ABSTRACT  A body of evidence supports the view that the signaling pathways governing cellular aging – as well as mechanisms of their modulation by longevity-extending genetic, dietary and pharmacological interventions - are conserved across species. The scope of this review is to critically analyze recent advances in our understanding of cell-autonomous mechanisms of chronological aging in the budding yeast \textit{Saccharomyces cerevisiae}. Based on our analysis, we propose a concept of a biomolecular network underlying the chronology of cellular aging in yeast. The concept posits that such network progresses through a series of lifespan checkpoints. At each of these checkpoints, the intracellular concentrations of some key intermediates and products of certain metabolic pathways - as well as the rates of coordinated flow of such metabolites within an intricate network of intercompartmental communications - are monitored by some checkpoint-specific "master regulator" proteins. The concept envisions that a synergistic action of these master regulator proteins at certain early-life and late-life checkpoints modulates the rates and efficiencies of progression of such processes as cell metabolism, growth, proliferation, stress resistance, macromolecular homeostasis, survival and death. The concept predicts that, by modulating these vital cellular processes throughout lifespan (i.e., prior to an arrest of cell growth and division, and following such arrest), the checkpoint-specific master regulator proteins orchestrate the development and maintenance of a pro- or anti-aging cellular pattern and, thus, define longevity of chronologically aging yeast.

INTRODUCTION
The budding yeast \textit{S. cerevisiae} is an advantageous model organism for unveiling fundamental mechanisms and biological principles underlying the inherent complexity of cellular aging in multicellular eukaryotes [1-6]. Because this unicellular eukaryote is amenable to comprehensive biochemical, genetic, cell biological, chemical biological, system biological and microfluidic dissection analyses [7-12], its use as a model in aging research provided deep mechanistic insights into cellular processes essential for longevity regulation in evolutionarily distant eukaryotic organisms. Due to the relatively short and easily monitored chronological and replicative lifespans of the yeast \textit{S. cerevisiae}, it played a pivotal role in discovering: (1) numerous genes that impact cellular aging and define organismal longevity not only in yeast but also in eukaryotic organisms across phyla; (2) some key nutrient- and energy-sensing signaling pathways that orchestrate an evolutionarily conserved set of longevity-defining cellular processes across species; and (3) several aging-decelerating and longevity-extending small molecules, many of which slow down aging, improve health, attenuate age-related pathologies and delay the onset of age-related diseases in evolutionarily distant multicellular eukaryotic organisms [1-6, 13-22]. These studies convincingly demonstrated that the signaling pathways governing cellular aging and mechanisms of their modulation by longevity-extending genetic, dietary and pharmacological interventions are conserved across species.

There are two different paradigms of yeast aging. Each of them is traditionally investigated separately from each other with the help of robust assays. These assays are conducted under controllable laboratory conditions [23-26]...
and have been recently automated to enable a systems-
level analysis of the aging process in a high-throughput
format [9-12, 27-29]. In the chronological aging paradigm,
yeast aging is defined by the length of time during which a
cell remains viable after an arrest of its growth and division
[23, 30, 31]. Yeast chronological aging under laboratory
conditions is assessed using a simple clonogenic assay. This
assay measures the percentage of yeast cells that in liquid
cultures remain viable at different time points following
entry of a cell population into the non-proliferative sta-
tionary phase. Cell viability in the clonogenic assay is as-
sessed by monitoring the ability of a cell to form a colony
on the surface of a solid nutrient-rich medium [3, 25, 30].
Chronological aging in yeast is believed: (1) to mimic aging
of non-dividing, post-mitotic cells (such as neurons) in a
multicellular eukaryotic organism; and (2) to serve as a
simple model for organismal aging [32, 33]. In the replicative
aging paradigm, yeast aging is defined by the maxi-
mum number of daughter cells that a mother cell can pro-
duce before becoming senescent [24, 34, 35]. S. cerevisiae
reproduces by asymmetric cell division; therefore, its repli-
cative aging under laboratory conditions is typically as-
sessed by using a micromanipulator to remove the budding
progeny of a mother cell and counting the cumulative
number of asymmetric mitotic divisions this mother cell
could undergo [24, 35]. Replicative aging in yeast is
thought to mimic aging of dividing, mitotically active cells
(such as lymphocytes) in a multicellular eukaryotic organ-
ism [2, 32]. The use of robust assays for elucidating longevity
regulation in chronologically or replicatively aging yeast
under controllable laboratory conditions has significantly
advanced our understanding of cell-autonomous mecha-
nisms that orchestrate longevity-defining cellular processes
within an individual cell in eukaryotic organisms across
phyla [1-3, 5, 6, 10].

Recent studies in yeast also advanced fundamental
knowledge about cell-non-autonomous intraspecies mech-
anisms of longevity regulation. Such mechanisms operate
within organized populations of yeast cells that are at-
tached to solid surfaces to form a colony or a biofilm; these
cells: (1) communicate with each other and cells in sur-
rounding colonies or biofilms; (2) age chronologically and
replicatively; and (3) undergo spatially organized growth,
differentiation, aging or death, depending on their position
within the colony [4, 36-43].

It seems that cell-autonomous and cell-non-
autonomous intraspecies mechanisms regulating yeast
longevity have evolved in the process of natural selection
within an ecosystem [44-46]. It has been recently proposed
that this process: (1) is governed by ecosystemic interspe-
cies mechanisms of lifespan regulation operating within
the ecosystem; and (2) is driven by the ability of yeast cells
to undergo specific pro-survival changes in their metabo-
lim and physiology in response to some chemical com-
 pounds that, after being released to the ecosystem by oth-
er groups of organisms, may trigger a hormetic and/or
cytostatic response in yeast [44-48].

In this review we analyze recent progress in under-
standing of cell-autonomous mechanisms of chronological
aging in the yeast S. cerevisiae. Our analysis suggests a
concept of a biomolecular network underlying the chro-
noology of cellular aging in yeast. This concept envisions
that: (1) the network integrates the vital processes of cell
metabolism, growth, proliferation, stress resistance, mac-
romolecular homeostasis, survival and death; (2) the net-
work progresses through a series of the early-life and late-
life “checkpoints”; (3) a gradual progression of the network
through these lifespan checkpoints is monitored by some
checkpoint-specific “master regulator” proteins; and (4)
such progression is critically important for establishing the
pace of cellular aging.

