Equation (15). Below we obtain this function for the stationary case when \( dQ/dr = 0 \).

Here we use dimensionless units for the magnetic field strength:

\[
\vec{H} = \sqrt{\frac{3}{\pi \rho_v \rho_i \mu_{in}}} H.
\]

Here \( \rho_v \) is the velocity of turbulent motions on the scale \( L \ll R \).

If a dimensionless large scale magnetic field \( \vec{H}_0 \ll 1 \), the energy of magnetic field fluctuations is concentrated near the correlation length, \( L_{corr} \), which is much smaller than the cloud size \( R \). Then the amplitude of magnetic fluctuations, \( \delta H \), is much larger than \( H_0 \) (see Istomin & Kiselev 2013),

\[
\delta H \gg H_0.
\]

(cf. Equation (8)).

By definition the correlation length is

\[
L_{corr} \simeq \frac{1}{b_0^2} \int_0^\infty \langle b_1(0) b_1(r) \rangle \ dr,
\]

and can be estimated if the function \( Q \) is known from Equation (15).

Then from numerical calculations of Equation (19) we obtain

\[
L_{corr} / R = 0.9 H_0,
\]

\[
\delta H = 1.4 \sqrt{H_0}.
\]

We apply this theory to the molecular cloud Sgr B2. For estimates we use the following parameters of the cloud and the intercloud medium. The gas density in the cloud is \( n_H \simeq 10^3 \text{ cm}^{-3} \), the ionization degree in the dense molecular clouds is \( n_H / n_H \simeq 10^{-8} \) (see, e.g., Oka 2006), the radius of the Sgr B2 region emitting gamma-rays is \( R = 7 \text{ pc} \) (see Yang et al. 2014b), the total magnetic field strength in Sgr B2 is \( H_0 = \delta H \geq 550 \mu\text{G} \) (Crutcher et al. 1996, 2010; Crutcher 1999), and the average large scale magnetic field in the GC is about \( H_0 \simeq 50 - 100 \mu\text{G} \) (Crocker et al. 2010). For the core of Sgr B2, where the gas density is \( n_H \sim 10^3 \text{ cm}^{-3} \) and \( \delta H / H_0 \simeq 5.5 \), Equation (20) gives \( L_{corr} \simeq 0.4 \text{ pc} \), and Equation (21) gives \( v_0 = 7.3 \text{ km s}^{-1} \). This estimation of the turbulent velocity is close to that presented in Crutcher (1999) for Sgr B2. In the outer envelope with \( n_H \sim 10^3 - 10^4 \text{ cm}^{-3} \), we expect that \( \delta H \ll H_0 \).

In a magnetic field \( H = 0.55 \text{ mG} \) the Larmor radius, \( \chi_L \), of particles with energies \( E < 10^8 \text{ GeV} \) is smaller than \( L_{corr} \). In this medium propagation of magnetized particles along tangled magnetic field lines can be described as diffusion with a
coefficients (see for details Dogiel et al. 1987)

\[ D_c(E) \sim \frac{c^3(E) L_{\text{corr}}}{2} \]

\[ \sim cL_{\text{corr}} \left[ \left( \frac{E}{m_p c^2} \right)^2 + 2 \left( \frac{E}{m_p c^2} \right) + 1 \right] \text{,} \quad (22) \]

where \( \beta(E) = u/c \) and \( u \) is the particle velocity. It follows from Equation (22) that

\[ D_c(E) \propto \sqrt{E}, \quad \text{if } u < c, \]

\[ \text{constant, if } u \sim c, \quad (23) \]

(cf. Equation (9)).

5. SPECTRUM OF CRS INSIDE AND OUTSIDE SGR B2

The background hydrogen in the GC is ionized by subrelativistic CRs (see Oka et al. 2005; for equations describing ionization processes see, e.g., Dogiel et al. 2013, 2014). The ionization rate of hydrogen, \( \zeta \), is

\[ \zeta = \int \sigma_{\text{II}} u N(E) dE, \quad (24) \]

where \( \sigma_{\text{II}} \) is the ionization cross-section of the molecular hydrogen by proton impact (see Rudd et al. 1983; Tatischeff 2003), \( u \) is the velocity of CR particles, and \( N(E) \) is their spectrum.

As we mentioned in Section 1 the ionization rate in the diffuse molecular gas, \( \zeta_0 \), is about \( 3 \times 10^{-15} \text{s}^{-1} \), while inside the core of Sgr B2 the rate, \( \zeta_c \), is one order of magnitude smaller. Dogiel et al. (2011, 2013, 2014) and Tatischeff et al. (2012) presented arguments in favor of hydrogen ionization by subrelativistic electrons, while the alternative process of ionization by high energy electrons was discussed in Yusef-Zadeh et al. (2013). Below we discuss these models.

