ABSTRACT

The first-year WMAP data, in combination with any one of a number of other cosmic probes, show that we live in a flat \(\Lambda\)-dominated CDM universe with \(\Omega_m \approx 0.27\) and \(\Omega_\Lambda \approx 0.73\). In this model the late-time action of the dark energy, through the integrated Sachs-Wolfe effect, should produce CMB anisotropies correlated with matter density fluctuations at \(z \lesssim 2\) (Crittenden & Turok 1996). The measurement of such a signal is an important independent check of the model. We cross-correlate the NRAO VLA Sky Survey radio source catalog (Condon et al. 1998) with the WMAP data in search of this signal, and see indications of the expected correlation. Assuming a flat \(\Lambda\)CDM cosmology, we find \(\Omega_\Lambda > 0\) (95\% CL, statistical errors only) with the peak of the likelihood at \(\Omega_\Lambda = 0.68\), consistent with the preferred WMAP value. A closed model with \(\Omega_m = 1.28, h = 0.33\), and no dark energy component (\(\Omega_\Lambda = 0\)), marginally consistent with the WMAP CMB TT angular power spectrum, would produce an anti-correlation between the matter distribution and the CMB. Our analysis of the cross-correlation of the WMAP data with the NVSS catalog rejects this cosmology at the 3\(\sigma\) level.

Subject headings: cosmic microwave background, cosmology: observations

1. Introduction

The recent WMAP results (Bennett et al. 2003c) place on a firm foundation the emerging standard model of cosmology: a flat adiabatic Λ-dominated CDM universe. However, the deficit of power in the CMB anisotropy spectrum on large angular scales (Bennett et al. 2003b; Hinshaw et al. 2003; Spergel et al. 2003) is surprising given that ΛCDM models predict an enhancement at $\ell \lesssim 10$ due to the late-time integrated Sachs-Wolfe (ISW) effect (Sachs & Wolfe 1967). The likelihood of observing so little power due to sample variance is only 0.15% (Spergel et al. 2003). Thus new physics may be indicated since the nature of the dark energy is poorly understood. Cross-correlating the CMB with radio sources provides a direct test for the recent acceleration predicted by the favored ΛCDM model and observed by the Type 1a supernovae experiments (Perlmutter et al. 1999; Riess et al. 1998). Thus, this test is an important check of the standard model.

Any recent acceleration of the universe will cause local gravitational potentials to decay. This decay is then imprinted on the CMB as the photons, which were blue-shifted on infall, suffer less of a red-shift as they climb out of the potential well. This produces temperature perturbations

$$\frac{\delta T(\hat{n})}{T_0} = -2 \int_0^{\eta_{\text{dec}}} d\eta \frac{d\Phi}{d\eta}(\eta \hat{n})$$

(1)

where $\Phi$ is the Newtonian gravitational potential, $\eta$ is conformal lookback time, and the integral runs from today ($\eta = 0$) to the CMB decoupling surface at $z_{\text{dec}} = 1089$. Figure 1 shows the recent evolution of $\Phi$ for a variety of cosmological models. Since $\Phi$ is related to the matter distribution via the Poisson equation, tracers of the mass will be correlated with the CMB through the late-ISW effect. In this paper we correlate the NRAO VLA Sky Survey (NVSS) source catalog (Condon et al. 1998) with the WMAP CMB map in search of the late-ISW effect. Boughn & Crittenden (2002) performed a similar analysis using the COBE/DMR map, and found no correlation. However, a recent re-analysis by the same authors using the WMAP data did see evidence for a correlation between the CMB, NVSS, and the hard X-ray background observed by the HEAO-1 satellite (Boughn & Crittenden 2003). Here we focus on the implications of this correlation for dark energy, specifically $\Omega_\Lambda$.