CELL-AUTONOMOUS MECHANISMS ORCHESTRATE
LONGEVITY-DEFINING CELLULAR PROCESSES IN
CHRONOLOGICALLY AGING YEAST PRIOR TO AN
ARREST OF CELL GROWTH AND DIVISION

A body of recent evidence supports the view that certain
cellular processes taking place early in life of a chronologi-
cally aging yeast cell, prior to entry into a non-proliferative
state, define the length of time during which this cell re-
mains viable after such entry - i.e., define longevity of
chronologically aging yeast grown under controllable la-
boratory conditions in liquid media [3, 20, 23, 49-73]. The-
se longevity-defining cellular processes: (1) are essential
for metabolism, growth, proliferation, stress resistance,
macromolecular homeostasis, survival and death of indi-
vidual yeast cells that age chronologically; and (2) are or-
chestrated via cell-autonomous mechanisms of lifespan
regulation operating within these cells. The longevity-
defining cellular processes and mechanisms orchestrating
their progression in chronologically aging yeast prior to
entry into a non-proliferative state (and, for some of them,
after such entry) are outlined below in this section.

Intracellular trehalose modulates cellular protein
homeostasis (proteostasis)

Recent studies revealed that the intracellular concen-
trations of trehalose prior to cell entry into a non-proliferative
state and following such entry play essential and differing
roles in defining longevity of chronologically aging yeast.
This is because trehalose is involved in modulating protein
folding, misfolding, unfolding, refolding, oxidative damage,
solubility and aggregation throughout lifespan [23, 61]
(Figure 1A). In chronologically “young” yeast cells, which
undergo growth and division, trehalose plays an essential
longevity-extending role because this non-reducing disac-
charide: (1) binds to newly synthesized cellular proteins,
thereby stabilizing their native folding states and attenuat-
ing their conversion into aberrantly folded and/or unfolded
protein species; (2) shields the contiguous exposed hydro-
phobic side chains of amino acids that are abundant in
misfolded, partially folded and unfolded protein species
and that are known to promote their aggregation, thereby
eliciting a direct inhibitory effect on the formation of insol-
able protein aggregates; and (3) protects cellular proteins
from oxidative carbonylation by interacting with their car-
bonylation-prone aberrantly folded species, thus having an
FIGURE 1: Cell-autonomous mechanisms define longevity of chronologically aging yeast by orchestrating trehalose metabolism and metabolic processes confined to peroxisomes. (A) A model for molecular mechanisms through which trehalose regulates the process of cellular aging in yeast by modulating protein folding, misfolding, unfolding, refolding, oxidative damage, solubility and aggregation in chronologically “young” and “old” cells. (B) A model for how the age-dependent efficiency of peroxisomal protein import in chronologically aging yeast defines the age-related metabolic pattern of peroxisomes, thus impacting longevity-defining processes in other cellular compartments and ultimately establishing a pro- or anti-aging cellular pattern. Activation arrows and inhibition bars denote pro-aging processes (displayed in blue color) or anti-aging processes (displayed in red color). Please see text for additional details. Ac-Carnitine, acetyl-carnitine; Ac-CoA, acetyl-CoA; DAG, diacylglycerol; ER, endoplasmic reticulum; ETC, electron transport chain; EtOH, ethanol; FFA, non-esterified ("free") fatty acids; LD, lipid droplet; ROS, reactive oxygen species; TAG, triacylglycerols; TCA, tricarboxylic acid cycle; ΔΨm, electrochemical potential across the inner mitochondrial membrane.
indirect inhibitory effect on the aggregation of oxidatively damaged proteins [23, 61] (Figure 1A).

In contrast, in chronologically “old” yeast cells, which do not grow or divide, trehalose plays a key role in shortening longevity. This is because in such cells trehalose shields the patches of hydrophobic amino acid residues that are abundant in aberrantly folded protein species [61]. Thus, in chronologically “old” yeast cells trehalose competes with molecular chaperones for binding with these patches of hydrophobic amino acid residues known to be required for the chaperone-assisted refolding of misfolded, partially folded and unfolded protein species [74-77] - either soluble or extracted from protein aggregates with the help of molecular chaperones [61] (Figure 1A). Importantly, it has been demonstrated that a caloric restriction (CR) diet and certain genetic interventions affecting trehalose synthesis or degradation extend longevity of chronologically aging yeast because they simultaneously: (1) increase the intracellular concentration of trehalose by 70-160% (above its level detected in yeast cultured under non-CR conditions) in chronologically “young”, proliferating cells; and (2) reduce the intracellular concentration of trehalose by 60-80% (below a threshold observed in yeast cultured under non-CR conditions) in chronologically “old”, non-proliferating cells [61]. These findings suggest the existence of at least two “checkpoints” during the lifespan of a chronologically aging yeast cell at which the intracellular concentration of trehalose (which depends on a balance between trehalose synthesis and degradation) defines its longevity by modulating cellular proteostasis. It seems that one of these checkpoints exists early in life of a chronologically aging yeast cell (i.e., prior to entry into a non-proliferative state), whereas the other checkpoint occurs late in its life (i.e., after such cell enters a non-proliferative state).

**Protein import into the peroxisome impacts longevity-defining processes in other cellular compartments**

The efficiency of peroxisomal protein import has been shown to decline with the chronological age of a eukaryotic cell [57, 58, 78, 79]. Such import is driven by Pex5p and Pex7p, the peroxisomal targeting signal type 1 (PTS1) and PTS2 cytosolic shuttling receptors, respectively [80-82]. Recent findings support the view that the age-dependent efficiency of protein import into the peroxisome defines the efficiencies of fatty acid oxidation, hydrogen peroxide turnover and anaplerotic metabolism within this organelle. These metabolic processes are known to modulate the dynamic communications of peroxisomes with other cellular compartments via a unidirectional or bidirectional flow of certain soluble metabolites and lipids [20, 57, 58, 65, 85-89]. By influencing longevity-defining cellular processes confined to these other compartments, the metabolic processes within the peroxisome cause the development of a pro- or anti-aging cellular pattern [20, 54, 57, 58, 65, 83-89].