For calculations we approximate the gas distribution in Sgr B2 according to Equations (1) or (2):

1. Model I: Sgr B2 consists of the two components as derived by Lis & Goldsmith (1991), a dense core with a density \( n_c \sim 10^5 \text{cm}^{-3} \) and a radius \( r_0 = 5 \text{pc} \) surrounded by a diffuse component with a density \( n_d \sim 10^3 - 10^4 \text{cm}^{-3} \) and a radius \( R = 20 \text{pc} \);

2. Model II: the mass of the cloud is concentrated in a dense core (as it follows from Protheroe et al. 2008) with a density \( n_c \sim 10^5 \text{cm}^{-3} \) and a radius \( r_0 = 5 \text{pc} \) without an outer envelope.

For both distributions the total mass of the cloud is between \((2-6) \times 10^6 \, M_\odot\), and the gas column density in the direction of the cloud center is \( L_{\text{II}} \sim 10^{24} \text{cm}^{-2} \) as follows from observations.

From Section 4 it is clear that magnetic fluctuations with \( \delta H > H_0 \) are excited in the dense core where the kinetic energy of turbulent motions is high enough. Only there we expect diffusion propagation of CRs with the coefficient (23). In the envelope, particles propagate without significant scattering because the fluctuations are damped by ion-neutral friction.

We assume that the spectrum of subrelativistic protons, \( N(E) \), in the intercloud medium can be presented as a power law,

\[ N(E) = K \left( \frac{E}{E_0} \right)^{\delta} (E_{\text{max}} - E), \quad (25) \]

where \( E \) is the kinetic energy of subrelativistic protons, \( E_{\text{max}} \) is the maximum energy of subrelativistic protons in the intercloud medium, and \( E_0 \) equals, e.g., 1 MeV. Then from the ionization rate, \( \zeta_0 = 3 \times 10^{-15} \text{s}^{-1} \), measured by Oka et al. (2005) in the diffuse molecular clouds (outer envelope) and the rate of ionization inside Sgr B2, \( \zeta_c = 3 \times 10^{-16} \text{s}^{-1} \) (Van der Tak et al. 2006), we can estimate parameters of the CR spectrum (25).

The magnetic fields are nonuniform inside molecular clouds and their strength correlates with the gas density as

\[ H \propto n_H^{0.65}, \quad (26) \]

see Crutcher et al. (2010). We cannot say whether this is due to the frozen effect of the magnetic fields on the gas only or whether this may be due to more effective generation of magnetic fluctuations in dense cores by the neutral gas turbulence as we assumed above.

Padovani & Galli (2011) assumed a convergent structure of magnetic field lines near molecular clouds and analyzed the effect of CR mirroring. They showed that this effect reduced the CR density in the clouds and the ionization rate there by a factor of \( \sim 4 \).

In the following we neglect variations of the large scale magnetic field in the outer envelope. We assume that inside the outer envelope subrelativistic CRs propagate through the medium without significant scattering, i.e., along field lines of the large scale magnetic field \( H_0 \) with their own velocity. This is a big simplification of the process, but it provides an upper limit for the density of CRs penetrating into the envelope. In this work we consider a stationary distribution of CRs in molecular clouds. Unlike the case of the source J1745.6–2858 near Sgr A* (right at the GC), we do not have evidence indicating a time-varying CR source at or near the location of Sgr B2. Nevertheless, one can find a solution for the time-dependent case in Chernyshov et al. (2014).

We describe CR propagation inside the outer envelope as

\[ c\beta(E) \frac{\partial N}{\partial x} - \frac{\partial}{\partial E} \left[ \left( \frac{dE}{dt} \right)_i N \right] = 0, \quad (27) \]

with a spectrum of CRs at the outer boundary of the envelope \((x = 0)\) as presented by (25). The goal is to calculate the spectrum of subrelativistic CRs that reach the surface of the core at \( r_0 = 5 \text{pc} \).