We take as our fiducial model the best fit power-law ΛCDM model to the combined WMAP, CBI, ACBAR, 2dFGRS, and Lyα data sets, with values $\omega_m = 0.133$, $\omega_b = 0.0226$, $n_s = 0.96$, $h = 0.72$, $A = 0.75$, and $\tau = 0.117$ (Spergel et al. 2003, Table 7). Cosmological parameters are drawn from this set unless otherwise noted.

In §2 we briefly describe the NVSS source catalog and its auto-correlation function. In §3 we describe the cross-correlation between the WMAP CMB map and the NVSS source map, and relate it to the late-ISW effect. We conclude in §4 and discuss effects which could mimic the observed signal.
2. The NVSS Source Catalog

The NRAO VLA Sky Survey (NVSS) is a 1.4 GHz continuum survey, covering the 82% of the sky with $\delta > -40^\circ$ (Condon et al. 1998). The source catalog contains over $1.8 \times 10^6$ sources, and is 50% complete at 2.5 mJy. Nearly all the sources away from the Galactic plane ($|b| > 2^\circ$) are extragalactic. The bright sources are predominantly AGN-powered radio galaxies and quasars, while at weaker fluxes the sources are increasingly nearby star-forming galaxies.

Galaxy counts are a potentially biased tracer of the underlying matter distribution, and thus the projected number density of NVSS sources per steradian, $n(z, \hat{n})$, is related to the matter distribution $\delta(z, \hat{n}) \equiv \delta \rho/\rho$ via

$$n(z, \hat{n}) \, dz \, d\Omega = \frac{dN}{dz} \left(1 + b_r(z) \delta(z, \hat{n})\right) \, dz \, d\Omega \quad (2)$$

where $dN/dz$ is the mean number of sources per steradian at a redshift $z$ and $b_r(z)$ is the radio galaxy bias parameter. Thus the observed fluctuation on the sky in projected source counts is given by

$$\delta N(\hat{n}) = \int dz \, b_r(z) \frac{dN}{dz} \delta(z, \hat{n}). \quad (3)$$

Since we are only interested in clustering on large scales, and hence the linear regime, the evolution of $\delta$ factors as $\delta(k, z) = D(z) \delta(k)$, where $\delta(k, z)$ is the Fourier transform of the matter distribution, $\delta(k) \equiv \delta(k, 0)$ its current value, and $D(z)$ is the linear growth factor (Peebles 1993, 5.111). While generally a function of time, we take the bias to be constant, as the determination of $dN/dz$ is uncertain and we only consider a modest redshift range ($0 < z < 2$).

While the individual NVSS source redshifts are unknown, for our purposes we need only the overall redshift distribution $dN/dz$ for the NVSS. We adopt the favored model of Dunlop & Peacock (1990) (model 1, MEAN-z data), which was found by Boughn & Crittenden (2002) to best reproduce the NVSS auto-correlation function. Like most models, it divides the sources by spectral index $\alpha$ (flux $S \propto \nu^{-\alpha}$) into two populations, flat-spectrum ($\alpha \approx 0$) and steep-spectrum ($\alpha \approx 0.8$) sources. The model is plotted in Figure 2. We limit the model to $0.01 < z < 5$; the lower limit corresponds to a distance of $\approx 42$ Mpc. The small peak at $z \approx 0.05$ is spurious (due to a breakdown in the DP90 fitting function), but has only a minor effect on the integrated predictions.

Given a cosmology, we can determine the radio bias $b_r$ from the amplitude of the NVSS auto-correlation function (ACF), by comparing the ACF to the unbiased prediction

$$C^{NN}(\theta) = \langle \delta N(\hat{n}) \delta N(\hat{n}') \rangle = \sum \frac{2l + 1}{4\pi} [b^N_l]^2 C^{NN}_l P_l(\hat{n} \cdot \hat{n}') \quad (4)$$

where $[b^N_l]^2$ is the pixel window function. Substituting equation (3) into this expression and Fourier transforming,