Altogether, these findings suggest a model for how the age-dependent efficiency of peroxisomal protein import in chronologically aging yeast defines the age-related metabolic pattern of peroxisomes, thus impacting longevity-defining processes in other cellular compartments and ultimately establishing a pro- or anti-aging cellular pattern (Figure 1B). The model envisions that chronologically “young” yeast cells develop and maintain an anti-aging cellular pattern in part because in these cells the efficiency of Pex5p- and Pex7p-dependent peroxisomal protein import exceeds a threshold. Specifically, such “young” cells are proficient in peroxisomal import of the following proteins: (1) catalase Cta1p and peroxiredoxin Pmp20p, both required for decomposition of hydrogen peroxide and other reactive oxygen species (ROS) within the peroxisome; (2) Fox1p, Fox2p and Fox3p, enzymes involved in peroxisomal β-oxidation of fatty acids to acetyl-CoA; and (3) the citrate synthase Cit2p and acetyl-carnitine synthase Cat2p, both facilitating the replenishment of tricarboxylic acid (TCA) cycle intermediates destined for mitochondria by catalyzing the anaplerotic conversion of acetyl-CoA to citrate and acetyl-carnitine, respectively [14, 20, 57, 58, 85, 90-92] (Figure 1B). The efficient peroxisomal import of all these proteins in chronologically “young” yeast cells enables the establishment of an anti-aging cellular pattern by: (1) minimizing the oxidative damage to peroxisomal proteins and membrane lipids; (2) maintaining the intracellular concentration of peroxisomally produced hydrogen peroxide at a threshold which is insufficient to damage cellular macromolecules but can activate transcription of nuclear genes essential for cell survival, thus promoting the longevity-extending cellular process of “stress-response hormesis”; (3) stimulating the TCA cycle and electron transport chain (ETC) in mitochondria, thus enabling to sustain mitochondrionally generated ROS at a non-toxic level which is sufficient to stimulate transcription of nuclear genes encoding stress-protecting and other anti-aging proteins [20, 23, 57, 58, 65, 92] (Figure 1B).

Noteworthy, peroxisomes in yeast house the polyamine oxidase Fms1p, an enzyme involved in the synthesis of spermidine [17, 93]. This natural polyamine has been shown to extend longevity of chronologically aging yeast by stimulating the essential cytoprotective cellular process of autophagy [13, 94, 95] (Figure 1B). Because the intracellular concentration of spermidine in chronologically “young” yeast exceeds that in chronologically “old” yeast [13], one could speculate that peroxisomal import of Fms1p early in life of a chronologically aging yeast cell is more efficient than it is late in life, after entry of a chronologically aging yeast cell population into a non-proliferative state. In this scenario, chronologically “young” yeast cells develop and maintain an anti-aging cellular pattern in part because they are proficient in peroxisomal import of a protein needed for the synthesis of a natural polyamine which promotes the longevity-extending cellular process of autophagy (Figure 1B).

Our model further posits that in chronologically “old” yeast cells the efficiencies of Pex5p- and Pex7p-dependent peroxisomal import of Cta1p, Pmp20p, Fox1p, Fox2p, Fox3p, Cit2p and Cat2p markedly decline (Figure 1B). Such deterioration of peroxisomal protein import below a threshold in these cells causes the development of a pro-aging cellular pattern by: (1) elevating the intracellular
concentration of peroxisomally produced hydrogen peroxide above a cytotoxic level, thus increasing the extent of oxidative damage to cellular macromolecules; (2) reducing the efficiency of Fox1p-, Fox2p- and Fox3p-driven peroxisomal oxidation of fatty acids derived from triacylglycerols that are synthesized in the endoplasmic reticulum (ER) and deposited within lipid droplets (LD) – thus elevating the concentrations of non-esterified ("free") fatty acids and diacylglycerol, both of which are known to elicit an age-related form of liponecrotic programmed cell death (PCD); (3) diminishing the replenishment of TCA cycle intermediates destined for the TCA cycle in mitochondria – thus triggering a cascade of events that reduce the ETC in mitochondria, lower electrochemical potential across the inner mitochondrial membrane (IMM), promote mitochondrial fragmentation, cause the efflux of cytochrome c and other pro-apoptotic proteins from fragmented mitochondria, and ultimately elicit an age-related form of apoptotic PCD [14, 20, 23, 54, 57, 58, 65, 84, 91, 92, 96-103] (Figure 1B).

Furthermore, our model envisions that chronologically "old" yeast cells develop and maintain a pro-aging cellular pattern in part because they exhibit a low efficiency of peroxisomal import of the polyamine oxidase Fms1p, which is required for the synthesis of spermidine [13, 17, 93-95] (Figure 1B). Noteworthy, both chronologically "young" and "old" yeast cells grown in a nutrient-rich medium under longevity-shortening non-CR conditions have been shown to accumulate ethanol, a product of glucose fermentation [23, 84]. Ethanol is known to repress the synthesis of Fox1p, Fox2p and Fox3p, thereby suppressing Fox1p-, Fox2p- and Fox3p-driven peroxisomal oxidation of fatty acids [90, 104] (Figure 1B). By suppressing peroxisomal oxidation of fatty acids to acetyl-CoA in chronologically "young" cells under non-CR conditions, the accumulated ethanol attenuates the anaplerotic conversion of acetyl-CoA to citrate and acetyl-carnitine - thus inhibiting an aging-decelerating cellular process of the replenishment of TCA cycle intermediates destined for mitochondria [57, 58, 90, 104] (Figure 1B). Moreover, by suppressing peroxisomal oxidation of fatty acids to acetyl-CoA in chronologically "old" cells under non-CR conditions, the accumulated ethanol also elevates the concentrations of non-esterified ("free") fatty acids and diacylglycerol - thus triggering an age-related form of liponecrotic PCD (Figure 1B) [14, 23, 54, 57, 58, 84, 103]. It should be stressed that neither chronologically "young" nor chronologically "old" yeast cells grown under longevity-extending CR conditions amass ethanol [23, 84]. Such inability of yeast cells limited in calorie supply to accumulate ethanol is one of the reasons why they are able to develop and maintain an anti-aging cellular pattern throughout lifespan [23, 54, 57, 58, 84] (Figure 1B).

