Applied magnetic fields underlie exotic quantum states, such as the fractional quantum Hall effect1 and Bose–Einstein condensation of spin excitations2. Superconductivity, however, is inherently antagonistic towards magnetic fields. Only in rare cases3–5 can these effects be mitigated over limited fields, leading to re-entrant superconductivity. Here, we report the coexistence of multiple high-field re-entrant superconducting phases in the spin-triplet superconductor UTe2 (ref. 1). We observe superconductivity in the highest magnetic field range identified for any re-entrant superconductor, beyond 65 T. Although the stability of superconductivity in these high magnetic fields challenges current theoretical models, these extreme properties seem to reflect a new kind of exotic superconductivity rooted in magnetic fluctuations3–5 and boosted by a quantum dimensional crossover1.

It is a basic fact that magnetic fields are destructive to superconductivity. The maximum magnetic field in which superconductivity survives, the upper critical field $H_{c2}$, is restricted by both the paramagnetic effect of electron spin polarization due to the Zeeman effect and the orbital pair-breaking effect of electron–cyclotron motion due to the Lorentz force. In a few very rare cases, however, magnetic fields can do the opposite and actually stabilize superconductivity3–6. In these cases, the applied magnetic field is most often compensated by an internal field produced by ordered magnetic moments through exchange interactions, resulting in a reduced total effective field3. A different set of circumstances involving unconventional superconductivity occurs in the ferromagnetic superconductor URhGe (refs. 7,8), in which field-induced superconductivity is attributed to very strong ferromagnetic fluctuations that emanate from a quantum instability of a ferromagnetic phase, strengthening spin-triplet pairing3.

Here, we report the presence of two independent high-field superconducting phases in the recently discovered triplet superconductor UTe2 (ref. 9), for a total of three superconducting phases (Fig. 1). This is an example of two field-induced superconducting phases existing in one system, one of which has the highest lower and upper limiting fields of any field-induced superconducting phase: more than 40 T and 65 T, respectively. It is probable that both of the field-induced superconducting phases are stabilized by ferromagnetic fluctuations that are induced when the magnetic field is applied perpendicular to the preferred direction of the electron spins. The high-field superconducting phase exists exclusively in a magnetic field-polarized state, unique among these superconductors. This discovery provides an excellent platform to study the relationship between ferromagnetic fluctuations, spin-triplet superconducting pairing and dimensionality in the quantum limit.

$\text{UTe}_2$ crystallizes in an anisotropic orthorhombic structure, with the $a$ axis the magnetic easy axis along which spins prefer to align in low magnetic fields. $H_{c2}$ is strongly direction-dependent and exceedingly large along the $b$ axis, with an unusual increase in its temperature dependence above 15 T. $H_{c2}$ is extraordinarily sensitive to the alignment of the magnetic field along the $b$ axis9,10, and accurate measurements require the use of a specialized two-axis rotator (Fig. 1b). When the magnetic field is perfectly aligned along the $b$ axis, superconductivity persists up to 34.5 T at 0.35 K (Fig. 2a). A small misalignment of less than 5° from the $b$ axis towards the $a$ axis decreases the $H_{c2}$ value by over half, to 15.8 T. However, even this misaligned superconductivity is resilient: when the magnetic field is further increased, superconductivity reappears between 21 T and 30 T. Our measurements show that this re-entrant phase, $\text{SC}_{\text{RE}}$, does not persist beyond misalignment greater than 7°. When the field is rotated towards the $c$ axis, $\text{SC}_{\text{RE}}$ does not persist beyond 3.9° (Supplementary Fig. 1). Future measurements will determine whether this phase boundary exhibits similar curvature.

Although $\text{UTe}_2$ is closely related to the ferromagnetic triplet superconductors7, the observation of re-entrant superconductivity in $\text{UTe}_2$ resembles neither that of $\text{URhGe}$ (refs. 10,11), which is completely separated from the low-field portion, nor the sharp $H_{c2}$ cusp in angle dependence12 in UCoGe. The angle dependence of the superconducting phase boundary suggests that $\text{SC}_{\text{RE}}$ may have a distinct order parameter from the lower-field superconductivity, $\text{SC}_{\text{LB}}$. However, unlike the case for both $\text{URhGe}$ (refs. 11,14) and $\text{UCoGe}$ (refs. 13,15), there is no normal-state change in the underlying magnetic order in $\text{UTe}_2$, that would drive a change in the superconducting order parameter symmetry. We discuss the magnetic interactions that stabilize this unusual behaviour after an excursion to an even higher field.