$$C^{NN}_l = 4\pi \int \frac{dk}{k} \Delta^2_\delta(k) \left[f^N_l(k)\right]^2 \quad (5)$$
where $\Delta_2^2(k) = k^3P_\delta(k)/2\pi^2$ is the logarithmic matter power spectrum and $P_\delta(k) = \langle |\delta(k)|^2 \rangle$. We use the WMAP normalization $\Delta_2^2(k_0) = 2.95 \times 10^{-9} A$ where $k_0 = 0.05~\text{Mpc}^{-1}$ (Verde et al. 2003), giving us $\delta_H = 6.1 \times 10^{-5}$ for our fiducial model. The filter function is given by

$$f_N^N(k) = b_r \int dz \frac{dN}{dz} D(z) j_l(k\eta).$$

(6)

where $j_l(x)$ is the spherical Bessel function. Note that the bias we measure is complicated by the uncertainty in $dN/dz$; errors in the normalization are absorbed into the bias.

To calculate the observed NVSS auto-correlation function (ACF), we made a HEALPix (Górski et al. 1998) resolution-5 map of $\delta N(\hat{n})$, which has 12,288 $1.8^\circ$ square pixels$^{10}$. As a precaution, we removed the $3 \times 10^5$ sources from the catalog which were resolved. The mean source count per pixel is 147.9, leading to a Poisson uncertainty of $\approx 8\%$. The ACF is estimated as

$$\hat{C}^{NN}(\theta_k) = \sum N_i N_j w_i^N w_j^N / \sum w_i^N w_j^N$$

(7)

where $N_i$ is the number of sources in pixel $i$ and the sum is over all pixel pairs separated by $\theta_k - \Delta\theta/2 < \theta < \theta_k + \Delta\theta/2$. The bin width $\Delta\theta$ is $2^\circ$. We mask out pixels at low Galactic latitude ($|b| < 10^\circ$) and those unobserved by the survey ($\delta < -37^\circ$); the weights $w_i^N$ are determined by the mask. The NVSS ACF is shown in Figure 2. The $\theta = 0^\circ$ bin is corrected for Poisson noise by subtracting the mean number of sources per pixel. For the fiducial model parameters (which are used to calculate $D(z)$ and $\eta(z)$), the derived bias is 1.7. This is somewhat higher than the value of 1.6 found by Boughn & Crittenden (2002). However, they assumed a scale-invariant spectrum (i.e., $n_s = 1$), and changing $n_s$ by $\pm 0.03$ changes the bias by $\mp 0.05$.

As noticed by Boughn & Crittenden (2002), the NVSS catalog mean source density varies with declination, introducing a spurious signal into the auto-correlation function. They corrected for this by adding and subtracting random sources from the map until the structure was removed. We considered two simple corrections; both broke the sources into $\sin(\delta)$ strips of width 0.1. The first method subtracted the mean from each strip; the second scaled each strip by the ratio of the global mean to the strip mean. Since the corrections are small, both produced similar results (Fig. 3).

### 3. WMAP–NVSS Cross-Correlation

Combining equation (1) and equation (3) we can calculate the expected cross-correlation spectrum between the NVSS catalog and the CMB:

$$C_l^{NT} = \langle a_l^N a_{lm}^{T*} \rangle = 4\pi \int \frac{dk}{k} \Delta_3^2(k) f^N_l(k) f^T_l(k)$$

(8)