The solution of Equation (27) is

\[ N(x, E) = K \left( \frac{E}{E_0} \right)^{1/2} \left[ \left( \frac{E}{E_0} \right)^2 + a \sqrt{m} \right]^{1/2} \times \theta \left( E_{\text{max}}^2 - E^2 - a \sqrt{m} \right). \quad (28) \]

Here we present the term of energy losses in Equation (3) as \( dE/dt = a/\sqrt{E} \), and the mean free path of a subrelativistic particle with mass \( m \) and energy \( E \) is \( x \sim E / (dE/dt) \sqrt{2E/m} = E^2 / a \sqrt{m} \).
The characteristic lifetime of a subrelativistic proton with energy $E$ is

$$\tau = \int \frac{dE}{(dE/dt)_h} = \frac{1}{3} \frac{m_e E^{3/2}}{\sqrt{2} \pi n_{H0} e^4 \sqrt{m} \Lambda}. \quad (29)$$

The energy loss gas column density, through which a subrelativistic proton with energy $E$ passes during its lifetime, is

$$L_\text{H} = \frac{m_e}{3 m} \frac{E^2}{\pi e^4 \Lambda}. \quad (30)$$

In Figure 1 we show the energy loss gas column density for electrons and protons derived from equations of energy losses taken from Hayakawa (1964), Ginzburg (1989), and Mannheim & Schlickeiser (1994). For the fixed gas column density of the outer envelope taken from Lis & Goldsmith (1989, 1990, 1991), which is presented by Equation (1), we can estimate the energy of protons that can reach the surface of the central core. For $L_\text{H} \approx 10^{23}$ cm$^{-2}$ this value is about $E \gtrsim 20$ MeV.

As an example, in Figure 2 we show the expected spectrum of protons at the boundary of the central core $\mathcal{N}_c(E)$ for $L_\text{H} = 10^{23}$ cm$^{-2}$ if the spectrum of protons in the intercloud medium is $\mathcal{N}(E) = K (E/E_0)^{-0.5}$.

According to Section 4, inside the core CR propagation is described as diffusion with the coefficient (see Dogiel et al. 1987)

$$D_c = \frac{u L_{\text{cont}}}{2}, \quad (31)$$

where $L_{\text{cont}} = 0.4$ pc.

The distribution function of protons, $\mathcal{N}_c(E)$, is described by the equation

$$- \frac{1}{r^2} \frac{\partial}{\partial r} \left( r^2 D_c \frac{\partial \mathcal{N}_c}{\partial r} \right) - \frac{\partial}{\partial E} \left[ \frac{dE}{dt} \right] \mathcal{N}_c = 0, \quad (32)$$

where $(dE/dt)_i$ is the rate of ionization losses in the dense core, calculated for the density $n_{\text{H}} \sim 10^5$ cm$^{-3}$.

The boundary condition on the core surface, $r = r_0$

$$\mathcal{N}_c(E) = K \left( \frac{E}{E_0} \right)^{1/2} \left( \frac{E}{E_0} \right)^2 + a (R - r_0) \sqrt{m} \right] \frac{E_0}{E^{1/2}} \times \theta \left( E_{\text{max}}^2 - E^2 - a (R - r_0) \sqrt{m} \right), \quad (33)$$

where $R$ and $r_0$ are the radius of the outer envelope and the central core (see Model I). We can ignore the unknown constant $K$ from the ratio of ionization rates outside and inside the core.

The ionization rate averaged over the scale $L_\text{H}$ of the outer envelope is $\zeta_c = 3 \times 10^{-15}$ s$^{-1}$.

$$\zeta_c \approx \frac{1}{L_\text{H}} \int_R \int dE \int \sigma_\text{H} \mathcal{N}_c(E, r) dE. \quad (34)$$

The ionization rate inside the central part of core is $\zeta = 3 \times 10^{-16}$ s$^{-1}$. Then

$$\frac{\zeta_c}{\zeta} \approx (R - r_0) \int_{r_0}^{R} \int dE \int_{E_{\text{max}}}^{E_{\text{max}}} dEN(x, E) \sigma_\text{I}(E) u(E) \int_{E_{\text{min}}}^{E_{\text{max}}} dEN_c(r, E) \sigma_\text{I}(E) u(E) \quad (35)$$

From Equation (35) we can derive the spectral index $\delta$ as a function of $E_{\text{max}}$ for a given value of $L_\text{H}$ in the outer envelope, where $L_\text{H} = n_{\text{H}} (R - r_0)$, $R = 20$ pc and $r_0 = 5$ pc. The constant $K$ is calculated then from the ionization rates inside or outside the cloud.

In Figure 3 we show the spectral index $\delta$ for different values of $n_{\text{H}}$. The case $n_{\text{H}} = 0$ corresponds to the case where the whole mass of Sgr B2 is concentrated in the core (i.e., Model II). One can see from the figure that for very hard spectra with $\delta = 0.2$ almost all particles reach the core surface. The required maximum energy $E_{\text{max}}$ of protons is in this case about 0.2 GeV independent of the gas density.