In sum, it is conceivable that there are at least two checkpoints during the lifespan of a chronologically aging yeast cell at which the age-dependent efficiency of peroxisomal protein import defines the age-related metabolic pattern of peroxisomes, thus impacting longevity-defining processes in other cellular compartments and ultimately establishing a pro- or anti-aging cellular pattern. It seems that one of these checkpoints occurs early in life of a chronologically aging yeast cell (i.e., prior to an arrest of cell growth and division), whereas the other checkpoint exists late in its life (i.e., following such arrest).

Coupled mitochondrial respiration, mitochondrial membrane potential and mitochondrial ROS production affect longevity-defining processes in other cellular locations

The functional state of mitochondria and mitochondrial ROS production early in life of a chronologically aging yeast cell, prior to entry into a non-proliferative state, have been shown to define the length of time during which this cell remains viable after such entry - i.e., define longevity of chronologically aging yeast [3, 14, 23, 31, 49-51, 53, 55, 56, 62, 64, 68-73, 105-108]. One key feature of the longevity-defining functional state of mitochondria in chronologically "young", proliferating yeast cells is the capacity of electron transport along the respiratory chain coupled to ATP synthesis [3, 14, 23, 49-51, 62, 64, 70, 72, 73, 106, 107]. Another such key feature is the value of mitochondrial membrane potential; it depends on a balance between the capacities of ETC-driven proton transport from the matrix to the intermembrane space and proton translocation across the IMM in the opposite direction [3, 14, 23, 50, 51, 56, 64, 70]. Moreover, the longevity-defining process of mitochondrial ROS production in chronologically "young" yeast cells depends on the efficiency of coupling between the ETC and oxidative phosphorylation (OXPHOS) system in mitochondria [50, 51].

Recent studies revealed how various genetic, dietary and pharmacological interventions having diverse effects on the ETC, OXPHOS system and/or ROS production in mitochondria of chronologically "young" yeast impact yeast longevity [3, 14, 23, 31, 49-51, 53, 55, 56, 62, 64, 68-73, 105-108]. These studies suggest a model for how coupled mitochondrial respiration, mitochondrial membrane potential maintenance and mitochondrial ROS production early in life of chronologically aging yeast cells define their longevity. This model is depicted schematically in Figure 2.

The model envisions that chronologically "young" yeast cells cultured under non-CR conditions develop and maintain a pro-aging cellular pattern because the capacities of these mitochondrial processes in such cells are below a certain level (Figure 2; these capacities are displayed in green color) [23, 53, 62, 72, 73]. Furthermore, the model posits that chronologically "young" yeast cells, in which the capacities of these mitochondrial processes exceed a critical threshold, develop and maintain an anti-aging cellular pattern. This is because such capacities have specific impacts on: (1) some longevity-defining processes confined to mitochondria; and (2) certain longevity-defining processes in other cellular locations (Figure 2; these capacities are displayed in red color) [14, 23, 50, 51, 56, 62, 64, 70, 73, 107]. The model also predicts that a significant further increase in the capacities of coupled mitochondrial respiration, mitochondrial membrane potential maintenance and mitochondrial ROS production above a critical threshold in chronologically "young" yeast cells has a negative impact.
FIGURE 2: The functional state of mitochondria and mitochondrial ROS production in chronologically "young" yeast cells define their longevity by orchestrating numerous "downstream" cellular processes. A model for how coupled mitochondrial respiration, mitochondrial membrane potential maintenance and mitochondrial ROS production early in life of chronologically aging yeast cells, prior to entry into a non-proliferative state, define their viability after such entry - i.e., define their longevity. Activation arrows and inhibition bars denote pro-aging processes (displayed in blue color) or anti-aging processes (displayed in red color). Please see text for additional details. CR, caloric restriction; D, diauxic growth phase; DAG, diacylglycerol; EtOH, ethanol; FFA, non-esterified ("free") fatty acids; IMM, inner mitochondrial membrane; L, logarithmic growth phase; LCA, lithocholic acid; LD, lipid droplet; PD, post-diauxic growth phase; PS, phosphatidylserine; ROS, reactive oxygen species; ST, stationary growth phase; $\Delta \Psi_m$, electrochemical potential across the IMM.
on their longevity (Figure 2; these capacities are displayed in blue color) [14, 23, 64, 107].

The capacities of coupled mitochondrial respiration, mitochondrial membrane potential maintenance and mitochondrial ROS production in chronologically “young” yeast cells are modulated by several “upstream” pathways (Figure 2). These longevity-defining pathways include: (1) the nutrient- and energy-sensing protein kinase Tor1p inhibits mitochondrial translation of the OXPHOS enzymes encoded by mitochondrial DNA (mtDNA) [14, 50, 51, 56, 62]; (2) a CR pathway, whose ability to modulate coupled mitochondrial respiration, mitochondrial membrane potential maintenance and mitochondrial ROS production in chronologically “young” yeast cells is mediated in part by Tor1p [3, 14, 23, 33, 50-52, 56, 62]; (3) a pathway for the maintenance of mitochondrial genome integrity and copy number, which is orchestrated by the mitochondrial base-excision repair enzyme Ntg1p [108]; (4) the mitophagy pathway of mitochondrial quality control responsible for autophagic degradation of aged, dysfunctional or damaged mitochondria - which requires the receptor protein Atg32p on the surface of mitochondria destined for such degradation [70]; and (5) a pathway for specific remodeling of the membrane lipidome of mitochondria - which is stimulated in response to accumulation of the exogenously added lithocholic acid (LCA), an anti-aging natural compound, predominantly in the IMM [64, 107] (Figure 2). Noteworthy, some of these “upstream” pathways overlap; such convergent pathways modulating the capacities of coupled mitochondrial respiration, mitochondrial membrane potential maintenance and mitochondrial ROS production in chronologically “young” yeast include the TOR and CR pathways [3, 14, 23, 33, 50-52, 56, 62], as well as the TOR and Ntg1p-governed pathways [108]. In contrast, it seems that other “upstream” pathways modulating the capacities of these three longevity-defining mitochondrial processes do not converge and act in synergy; such “parallel” pathways include: (1) a CR pathway and an LCA-driven pathway for remodeling of the membrane lipidome of mitochondria [64, 107]; and (2) a CR pathway and the Ntg1p-governed pathway [108].