$^{10}$For more information on HEALPix visit http://www.eso.org/science/healpix/. The resolution of a HEALPix map indicates its pixel count. A resolution-$r$ map has $12 N_{side}^2$ pixels, where $N_{side} = 2^r$. A resolution-$(r+1)$ map is created by dividing each resolution-$r$ pixel into four subpixels.
where $f^N_l$ and $f^T_l$ are the NVSS and ISW filter functions. The ISW filter function is derived analogously to the NVSS filter function. The local gravitational potential is related to the matter distribution via the Poisson equation $\nabla^2 \Phi = 4\pi G a^2 \rho_m \delta_m$, where the gradient is taken with respect to comoving coordinates. Fourier transforming, we have

$$\Phi(k, \eta) = -\frac{3}{2} \Omega_m (H_0/k)^2 g(\eta) \delta(k)$$

(9)

where $H_0$ is the Hubble constant, $\Omega_m H_0^2 = 8\pi G \rho_m^0 / 3$, and $g(\eta) \equiv D(\eta)/a(\eta)$ is the linear growth suppression factor. Thus

$$f^T_l(k) = 3\Omega_m (H_0/k)^2 \int d\eta \frac{dg}{d\eta} j_l(k\eta).$$

(10)

We use the fitting function for $g(\eta)$ provided by Carroll et al. (1992). In a flat $\Omega_m = 1$ universe, $g(\eta)$ is constant, and thus there is no ISW effect and hence no correlation between the CMB and the local matter distribution. In $\Lambda$CDM universes, $D(\eta)$ approaches a constant during $\Lambda$-domination, leading to a decay of $g(\eta)$ as time increases.

We computed the WMAP–NVSS cross-correlation function (CCF) as

$$\hat{C}^{NT}(\theta_k) = \sum N_i T_j w^N_i w^T_j / \sum w^N_i w^T_j$$

(11)

where $T_i$ is the CMB map, $N_j$ the NVSS map (described in the previous section), and the sums are over all pixel pairs separated by $\theta_k - \Delta \theta / 2 < \theta < \theta_k + \Delta \theta / 2$. The bin width $\Delta \theta$ is $2^\circ$. As before, we work at HEALPix resolution-5. Since we are working at large scales where the detector noise is negligible, we use the WMAP internal linear combination (ILC) map for the CMB (Bennett et al. 2003b). We limit residual foreground contamination by masking the map with the WMAP Kp0 galaxy mask and the WMAP source mask (Bennett et al. 2003a). The CMB weight $w^T_i$ is the number of unmasked resolution-9 subpixels of the resolution-5 pixel $i$. The CCF is plotted in Figure 3. The CCF is insensitive to the form of the NVSS declination correction.

Assessing the significance of the CCF is complicated by the high degree of correlation between points. Accidental alignments between the NVSS map and the CMB fluctuations at the decoupling surface (which are uncorrelated with those generated by the late-ISW) can produce spurious correlations. We quantified this uncertainty with Monte Carlo simulations, creating 500 realizations of the CMB sky drawn from the $C^{TT}_\ell$ power spectrum for our fiducial model with our estimate of the NVSS-correlated late-ISW contribution subtracted. The covariance matrix $\Sigma$ was calculated from the resulting CCFs, keeping the NVSS map fixed. Table 1 shows the $0^\circ < \theta < 20^\circ$ submatrix of $\Sigma$, showing that the CCF points are highly correlated. We define $\chi^2 = \delta C^{TT} \Sigma^{-1} \delta C$ where $\delta C = \hat{C}^{NT} - C^{NT}$ is the difference between observed (eq. [11]) and model (eq. [8]) correlation functions, and we limit $\theta < 20^\circ$. For the null model of no correlation ($C^{NT} = 0$), $\chi^2_0 = 17.2$. Since there are 10 degrees of freedom this is a $1.8\sigma$ deviation.