The upper-field limit of $\text{SC}_{\text{RE}}$ of 35 T coincides with a dramatic magnetic transition into a field-polarized phase (Fig. 2c). The magnetic moment along the $b$ axis jumps from 0.35 to 0.65 μB discontinuously, due to a spin rotation from the easy $a$ axis to the orthogonal $b$ axis. The abrupt change in moment direction is accompanied by a jump in magnetoresistance $R_b$ and a sudden change of frequency $f$ in the proximity detector oscillator (PDO) circuit (Fig. 2b). The critical field $H_m$ of this magnetic transition has little temperature dependence up to 10 K, but $H_b$ increases as the magnetic field rotates away from the $b$ axis to either the $a$ or $c$ axis (Fig. 1c). Meanwhile, the magnitude of the jump in magnetic moment, 0.3 μB, seems to

The mechanism responsible for the large magnetic field and temperature stability of the SCFP phase of UTe₂, which lacks the requisite localized atomic moments, suggests that although it is stabilized at a remarkably high field, the superconducting critical field values of the SCPM and SCRE phases are based on d.c. field measurements. This new superconducting phase involves a similar pairing energy scale to the zero-field superconductor. This antiferromagnetic type of exchange interaction can lead to an internal magnetic field that is opposite the external magnetic field, resulting in a much smaller total magnetic field. This compensation mechanism has successfully explained the field-induced superconductivity in Chevrel-phase compounds and organic superconductors, but it probably does not apply to the SCFP phase of UTe₂, which lacks the requisite localized atomic moments. Furthermore, SCFP persists over a wider field–angle range than is typical of the compensation effect.

The temperature dependence of the SCFP phase and its close relationship with the magnetic transition are reminiscent of the field-induced superconducting phase in URhGe, which has been attributed to ferromagnetic spin fluctuations associated with the competition of spin alignment between two weakly anisotropic axes. In URhGe, a magnetic field transverse to the direction of the ordered magnetic moments leads to the collapse of the Ising ferromagnetism; this instability enhances ferromagnetic fluctuations, which in turn induce superconductivity.

UTE₂, however, is not ferromagnetic. Nevertheless, the similarities between UTe₂ and the ferromagnetic superconductors with regard to the relationship between the preferred magnetic axis and the direction of high $H$, suggest that strong spin fluctuations transverse to the preferred orientation or easy axis of the magnetic moment play a central role in these superconducting phases. The $H$ and directionality in UTe₂ can thus be understood in the following manner. Starting from zero magnetic field, superconductivity is most resilient to a magnetic field applied along the $b$ axis, which is perpendicular to the easy magnetic $a$ axis. A magnetic field applied along the $b$ axis thus induces spin fluctuations that stabilize superconductivity against field-induced pair breaking. At 34.5 T, however, a magnetic phase transition occurs, and magnetic moments rotate from the $a$ axis to the $b$ axis. In the high-field-polarized phase, a magnetic field along the $b$ axis no longer induces transverse spin fluctuations, and superconductivity is suppressed completely. However, it is possible to induce transverse spin fluctuations by applying a magnetic field along the $c$ axis. When viewed as a vector sum of fields along the $b$ and $c$ axes (Fig. 3), it is clear that $H$ stabilizes the magnetic phase, while a range of $H$ strength values stabilize superconductivity with the highest re-entrant magnetic field values observed.

This ferromagnetic fluctuation scenario is qualitatively consistent with the wider picture of field-induced superconducting phases in UTE₂, yet a very important distinction exists between the SCFP phase and the field-induced superconducting phase in URhGe: the SCFP phase exists only in the field-polarized state. This challenges the current theory proposed for URhGe, which allows superconductivity to exist on both sides of the phase boundary.

Through the suppression of the orbital limit, reduced dimensionality has been theorized to stabilize high-field superconductivity. A model proposed by Lebed and Seppäë invoking spin-triplet pairing predicts re-entrant superconductivity at very high magnetic fields applied transverse to the axis of a quasi-one-dimensional conductor. The field-induced lower dimensionality is field–angle dependent and facilitates the recovery of the zero-field superconducting critical temperature, as we observe in SCFP (Figs. 3 and 4). The possibility that field-stabilizing effects may also exist in quasi-two-dimensional superconductors suggests that high-field dimensionality is a useful starting point for understanding the SCFP phase. Furthermore, the suppression of the orbital limit permits superconductivity in a pure material to survive in any magnetic field, making UTE₂ an exciting basis for further testing of the limits of high-field-boosted superconductivity.