The capacities of coupled mitochondrial respiration, mitochondrial membrane potential maintenance and mitochondrial ROS production in chronologically “young” yeast cells define their longevity by orchestrating numerous “downstream” cellular processes throughout lifespan - i.e., prior to entry into a non-proliferative state and after such entry (Figure 2). Among them are the following “downstream” processes (Figure 2): (1) the maintenance of trehalose homeostasis, a longevity-defining process known to modulate proteostasis in chronologically “young” and “old” cells [23, 61] (Figure 1A); (2) the maintenance of the homeostasis of glycojen, a reserve carbohydrate whose elevated level in chronologically “young” and “old” cells is a hallmark of carbohydrate metabolism remodeling in yeast cultured under CR [23]; (3) the maintenance of the homeostasis of neutral lipids deposited within LD, a process known to play an essential role in regulating longevity of chronologically aging yeast [14, 23, 92] (Figure 1B); (4) peroxisomal氧化 of fatty acids, a process implicated in yeast chronological aging [14, 23, 91, 92] (Figure 1B); (5) the maintenance of the homeostasis of non-esterified (“free”) fatty acids and diacylglycerol, whose reduced levels in chronologically “young” and “old” cells are characteristic of lipid metabolism remodeling in yeast cultured under CR - a pattern likely linked to the demonstrated abilities of both lipid species to elicit an age-related form of liponecrotic PCD [14, 23, 103] (Figure 1B); (6) the maintenance of a balance between the relative rates of glycolysis and gluconeogenesis, a process known to impact the level of ethanol in chronologically “young” and “old” yeast - thus defining the extent to which this product of glucose fermentation suppresses the longevity-extending process of peroxisomal oxidation of fatty acids [14, 23] (Figure 1B); (7) the longevity-extending process of mitochondrial translation [23, 50, 51, 56]; (8) the maintenance of a balance between the relative rates of mitochondrial fusion and fission, a process known to define the size and number of mitochondria, the length of mitochondrial cristae extending from the IMM, and the level of ATP synthesized in mitochondria of chronologically “young” and “old” yeast [14, 23, 64, 70]; (9) the development of an age-related pattern of susceptibility to chronic oxidative, thermal and osmotic stresses [3, 14, 23, 33, 50, 56, 59, 62]; (10) an age-related form of apoptotic PCD, which in chronologically “young” yeast is manifested in such early hallmark events of this PCD as the fragmentation of a tubular mitochondrial network into individual mitochondria, release of cytochrome c from mitochondria into the cytosol and phosphatidylserine (PS) translocation from the inner to the outer leaflet of the plasma membrane [14, 23] (Figure 1B); and (11) the development of a pattern of cell susceptibility to an age-related forms of apoptotic and liponecrotic PCD elicited by an exposure to exogenous hydrogen peroxide or palmitoleic acid, respectively [14, 23, 59, 103].

The molecular mechanisms through which the capacity of mitochondrial ROS production in chronologically “young” yeast cells defines their longevity have begun to emerge; they involve communication between mitochondria and the nucleus via two signaling pathways [71, 108]. In one of these signaling pathways, hormetic concentrations of ROS released from mitochondria trigger a pro-longevity transcriptional program in the nucleus by stimulating Gis1p, Msn2p and Msn4p [68, 71, 108]; these transcriptional factors are known to activate expression of numerous genes essential for the resistance to various stresses, stationary phase survival, carbohydrate metabolism, nutrient sensing and chronological longevity assurance [109-111]. Another mitochondria-to-nucleus signaling pathway initiated by hormetic concentrations of ROS in chronologically “young” yeast cells involves a cascade of events within the nucleus. In this cascade, the DNA damage response (DDR) kinase Tel1p responds to hormetic concentrations of ROS released from mitochondria by phosphorylating and activating the DDR kinase Rad53p. Active Rad53p then phosphorylates and inactivates the histone demethylase Rph1p confined to subtelomeric...
chromatin regions, thereby repressing their transcription, minimizing telomeric DNA damage and ultimately extending longevity of chronologically aging yeast [68, 71]. Noteworthy, it seems that the Tel1p-Rad53p-Rph1p signaling pathway overlaps with and is regulated by the "upstream" Ntg1p-governed pathway (Figure 2) for the maintenance of mitochondrial genome integrity and copy number [108].

Altogether, these findings suggest that there is a checkpoint early in life of chronologically aging yeast cells (i.e., prior to entry into a non-proliferative state) at which the capacities of coupled mitochondrial respiration, mitochondrial membrane potential maintenance and mitochondrial ROS production define their viability after such entry - i.e., define their longevity. It seems that the capacities of these three mitochondrial processes at such checkpoint define yeast longevity by orchestrating a number of “downstream” processes taking place in various cellular locations throughout lifespan, before an arrest of cell growth and division, and following such arrest.

Metabolite flow within glycolytic and non-glycolytic pathways of carbohydrate metabolism defines the establishment of a pro- or anti-aging cellular pattern

Recent studies provided evidence that the relative rates of reactions comprising glycolytic and non-glycolytic pathways of carbohydrate metabolism, as well as the intracellular concentrations of some key intermediates in these pathways, define the development and maintenance of a pro- or anti-aging cellular pattern in chronologically aging yeast [3, 10, 23, 33, 52, 54, 57, 58, 63, 65-67, 69, 84, 112-117]. The major findings of these studies can be summarized as follows: (1) the establishment of a certain metabolic pattern of such coordinated pathways early in life of chronologically aging yeast cells, prior to entry into a non-proliferative state, defines their longevity; and (2) some dietary, genetic and pharmacological interventions extend yeast longevity by causing a specific remodeling of such metabolic pathways in chronologically "young", proliferating cells [23, 52, 66, 67, 69, 112-117]. These findings suggest a model for how metabolic flux within the network integrating glycolytic and non-glycolytic pathways of carbohydrate metabolism modulates longevity-defining cellular processes. This model is depicted schematically in Figure 3.