How does the measured CCF constrain $\Omega_\Lambda$? Rather than exploring the full parameter space, we assume a flat universe with fixed $\omega_b$ and explore the locus of values of $\Omega_m$ and $h$ consistent with
the measured location of the first acoustic peak of the CMB TT anisotropy power spectrum. The first peak position is set by the angular scale of the sound horizon at decoupling, \( \theta_A \), which Page et al. (2003) found to be \( \theta_A = 0.6^\circ \). Percival et al. (2002) showed that \( \theta_A \approx 0.85\Omega_{m}^{0.14}h^{0.48} \); this is the horizon angle degeneracy. The normalization \( A \) is varied to fix the amplitude of the first peak; from a fit to CMBFAST (Seljak & Zaldarriaga 1996) spectra we found \( A \propto \Omega_{m}^{0.248} \) along the horizon degeneracy. The results are shown in Figure 4. The difference in \( \chi^2 \) between models with \( \Omega_\Lambda = 0 \) (i.e., no correlation) and \( \Omega_\Lambda = 0.68 \) (the minimum, with \( \chi^2_{\text{min}} = 12.5 \)) is \( \Delta \chi^2 = 4.7 \). Since we are varying a single parameter, the significance is \( \sqrt{\Delta \chi^2} \); thus \( \Omega_\Lambda > 0 \) is preferred at the 2.2\( \sigma \) level.

The WMAP team imposed a prior on the Hubble constant, \( h > 0.5 \), in determining the cosmological parameters (Spergel et al. 2003). While lower values of the Hubble constant would contradict a host of other experiments, especially the Hubble Key Project (Freedman et al. 2001), models with very low \( h \) and \( \Omega_m \approx 1.3 \) are marginally consistent (\( \Delta \chi^2 = 4.9 \)) with the WMAP TT and TE angular power spectra. Since these universes are closed and matter dominated the growth factor \( D(a) \) grows faster than \( a \), and \( g(a) \) is better termed the linear growth enhancement factor. Thus we would expect to observe an anti-correlation between the NVSS and CMB maps, since \( \frac{dg}{d\eta} \) in equation (10) changes sign (see Figure 1). For \( \Omega_m = 1.28 \) and \( h = 0.33 \), \( \chi^2 = 24.2 \) (with a bias of 2.7). Based on the cross-correlation analysis alone, this model is disfavored by more than 3\( \sigma \).

4. Discussion

The recent acceleration of the universe due to dark energy should correlate large-scale CMB anisotropies with fluctuations in the local matter density through the late-time integrated Sachs-Wolfe effect. We have correlated the NVSS radio source catalog with the CMB anisotropies observed by the WMAP satellite, and find that \( \Omega_\Lambda > 0 \) is preferred at the 95\% confidence level (\( \Delta \chi^2 = 4.7 \)), considering statistical errors only. The statistical uncertainty is due to accidental alignments with the background primary anisotropies generated at decoupling. The likelihood peaks at \( \Omega_\Lambda = 0.68 \), consistent with the value derived from the CMB angular power spectrum.

The correlation between the NVSS source count and WMAP CMB maps appears robust. We interpret it as arising from the late-ISW, but other effects could correlate the two maps. For instance, obscuration by dust clouds tends to reduce the number of sources observed in their direction. We cross-correlated the NVSS map with the \( E(B-V) \) extinction map of Schlegel et al. (1998) and see evidence for a small negative correlation at separations \( \theta < 20^\circ \). However, since the extinction map is positively correlated with the CMB map due to dust emission, this effect has the wrong sign to mimic the late-ISW. The extinction correction is estimated as \( r_E(\theta) = \langle EN \rangle \langle ET \rangle / \langle EE \rangle \), where \( N, T, E \) are the NVSS, CMB, and extinction maps and \( \langle XY \rangle \) denotes the correlation between maps \( X \) and \( Y \) evaluated at separation \( \theta \). We find a value of \( r_E(0) \approx -4 \mu \text{K cnts} \) (compared to 22 \( \mu \text{K cnts} \) for the CCF) and the correction is negligible for \( \theta > 15^\circ \), except for a few
glitches when \langle EE \rangle crosses zero. Subtracting \( r_E \) from the CCF, we find the preferred value of \( \Omega_\Lambda \) increases to 0.76; at the minimum \( \chi^2_{\text{min}} = 14.8 \), and \( \Delta \chi^2 = 6.1 \).