The derived spectrum of subrelativistic protons is shown in Figure 4 for different values of $n_{\text{H}}$ in the envelope and $R - r_0 = 15$ pc. The derived values of $E_{\text{max}}$, the density of hydrogen $n_{\text{H}}$, and the energy density of subrelativistic protons needed for the ionization rate in Sgr B2 are also shown in the figure.
The relativistic component of the CR spectrum inside Sgr B2 can be derived from the observed flux of gamma-rays there (see Yang et al. 2014b). Gamma-ray flux generated by relativistic protons in molecular clouds can be calculated by

\[ F_\gamma(E) = 4\pi c \int_0^R n_H(r)r^2dr \int E N(E, r) \frac{d\sigma}{dE}\gamma(E, E_\gamma)dE, \]  

(36)

where \( n_H(r) \) is the hydrogen distribution, \( d\sigma/dE, (E, E_\gamma) \) is the differential cross-section for gamma-ray production in proton-proton collisions (Kamae et al. 2006), and \( N(E, r) \) is the distribution of relativistic protons in Sgr B2.

If the mass of Sgr B2 is concentrated in the envelope (i.e., Model I), then according to our analysis relativistic protons uniformly fill this region and their density is the same as in the intercloud medium. It is clear from Figure 2 that even protons with \( E \approx 0.2 \) GeV can penetrate through the outer envelope. Protons with energies \( E \gtrsim 1 \) GeV pass through the envelope without absorption \((\tau_n, \tau_{pp} > \tau_{pp})\). The spectrum derived for this case by Yang et al. (2014a, 2014b) is shown as shaded areas in Figure 4. Variations of the spectrum are governed by the uncertainties of the mass of Sgr B2, which is in the range of \((2-10) \times 10^6 M_\odot\). The energy density of relativistic protons is then within \(1-4 \) eV cm\(^{-3}\).

It is interesting to note that in this case the required energy density of subrelativistic protons is more than one order of magnitude higher than that of relativistic protons.

If the mass of Sgr B2 is mainly concentrated in the core (i.e., Model II), the distribution of relativistic protons in the cloud is calculated similarly to Equation (32),

\[ \frac{N_c}{\tau_{pp}(E)} - 1 = \frac{\partial}{\partial r} \left( r^2 D_c \frac{\partial N_c}{\partial r} \right) = 0, \]  

(37)

where \( D_c \sim cL_{corr}/2 = \) constant and \( \tau_{pp} = (n_Hc\sigma_{pp}(E))^{-1} \) is the characteristic time of pp collisions. The boundary condition is

\[ N_c(E)|_{r=r_0} = \bar{N}(E), \]  

(38)

where \( \bar{N}(E) \) is the spectrum of relativistic protons in the intercloud medium, which is supposed to be a power law.

In this case protons are distributed in the core nonuniformly \((\tau_{pp} < \tau_{pp})\) and their spectrum can be derived from Equations (36) and (37). Results of the calculations are shown as the solid line in Figure 4. One can see that the energy density of relativistic protons is about one order of magnitude higher than that near Earth, but it is still smaller than that of subrelativistic CRs.

From Figure 4, it is reasonable to conclude that relativistic and subrelativistic protons have different sources in the GC because their spectra have a gap in intensities in the range of about several hundred MeV and they do not match smoothly with each other at these energies. An exception is the case where the whole mass of Sgr B2 is concentrated in the core (the solid line in the subrelativistic energy range and the straight line in the relativistic energy range). It seems from the figure that in this case the distribution of subrelativistic and relativistic protons can be described by a unified spectrum with a break of the spectral index from \( \delta \approx -3 \) in the relativistic energy to \( \delta \approx 0.2 \) in the subrelativistic energies. A similar spectrum can be formed in the intercloud space, e.g., by ionization losses (see Equation (3)) if the spectrum of protons injected by sources has a cut-off, \( Q(E) = KE^q\theta(E - E_{min}) \). For the equation

\[ \frac{d}{dE} \left[ \frac{dE}{dt_i} \right] N(E) = Q(E), \]  

(39)

the solution for \( E < E_{min} \) is

\[ N(E) \propto E^{0.5}. \]  

(40)

For more details of this solution see Dogiel et al. (2009b).
BY-PRODUCTS OF THE MODEL OF HYDROGEN IONIZATION BY SUBRELATIVISTIC PROTONS

With the spectrum of protons derived in the previous section we can analyze whether this model can be proved or disproved from observations.