The model posits that glucose, the primary carbon source used in most assays for investigating yeast chronological aging under laboratory conditions, is initially converted to pyruvate via the glycolytic pathway and also enters the pentose phosphate pathway (PPP) [23, 25, 27, 30, 33, 57, 66] (Figure 3). In chronologically "young" yeast cells progressing through logarithmic (L) phase, the PPP generates not only ribose-5-phosphate for nucleic acid synthesis but also NADPH, the primary source of cellular reducing equivalents required for the reductive synthesis of fatty acids, sterols and some amino acids [60, 63, 66, 118]. Importantly, NADPH - which is produced in the Zwf1p- and Gnd1p-driven oxidative reactions of the PPP - also functions as the electron donor essential for sustaining cellular redox homeostasis via thioredoxin and glutathione reduction systems [63, 66, 118] (Figure 3). These two NADPH-dependent systems have been shown to reduce the extent of oxidative damage to numerous thiol-containing cytosolic, nuclear and mitochondrial proteins in chronologically "young" yeast cells; as such, both reductase systems play essential roles in longevity assurance and underlie, in part, the robust longevity-extending effect of CR [63, 66] (Figure 3).

After chronologically aging yeast cells consume glucose during L phase, they enter diauxic (D) and then post-diauxic (PD) phases of slow growth [23, 25, 30, 33]. During D and PD phases, prior to an arrest of cell growth and division and entry into the non-proliferative stationary (ST) phase, the pyruvate formed by glycolysis can enter several alternative pathways of carbon metabolism; all these pathways have been implicated in modulating various longevity-defining cellular processes [3, 10, 23, 33, 52, 54, 57, 58, 63, 65-67, 69, 84, 112-117]. One of these alternative metabolic pathways is fermentation leading to the formation of ethanol and/or acetic acid in the cytosol of a chronologically "young" yeast cell; the nature of a product of such fermentation depends on the type of a synthetic or nutrient-rich growth medium used and/or aeration conditions applied [3, 10, 23, 33, 52, 112-115, 117] (Figure 3). As discussed above, the level of ethanol in chronologically aging yeast defines the extent to which it suppresses the longevity-extending process of peroxisomal oxidation of fatty acids [14, 23] (Figure 1B). The steady-state level of this product of glucose fermentation depends on the relative enzymatic activities of Adh1p and Adh2p, which are required for ethanol formation or oxidation, respectively [3, 23, 52, 112, 117] (Figure 3). Acetic acid, the alternative product of glucose fermentation in the cytosol of chronologically "young" yeast cells, shorts their longevity – likely because it can elicit an age-related form of apoptotic PCD [3, 27, 113-115] (Figure 3). Of note, the Ald6p-dependent acetaldehyde dehydrogenase reaction in the cytosol of these cells yields not only acetic acid but also NADPH [60, 66, 118] (Figure 3). As discussed above, the NADPH-dependent thioetherin and glutathione reductase systems are vital for longevity assurance and are essential for the longevity-extending effect of CR because they reduce the extent of oxidative damage to many thiol-containing cellular proteins in chronologically "young" yeast cells [63, 66, 118] (Figure 3). Moreover, acetic acid can be converted to acetyl-CoA in the nucleo-cytosolic Acs2p-dependent reaction [116, 118]. The acetyl-CoA formed in the nucleus has been shown to shorten longevity of chronologically aging yeast by causing histone H3 hyperacetylation, thereby selectively suppressing transcription of the ATG5, ATG7, ATG11 and ATG14 genes; these genes encode proteins needed for the longevity-extending process of autophagy [116] (Figure 3). It remains to be determined what are the relative impacts of acetic acid (a pro-aging metabolite), NADPH (an anti-aging metabolite) and acetyl-CoA (a pro-aging metabolite) on longevity of chronologically aging yeast.

The model depicted in Figure 3 further envisions that glucose fermentation to glycerol in the cytosol of a chronologically "young" yeast cell operates as a longevity-exten-
FIGURE 3: The coordinated metabolite flow within glycolytic and non-glycolytic pathways of carbohydrate metabolism defines yeast longevity by modulating vital cellular processes. A model for how metabolic flux within the network integrating glycolytic and non-glycolytic pathways of carbohydrate metabolism in chronologically "young", proliferating yeast cells defines the development and maintenance of a pro- or anti-aging cellular pattern throughout lifespan, before an arrest of cell growth and division and after such arrest. Activation arrows and inhibition bars denote pro-aging processes (displayed in blue color) or anti-aging processes (displayed in red color). Please see text for additional details. Ac-CoA, acetyl-CoA; DHAP, dihydroxyacetone phosphate; EtOH, ethanol; GA-3-P, glyceraldehyde-3-phosphate; GLR, glutathione reductase; NADPH, nicotinamide adenine dinucleotide phosphate; PCD, programmed cell death; TCA, tricarboxylic acid; TORC1, target of rapamycin complex 1; TRR, thioredoxin reductase.
ding cellular process – likely because it reduces metabolite flow into the longevity-shortening cellular process of glucose fermentation to ethanol and/or acetic acid [52, 113] (Figure 3). The term “phantom carbon source” has been coined for defining this aspect of the essential longevity-extending role of glycerol in yeast [52]. Glycerol formed by glucose fermentation in the cytosol of a chronologically “young” yeast cell has been proposed to extend its lifespan also because it is known to reduce cell susceptibility to chronic oxidative, thermal and osmotic stresses [52] (Figure 3). Furthermore, glucose fermentation to glycerol in chronologically “young” yeast cells may also play an essential role in longevity assurance by maintaining an NAD+/NADH ratio characteristic of an anti-aging cellular pattern [52] (Figure 3).