The existence of the SCFP phase in only the field-polarized state, and in such a high magnetic field, suggests that the superconducting state probably has odd parity with time-reversal symmetry breaking.
Odd parity is the cornerstone of topological superconductivity\(^\text{22}\), and it is certain that the SCFP phase has non-trivial topology. Since time-reversal symmetry is also broken, a special topological superconducting state is highly likely, such as chiral superconductivity\(^\text{23}\), which hosts Majorana zero modes, the building blocks for topological quantum computing\(^\text{24,25}\).
Fig. 4 | Temperature dependence of SCFP in UTe$_2$. a, b, Colour contour plots of $R$ (a) and $f$ (b) of PDO measurements as a function of $T$ and $H$ at $\theta = 23.7^\circ$ (a) and $\theta = 33^\circ$ (b). The blue dots are the critical fields for SCFP and the dashed lines are guides to the eye, extrapolated to the region where there are no data. c, d, The corresponding data as a function of the applied magnetic fields at selected temperatures.

Note added in proof: While our manuscript has been under review, we became aware of other independent reports of the field-polarized state and the lower-field re-entrant superconductivity in UTe$_2$.

Methods

Single crystals of UTe$_2$ were synthesized by the chemical vapour transport method using iodine as the transport agent. Crystal orientation was determined by Laue X-ray diffraction performed with a Photonic Science X-ray measurement system. Magnetoresistance measurements were performed at the National High Magnetic Field Laboratory (NHMFL), Tallahassee, using the 35 T d.c. magnet, and at NHMFL, Los Alamos, using the 65 T short-pulse magnet. PDO and magnetization measurements were performed at NHMFL, Los Alamos, using the 65 T short-pulse magnet.

To perfectly align the magnetic field along the $b$ axis in the d.c. magnet, a single crystal of UTe$_2$ was fixed to a home-made sample mount on top of an Attocube ANR31 piezo-actuated rotation platform (Fig. 1b). Thin copper wires were fixed between the probe and rotation platform, in order to measure the sample and two orthogonal Toshiba THS118 Hall sensors. All three measurements were performed using a conventional four-terminal transport set-up with Lake Shore Cryotronics 372 a.c. resistance bridges. Adjustments to $\theta$ were made using a low-friction apparatus$^{28}$ to find the centre of the range, where the sample resistance was zero at $H = 25.5$ T. With a lower field of 0.5 T, small changes were then made to the $\phi$ orientation while monitoring the Hall sensors. With the field aligned near the $b$ axis, the magnetic field was swept to 34.5 T.

The contactless conductivity was measured using the PDO circuit described in refs. $^{29,30}$ that has been used to study field-stabilized superconducting phases$^{31}$. A coil comprising 6–8 turns of 46-gauge high-conductivity copper wire was wound about the single-crystal sample; the number of turns employed depends on the cross-sectional area of the sample, with a larger number of turns needed for smaller samples. The coil formed part of a PDO circuit resonating at 22–29 MHz. A change in the sample skin depth$^{29}$ or differential susceptibility$^{30}$ causes a change in the inductance of the coil, which in turn alters the resonant frequency of the circuit. The signal from the PDO circuit was mixed down to about 2 MHz using a double-heterodyne system$^{29,30}$. Data were recorded at 20 million samples per second, well above the Nyquist limit. Two samples in individual coils coupled to independent PDOs were measured simultaneously using a single-axis, worm-driven, cryogenic goniometer to adjust their orientation in the field.

The pulsed field magnetization experiments used a 1.5-mm-bore, 1.5-mm-long, 1,500-turn compensated-coil susceptometer constructed from 50-gauge high-purity copper wire$^{32}$. When a sample is within the coil, the signal is proportional to $dM/dt$, where $M$ is magnetization and $t$ is time. Numerical integration was used to evaluate $M$. The sample was mounted within an ampoule of 1.3 mm diameter that could be moved in and out of the coil. Accurate values of $M$ were obtained by subtracting empty coil data from that measured under identical conditions with the sample present. These results were calibrated against results from the Quantum Design’s magnetic property measurement system.

Data availability

The data represented in Figs. 1–4 are available as source data in Supplementary Data 1–4. All other data that support the plots within this paper and other findings of this study are available from the corresponding authors on reasonable request.