6.1. Emission of the 6.4 keV Iron Line

First we would like to mention that subrelativistic protons not only ionize hydrogen molecules in the clouds but also atoms of heavier elements, e.g., iron, whose ionization of the K-\(\alpha\) shell is observed as the 6.4 keV line emission. It was proved that this emission is generated by a front of hard X-ray photons that were emitted by Sgr A* (see Koyama et al. 1996) whose luminosity was much higher in the past than it is at present (see, e.g., Ryu et al. 2013). The emission shows time variability (see, e.g., Koyama et al. 2008), and it has decreased by one order of magnitude from the peak period in 2000–2013 (Inui et al. 2009; Nobukawa et al. 2011, 2014). It is expected that for about 20 years of observations of Sgr B2, the front of X-rays has (almost) left the cloud. Thus we may expect that a background flux of the line emission from Sgr B2 generated by CRs can be seen at present or will be seen in the near future (see Dogiel et al. 2011).

Temporal variations of the 6.4 keV Sgr B2 flux in the period 2005–2013 are presented in Table 1.

Below we compare these Suzaku data with model estimations. From the spectrum shown in Figure 4 we can estimate the expected 6.4 keV line emission generated by the protons:

\[
I_{6.4} = \frac{1}{R_{GC}^2} \int_0^R n_{H}(r)r^2dr \int E N(E, r)\nu \sigma_{6.4}dE,
\]

where the cross-section of 6.4 keV photon production by proton impact \(\sigma_{6.4}\) is from Tatischeff (2003).

The expected intensity depends weakly on model parameters and is about

\[
I_{6.4} \approx (3.5) \times 10^{-6} \eta \text{ ph cm}^{-2} \text{ s}^{-1},
\]

where \(\eta\) is the abundance of iron atoms with respect to solar. The estimated iron abundance \(\eta\) in the Sgr B2 is in the range 1.3–1.9 (see, e.g., Revnivtsev et al. 2004; Nobukawa et al. 2011). The estimated flux of the 6.4 keV line in Equation (42) is three times smaller than it was in 2013. Hence in the framework of the model, in 2013 subrelativistic protons might have produced about 30% of the total flux from Sgr B2. We cannot exclude the fact that at present, the front of hard X-rays has left Sgr B2 and this emission is generated by subrelativistic CRs. The intensity should then fall back to the level predicted by Equation (42). Future analysis of the X-ray data for the period after 2013 may confirm our conclusion. Restrictions on processes of 6.4 keV line production can be obtained from measurements of the line broadening (see Dogiel et al. 1998). We hope that this crucial information for constraining the origin of the 6.4 keV emission from Sgr B2 will be obtained by ASTRO-H (see Koyama et al. 2014).

6.2. Hard X-Ray Continuum

Hard X-ray photons and subrelativistic CRs also produce a flux of continuum emission by Thomson scattering of photons (Compton echo) or by bremsstrahlung losses of charged particles. Observations presented by Terrier et al. (2010) showed time variability of the X-ray flux from Sgr B2 in the range from 20 to 100 keV which correlated nicely with the variability of the 6.4 keV line emission from Sgr B2. This confirmed that their common origin is due to X-ray irradiation from Sgr A*.

The X-ray emission produced by inverse bremsstrahlung of protons can be calculated from

\[
I_x(E_x) = \frac{1}{R_{GC}^2} \int_0^R n_{H}(r)r^2dr \int E N(E, r)\nu \frac{d\sigma_x}{dE_x}(E, E_x)dE_x,
\]

where \(\sigma_x/dE_x\) is the cross-section of the inverse bremsstrahlung

\[
\frac{d\sigma_x}{dE_x}(E, E_x) = \frac{8}{3} \frac{e^2}{\hbar c} \left( \frac{m_ec^2}{m_p}\right)^2 \frac{\hat{E} - \sqrt{\hat{E}^2 - E_x^2}}{E_x} \ln \left( \frac{\sqrt{\hat{E}^2 - E_x^2}}{E_x} \right),
\]

where \(\hat{E} = (m_e/m_p)E\) for protons and \(\hat{E} = E\) for electrons. Below we adopt the cross-section from Haug (1997). Subrelativistic protons with energy \(E\) emit bremsstrahlung photons with energies \(E_x \lesssim (m_e/m_p)E\) (see Hayakawa 1964). Therefore, for the cut-off energy of subrelativistic protons of about 0.2–0.5 GeV, we expect that they generate hard X-ray emission in the range \(E_x \lesssim 10–30\) keV.