A potentially more serious concern is that the correlation is due to microwave emission by the sources themselves. However, if this were the case then the CCF should have a similar angular profile as the auto-correlation function (ACF). Yet while the ACF falls steeply with increasing separation \( [\hat{C}^{NN}(0^\circ)/\hat{C}^{NN}(3^\circ) \sim 5] \), the CCF does not \( [\hat{C}^{NT}(0^\circ)/\hat{C}^{NT}(3^\circ) \sim 1] \). The lack of an enhanced signal in the zero lag CCF bin thus argues against any significant microwave emission from the NVSS radio sources.

We are indebted to Steve Boughn for significant and helpful discussions throughout the preparation of this paper. We also thank Hiranya Peiris and Licia Verde for useful comments. The WMAP mission is made possible by the support of the Office of Space Sciences at NASA Headquarters and by the hard and capable work of scores of scientists, engineers, technicians, machinists, data analysts, budget analysts, managers, administrative staff, and reviewers.

Note. — The correlation matrix $\Sigma$ of the WMAP–NVSS cross-correlation function due to accidental alignments with the anisotropies produced at decoupling. Units are $(\mu\text{K cnts})^2$. 
Fig. 1.— The gravitational potential $\Phi$ as a function of redshift $z$ for a variety of cosmological models. The models are normalized to unity at $z = 0$. 

$\Omega_m = 0.27, \Lambda = 0.73$

$\Omega_m = 0.775, \Lambda = 0.365$

$\Omega_m = 1.28, \Lambda = 0$
Fig. 2.— The adopted $dN/dz$ model (RLF1) for the distribution of NVSS sources from Dunlop & Peacock (1990, DP90), normalized to integrate to unity (left panel). The small blip at $z \approx 0.05$ is spurious, due to breakdown in the DP90 fitting function. Also plotted is the “luminosity/density evolution” (LDE) model also from DP90, which is a poor fit to the observed auto-correlation function (right panel).
Fig. 3.— The WMAP–NVSS cross-correlation function (CCF). The CCF is insensitive to the details of the declination correction. Two simple methods are compared; both broke the sources into \( \sin(\delta) \) strips of width 0.1. The first (diamonds) subtracted the mean from each strip. The second (triangles) scaled each strip by the ratio of the global mean to the strip mean. The cross points are uncorrected, showing the correction is only important for \( \theta \gg 25 \). We used the WMAP internal linear combination (ILC) CMB map; substituting the map of Tegmark et al. (2003) instead produces the same results (square points). The solid and dashed lines are derived from the diagonal elements of the correlation matrix due to accidental alignments; they would be the 1\( \sigma \) and 2\( \sigma \) contours in the absence of off-diagonal correlations. The points, however, are highly correlated as shown in Table 1.
Fig. 4.— Effect of varying ΩΛ on the cross-correlation function. In all panels we assume a flat universe with fixed ωb, and trade off between ΩΛ and h by keeping the combination Ωmh^3 constant; when ΩΛ = 0, h = 0.48. Panel (a) shows the inferred radio bias as a function of ΩΛ. Panel (b) shows the bias-corrected NVSS auto-correlation function (ACF) compared with the measured ACF. Panel (c) shows the predicted cross-correlation function (CCF) for a range of values of ΩΛ, compared with the measured CCF (diamonds). The amplitude of the predicted CCF is proportional to ΩΛ, which is stepped in increments of 0.1 from 0.0 to 0.9. Panel (d) shows the χ^2 of the model CCF as a function of ΩΛ. The χ^2 was computed using the first 10 points of the CCF (0° < θ < 20°) and Table 1. The minimum χ^2 is 12.5 at ΩΛ = 0.68; at ΩΛ = 0, χ_0^2 = 17.2. The dashed line is the likelihood ∝ exp(−χ^2/2). The 1σ limits are 0.42 < ΩΛ < 0.86.