In addition to being converted to ethanol, acetic acid, NADPH and/or acetyl-CoA, the pyruvate formed by glycolysis can enter the gluconeogenesis pathway leading to the formation of glucose; in chronologically aging yeast, this newly synthesized glucose can be further used for the synthesis of trehalose [23, 61, 62, 117] (Figure 3). As discussed above [23, 61] (Figure 1A): (1) in chronologically “young” yeast cells progressing through D and PD growth phases, trehalose plays an essential longevity-extending role, whereas (2) in chronologically “old”, non-proliferating cells, trehalose plays a key role in shortening longevity (Figure 1).

In chronologically “young” yeast cells progressing through D and PD growth phases, the pyruvate formed by glycolysis - as well as the acetaldehyde and acetate derived from it - can also fuel several longevity-defining metabolic processes in mitochondria. One of these metabolic processes is the TCA cycle. Two intermediates of the cycle, malate and isocitrate, can be used to form NADPH in the Mae1p- and Idp1p-dependent reactions, respectively [60, 66, 118] (Figure 3). NADPH in mitochondria of chronologically “young” yeast cells progressing through D and PD growth phases can also be formed in the Ald4p-dependent acetaldehyde dehydrogenase reaction and in the Pos5p-dependent NADH kinase reaction [60, 66, 118] (Figure 3). As discussed above, NADPH can play a vital longevity-extending role by being used for a thiodioxidin- and glutathione reductase-driven decrease in the extent of oxidative damage to thiol-containing mitochondrial proteins and proteins in other cellular locations [63, 66, 118] (Figure 3). Moreover, the oxaloacetate and α-ketoglutarate intermediates of the TCA cycle in mitochondria of chronologically “young” yeast cells progressing through D and PD growth phases are known to be used for the synthesis of amino acids [60, 118, 119] (Figure 3). After their exit from mitochondria to the cytosol, some of these amino acids - including aspartate, asparagine, glutamate and glutamine - cause a significant increase in protein kinase activity of the TOR complex 1 (TORC1) on the surface of vacuoles [20, 119-124] (Figure 3). The resulting stimulation of the TOR signaling pathway in chronologically “young” yeast cells is known to initiate the establishment of a pro-aging cellular pattern by: (1) activating the longevity-shortening process of protein synthesis in the cytosol; (2) suppressing the longevity-extending process of autophagy in vacuoles; (3) inhibiting the longevity-extending process of transcription of numerous stress-response genes in the nucleus; and (4) suppressing the longevity-extending process of protein synthesis in mitochondria [20, 50, 51, 119-124] (Figure 3).

Taken together, these findings strongly suggest that there are several checkpoints early in life of chronologically aging yeast cells - during L, D and PD phases preceding entry into the non-proliferative ST phase - at which the coordinated metabolite flow within glycolytic and non-glycolytic pathways of carbohydrate metabolism defines yeast longevity. It seems that at each of these early-life checkpoints some key intermediates in such pathways affect - in a different manner and in a concentration-dependent fashion - the vital processes of cell metabolism, growth, proliferation, stress resistance, macromolecular homeostasis, survival and death. By modulating such longevity-defining cellular processes throughout lifespan - prior to an arrest of cell growth and division and following such arrest - these key metabolic intermediates define the development and maintenance of a pro- or anti-aging cellular pattern.

A STEPWISE PROGRESSION OF A BIOMOLECULAR NETWORK OF CELLULAR AGING THROUGH A SERIES OF LIFESPAN CHECKPOINTS DEFINES LONGLIFE OF CHRONOLOGICALLY AGING YEST

The above analysis of the current knowledge about cell-autonomous mechanisms underlying chronological aging in yeast suggests the existence of several lifespan checkpoints that are critically important for establishing the pace of such aging. A recently reported ability of a natural chemical compound to extend longevity of chronologically aging yeast only if added at some of these checkpoints [59] supports the notion that a stepwise progression through such checkpoints may define the development and maintenance of a pro- or anti-aging cellular pattern. Therefore, in this review we extend the recently proposed network theories of yeast chronological aging [3, 20, 23, 58, 59, 61, 62, 125-127] by putting forward a concept of a biomolecular network underlying the chronology of cellular aging in yeast. This concept is depicted schematically in Figure 4. The concept posits that the network progresses through a series of the early-life checkpoints (that exist in L, D and PD phases) and late-life checkpoints (that exist in ST phase). At each of these checkpoints, the intracellular concentrations of some key intermediates and products of certain metabolic pathways - as well as the rates of coordinated flow of such metabolites within an intricate network of intercompartmental (i.e., organelle-organelle and organelle-cytosol) communications - are monitored by some checkpoint-specific “master regulator” proteins (Figure 4). The concept further envisions that, because each of these master regulator proteins is known for its essential role in longevity regulation, their synergistic action at certain early-life and late-life checkpoints modulates the rates and efficiencies of progression of such essential processes as cell metabolism, growth, proliferation, stress resistance, macromolecular homeostasis, survival and death (Figure 4). The concept predicts that, by modulating these vital cellular processes
Throughout lifespan - prior to an arrest of cell growth and division and following such arrest - the checkpoint-specific "master regulator" proteins orchestrate the development and maintenance of a pro- or anti-aging cellular pattern and, thus, define longevity of chronologically aging yeast (Figure 4).