The calculated X-ray fluxes depending on the Sgr B2 mass are about

\[
I_{x}^{10} = (4–6) \times 10^{-13} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ for } 2 \text{ keV} \leq E_x \leq 10 \text{ keV},
\]

\[
I_{x}^{20} = 7.5 \times 10^{-13} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ for } 20 \text{ keV} \leq E_x \leq 60 \text{ keV}.
\]

One can see that the model estimations are significantly below the experimental data presented in Nobukawa et al. (2011) for the range 2–10 keV and in Terrier et al. (2010) for the range 20–60 keV. However, the continuum X-ray flux shows a strong decrease in the Suzaku (2–10 keV) and the INTEGRAL (20–100 keV) ranges. For the period from 2003 to 2009 the flux dropped down by a factor of 0.4 (Terrier et al. 2010; Nobukawa et al. 2011). Thus, one can expect that continuum emission produced by subrelativistic CRs (Equations (45) and (46)) may be seen in the near future.
For the double solar abundance in the GC the line from there is about nevertheless that the discovery of gamma-ray lines will be possible gamma-ray telescopes is not high enough. It seems never-be detected even in the GC because the sensitivity of existing the spectrum of subrelativistic protons, derived in Section 5. fl with the new generation telescopes. Bearing this in mind, we 330 MHz Figure 5. The Astrophysical Journal, f r o m 0 . 1 t o 1 0 M e V for the expected spectral index of the secondary component f r o m Tatischeff 2003. Estimations of Dogiel et al. (2009b) and Benhabiles-Mezhoud et al. (2013) showed, however, that this line emission cannot be detected even in the GC because the sensitivity of existing gamma-ray lines will be possible with the new generation telescopes. Bearing this in mind, we estimated the flux of C and O lines from Sgr B2, expected for the spectrum of subrelativistic protons, derived in Section 5. For the double solar abundance in the GC the flux of the O line from there is about 1.38 × 10^{-7} ph cm^{-2} s^{-1} and the C line 8.34 × 10^{-8} ph cm^{-2} s^{-1}.

### 6.3. De-excitation Nuclear Lines

In the interstellar medium subreletivistic protons and nuclei with energies between a few MeV and several hundred MeV generate emission of nuclear gamma-ray lines in the range from 0.1 to 10 MeV (see the review of Tatischeff 2003). Estimations of Dogiel et al. (2009b) and Benhabiles-Mezhoud et al. (2013) showed, however, that this line emission cannot be detected even in the GC because the sensitivity of existing gamma-ray telescopes is not high enough. It seems nevertheless that the discovery of gamma-ray lines will be possible with the new generation telescopes. Bearing this in mind, we estimated the flux of C and O lines from Sgr B2, expected for the spectrum of subrelativistic protons, derived in Section 5. For the double solar abundance in the GC the flux of the O line from there is about 1.38 × 10^{-7} ph cm^{-2} s^{-1} and the C line 8.34 × 10^{-8} ph cm^{-2} s^{-1}.

### 6.4. Secondary Electrons and Radio Emission from Sgr B2

As a result of pp collision relativistic protons generate not only gamma-rays, as discussed in Section 5, but also secondary electrons, which should produce a synchrotron radio emission in the relatively strong magnetic fields of Sgr B2. From the observed gamma-ray flux we can estimate the density of secondary electrons and the flux of radio emission using the equations for these processes presented, e.g., in Berezinskii et al. (1990). The flux of radio emission from Sgr B2 in the range 330–2368 MHz was presented in Jones et al. (2011) who concluded that they did not find any evidence for nonthermal emission from Sgr B2 and the observed radio flux from Sgr B2 is of thermal origin.

We estimated a synchrotron component generated by secondary electrons. As an upper limit for the density of secondary electrons we derive their spectrum from the gamma-ray data from Sgr B2 whose mass is 2 × 10^6 M_☉. The derived angular distribution of the 330 MHz emission for this case is shown in Figure 5 together with experimental data taken from Jones et al. (2011).

We see that even for the most favorable parameters of the model the nonthermal component is below the intensity of thermal emission.

The flux of the nonthermal component can be subtracted from the total radio emission from Sgr B2 by observation of polarization. A flux of synchrotron emission is polarized if the strength of large scale magnetic fields is high enough (see, e.g., Ginzburg 1989).

However, as we concluded in Section 3 the chaotic component of the magnetic field, δH, is five times larger than the large scale magnetic field, H_0, whose strength is estimated as 100 μG. The expected linear polarization degree, p_l, was derived by Korchak & Syrovatskii (1961), which is

$$p_l = \frac{(\gamma + 1)(\gamma + 3)(\gamma + 5)}{(\gamma + 7/3)32} \times \left(1 + \left(\frac{\gamma^2 + 8\gamma + 3}{24}\frac{H_0^2}{\delta H^2}\right)\delta H^2\right)$$

for δH ≫ H_0. (47)

For the expected spectral index of the secondary component γ (for the electron spectrum $\propto E^{-\gamma}$) with γ ≈ 3–4, the estimated polarization degree of the nonthermal component of Sgr B2 is about $p_l \approx 3.5\%–4.8\%$.

If, however, the turbulence inside the clouds is not strong enough and the amplitude of magnetic fluctuations is small (δH ≪ H_0), then the polarization degree is described by the equation (see Korchak & Syrovatskii 1961)

$$p_l = \frac{(\gamma + 1)}{(\gamma + 7/3)} \left(1 - \frac{2}{3}\frac{\delta H^2}{H_0^2}\right)$$

for δH ≪ H_0. (48)

The upper limit of linear polarization of synchrotron radiation can reach a level of about 75%–80%, if the scale of H_0 is about the cloud radius.

We hope that the next generation radio telescopes such as the Square Kilometre Array (SKA; see Strong et al. 2014; Dickinson et al. 2015) may be able to detect the nonthermal flux of Sgr B2.

### 7. HYDROGEN IONIZATION BY PRIMARY ELECTRONS IN SGR B2

Alternatively, ionization of the molecular gas may be caused by high energy electrons (see Yusuf-Zadeh et al. 2013). Below we analyze whether the molecular hydrogen in Sgr B2 is ionized by electrons and whether we can distinguish this from observations between processes of proton and electron ionization.

As follows from Figure 1 subrelativistic CRs are absorbed in the outer envelope, and electrons with energies above 1 MeV are able to penetrate into the dense core. Therefore, for estimates of processes of hydrogen ionization and bremsstrahlung emission from there we can use equations in the relativistic energy range, which simplifies the calculations significantly. The intensity of bremsstrahlung emission is determined by a cut-off position derived from the rate of ionization losses in the outer envelope (see, e.g., Figure 2).

Electrons lose about 42 eV per one act of ionization (see Dalgarno et al. 1999). We can estimate the ionization rate of
The X-ray spectrum from Terrier et al. (2010; Nobukawa et al. 2011) is shown by solid lines. The X-ray spectrum from Terrier et al. (2010) is shown by dashed lines.

The conclusion of this paper can be itemized as follows.

1. The total mass and the gas distribution in the cloud Sgr B2 is highly uncertain. Therefore, we study two extreme cases: (1) when the mass is mainly distributed in the relatively low density outer envelope \((n_H \sim 10^3-10^4 \text{ cm}^{-3})\) with a radius of about 22 pc (Model I) and (2) when most of the mass is concentrated in the dense core \((n_H \sim 10^5 \text{ cm}^{-3})\) with a radius of about 5 pc (Model II).

2. We conclude that propagation of high energy particles in dense molecular clouds is determined by the amplitude of magnetic fluctuations generated by turbulent motions of neutral gas and their damping due to ion-neutral friction. In the outer envelope of Sgr B2, with a density of about \(10^3-10^4 \text{ cm}^{-3}\) the kinetic energy of turbulent motions is quite low and does not generate fluctuations with an amplitude higher than the strength of the large-scale magnetic field, \(H_0 \sim 100 \mu G\). Therefore we assume that particles propagate there without scattering.

3. In the dense core with a density of about \(10^5 \text{ cm}^{-3}\) the neutral gas turbulence generates fluctuations with an amplitude of \(\delta H \gg H_0\). Our estimations show that \(\delta H \sim 500 \mu G\) for the parameters of the Sgr B2 core. Then, unlike previous models of CR propagation in molecular clouds, we conclude that this process is determined by chaotic magnetic fields generated by turbulent motions of the molecular gas in the core. The key parameter of this process is the correlation length of the chaotic field, \(L_{\text{corr}}\) which determines the diffusion propagation of particles inside the core. For the magnetized particles the diffusion coefficient is constant in the relativistic energy range, and is proportional to \(\sqrt{E}\) in the subrelativistic energy range. For the parameters of Sgr B2 the correlation length is about \(L_{\text{corr}} \sim 0.4 \text{ pc}\).

4. For the model of hydrogen ionization by subrelativistic protons we derived their spectrum depending on the hydrogen density in the outer envelope. We showed that the hydrogen ionization is provided by protons with an energy above 20 MeV. Their energy density is about or above 50 eV cm\(^{-3}\).

5. The spectrum of relativistic protons was derived from the observed gamma-ray flux of Sgr B2. If the mass of the cloud is mainly distributed in the outer envelope with the radius of 22 pc, then the energy density of these protons is about the same as it is near Earth, i.e., 1–4 eV cm\(^{-3}\). If, however, most of mass is concentrated in the core with a radius of 5 pc then the required energy density of the protons is about 10 eV cm\(^{-3}\).