In the proposed concept of a biomolecular network underlying the chronology of cellular aging in yeast, the key intermediates and products of longevity-defining metabolic pathways include the following metabolites: NADPH (an anti-aging metabolite), trehalose (an anti-aging metabolite), glycerol (an anti-aging metabolite), trehalose (an anti-aging metabolite), acetyl-carnitine (an anti-aging metabolite), citrate (an anti-aging metabolite), hydrogen peroxide (an anti-aging metabolite if it is maintained at an "adaptive" level eliciting a hormetic response but a pro-aging metabolite if it amasses above a cytotoxic level), spermidine (an anti-aging metabolite), ethanol (a pro-aging metabolite), acetyl-CoA (a pro-aging metabolite), non-esterified fatty acids (pro-aging metabolites), diacylglycerol (a pro-aging metabolite) and amino acids (pro-aging metabolites) (Figure 4). The proposed concept posits that these key metabolites undergo an age-related flow within an intricate network of intercompartmental communications. Such unidirectional and bidirectional flow of the critical metabolites...
between different cellular compartments connects mitochon-
draria and the nucleus, peroxisomes and the nucleus, vacuoles and the nucleus, the cytosol and the nucleus, mitochondria and peroxisomes, lipid droplets and peroxi-
somes, mitochondria and vacuoles, peroxisomes and the
cytosol, mitochondria and the cytosol, and vacuoles and the
cytosol (Figure 4). In the proposed concept, a CR diet and some pharmacological interventions (such as rapamy-
cin and LCA) - as well as some other environmental cues (such as the intake of certain dietary supplements and horneretic environmental stresses) - extend longevity of chronologically aging yeast by altering the age-related dy-
namics of changes in the intracellular concentrations of the
key metabolites and/or by modulating the intercompartment-
mental flow of these critical metabolites (Figure 4). The
following proteins and protein complexes operate as
checkpoint-specific master regulators that - according to
the proposed concept - respond to age-related changes in
the intracellular concentrations of the key metabolites and
in the intensity of their intercompartmental flow by modu-
lating the longevity-defining processes of cell metabolism,
growth, proliferation, stress resistance, macromolecular
homeostasis, survival and death: (1) thioredoxin and gluta-
thane reductase systems (anti-aging master regulators); (2)
Rim15p, Msn2p, Msn4p and Gis1p (anti-aging master
regulators); (3) TEL1p and RDS3p (anti-aging master regu-
lators); (4) components of the ATG protein machinery in-
volved in the essential cytoprotective cellular process of
autophagy (anti-aging master regulators); (5) Rph1p (a pro-
aging master regulator); (6) Iki3p and Ssa3p (pro-aging master
regulators); and (7) TORC1 and protein kinase A (PKA) (pro-aging master regulators) (Figure 4). Future stud-
ies are likely to reveal some other checkpoint-specific mas-
ter regulator proteins. Finally, the proposed concept posits
that the checkpoint-specific master regulators define lon-
gevity of chronologically aging yeast by orchestrating cer-
tain “downstream” cellular processes and features
throughout lifespan - i.e., prior to entry into a non-
proliferative state and after such entry (Figure 4). These
“downstream” processes and features include (Figure 4):
(1) susceptibility to chronic oxidative, thermal and osmotic
stresses; (2) oxidative damage to numerous thiol-
containing cysteins, nuclear and mitochondrial proteins;
(3) cellular proteostasis, which depends on the relative
rates and efficiencies of protein folding, misfolding, unfolding,
refolding, oxidative damage, solubility and aggregation;
(4) transcription of subtelomeric chromatin regions,
which defines the extent of age-related telomeric DNA
damage; (5) protein synthesis in the cytosol; (6) protein
synthesis in mitochondria; (7) autophagy, an essential
mechanism of cellular quality control responsible for the
autophagic degradation of aged, dysfunctional and dam-
aged macromolecules and organelles; and (8) liponecrotic
and apoptotic forms of age-related PCD.

CONCLUSIONS
Emergent evidence supports the view that the processes of
cell metabolism, growth, proliferation, stress resistance,
macromolecular homeostasis, survival and death in chron-
ologically aging yeast are integrated into a biomolecular
network of cellular aging. Recent findings imply that a stepwise progression of this network through a series of
the early-life and late-life checkpoints is monitored by
some checkpoint-specific master regulator proteins; these
proteins act in synergy to orchestrate the development
and maintenance of a pro- or anti-aging cellular pattern
and, thus, to define longevity of chronologically aging yeast.
The major challenge now is to understand if a process of
yeast chronological aging - whose progression through a
series of lifespan checkpoints is monitored and controlled
by a distinct set of master regulator proteins - is a program.
We hypothesize that, although yeast chronological aging is
a gradual and controllable process progressing through a
series of consecutive lifespan checkpoints, it is not a pro-
gram aimed at the termination of lives of individual yeast
cells and of their organized populations. Rather, chronolog-
ical aging in yeast is probably due to the inability of
chronologically “young”, proliferating cells to maintain
the capacities of some crucial cellular processes above a critical
threshold; these key cellular processes may include ones
that ensure robust cell growth and proliferation, imple-
ment a spatiotemporal control of cell development and
differentiation into quiescent and non-quiescent cell popu-
lations, and limit an age-related accumulation of molecular
and cellular damage. The proposed here hypothesis also
posits that the extreme cellular stress caused by the exces-
sive accumulation of such damage in chronologically “old”,
non-proliferating cells may activate pathways known to
orchestrate the apoptotic, regulated necrotic, autophagic
and/or liponecrotic subroutines of PCD; these subroutines
are believed to constitute modules that are dynamically
integrated into a so-called PCD network [103, 128-135]. In
sum, the hypothesis of non-programmed chronological
aging in yeast envisions that: (1) the processes of cell me-
tabolism, growth, proliferation, stress response, macromo-
lecular homeostasis, development and differentiation have
evolved in the course of natural selection within diverse
ecosystems (and perhaps under laboratory conditions) as
programs aimed at sustaining the long-term survival of
individual yeast cells under various environmental condi-
tions; (2) the processes of various subroutines of PCD have
evolved throughout natural selection within different eco-
systems (and perhaps under laboratory conditions) as
“altruistic” programs aimed at sustaining the long-term
survival of organized yeast populations (such as colonies
and biofilms of yeast cells attached to solid surfaces) by
eliminating individual yeast cells that are damaged, unable
to mate and reproduce, poorly adapted to diverse envi-
ronmental conditions, and/or release excessive quantities
of ROS and other harmful metabolites (for a comprehen-
sive discussion of this topic, see refs. [136, 137]); and (3) a
trade-off between these programs aimed at sustaining the
long-term survival of individual yeast cells or that of orga-
nized yeast populations under diverse environmental con-
ditions drives the evolution of yeast longevity towards
maintaining a finite yeast chronological lifespan within an
ecosystem. The proposed here hypothesis of non-
programmed chronological aging in yeast provides a framework for future studies aimed at testing its validity.