6. We conclude that if subrelativistic protons are responsible for hydrogen ionization in Sgr B2, they also generate the 6.4 keV line emission and continuum emission in the X-ray energy range \(\lesssim 30\) keV. The expected flux in the K-\(\alpha\) iron line from Sgr B2 is about \(10^{-5}\) ph cm\(^{-2}\) s\(^{-1}\), from our calculations that the origin of ionization in Sgr B2 can, in principle, be determined from the INTEGRAL observations. If these observations show an excess of hard X-ray emission above the power law \(\propto E^{-2}\) at large energies, then that result is in favor of an electron origin of hydrogen ionization. If not, then only a proton origin is acceptable.

8. CONCLUSION
which is only three times below the line flux observed in 2013 by Suzaku. It was shown that the observed flux of the line from Sgr B2 was generated by X-ray photons emitted by Sgr A* in the past. However, this flux is decreasing rapidly and we expect that in the near future we might observe a component of the 6.4 keV emission from Sgr B2 generated by CRs.

7. The expected continuum X-ray emission generated by proton bremsstrahlung is about \( L_x = (4-6) \times 10^{-11} \text{erg cm}^{-2} \text{s}^{-1} \) in the range 2–10 keV, and \( L_x = 7.5 \times 10^{-13} \text{erg cm}^{-2} \text{s}^{-1} \) in the range 20–60 keV. Both fluxes are below the continuum fluxes from Sgr B2 measured by Suzaku and INTEGRAL in 2009. However, we expect that the continuum X-ray fluxes might decrease to the level predicted by the model of proton bremsstrahlung. It is highly desirable to get updated results from Suzaku and INTEGRAL.

8. Subrelativistic protons also generate de-excitation gamma-ray lines. However, the estimated flux of the C and O lines from Sgr B2 is too low for detection by present gamma-ray telescopes. We hope that it may be a target for future gamma-ray missions.

9. Relativistic protons in Sgr B2 produce secondary electrons by pp collisions whose density can be derived from the observed gamma-ray flux. Thus, a flux on nonthermal synchrotron radio emission is expected from Sgr B2. However, observations showed that the flux of thermal radio emission was much higher than the estimated flux of synchrotron emission. Therefore, it is problematic to subtract the nonthermal component from the total Sgr B2 radio flux. However, unlike the thermal component, the flux of synchrotron emission is polarized. We estimated the expected degree of polarization of the nonthermal component. If the amplitude of the chaotic magnetic fields excited by the turbulence of neutral gas is higher than the strength of large scale magnetic fields in the halo, the degree of polarization is small, around 3%–4%. If the kinetic energy of turbulent motions is relatively small, the large-scale fields are not perturbed significantly by the turbulence. In this case the upper limit of linear polarization of the synchrotron component may reach a level of 75%.

10. An alternative model for hydrogen ionization in Sgr B2 is irradiation by high energy electrons. The energy of these electrons should be around or above 1 MeV. These electrons generate a bremsstrahlung X-ray emission with a spectrum \( \propto E_x^{-1} \) which is harder than the emission from the Compton echo \( \propto E_x^{-2} \) as observed by Suzaku and INTEGRAL. Therefore, we expect that the bremsstrahlung component can be seen at high energies. Our estimations show that the calculated bremsstrahlung component should be seen even in the 2009 data in the range 20–60 keV if it is generated by electrons. If observations do not show any excess above the spectrum \( E_x^{-2} \), then that is an argument against the leptonic origin of hydrogen ionization at least in Sgr B2, although more detailed analysis of the X-ray data after 2009 is needed.

The authors would like to thank M. Goto, K. Mori, D. Prokhorov, T. Oka, D. Strelov, and A. Strong for comments that greatly helped them to perform this analysis. V.A.D. and D.O.C. acknowledge partial support from the MOST-RFBR grant 15-52-52004 and the RFBR grant 15-02-02358. D.O.C. and A.M.K. are supported in parts by the LPI Educational-Scientific Complex and Dynasty Foundation. K.S.C. is supported by the G.R.F. Grants of the Government of the Hong Kong SAR under HKU 701013. C.M.K. is supported in part by the Taiwan Ministry of Science and Technology Grants MOST102-2112-M-008-019-MY3 and MOST104-2923-M-008-001-MY3. C.Y.H. is supported by the National Research Foundation of Korea through grant 2014R1A1A2058590. K.K. N. is supported by Research Fellowships of JSPS for Young Scientists. V.A.D., D.O.C., A.M.K., K.S.C., and C.Y.H. acknowledge support from the International Space Science Institute-Beijing to the International Team “New Approach to Active Processes in Central Regions of Galaxies.”
