(Dated: August 25, 2014)

When Dirac electrons on the surface of a topological insulator are gapped, the resulting quantum anomalous Hall effect leads to universal magneto-optical Faraday and Kerr effects in the low frequency limit. However, at higher frequencies different excitations can leave their own fingerprints on the magneto-optics and can therefore be probed. In particular, we investigate the role of localized in-gap states—which inevitably appear in the presence of charged impurities—on these higher frequency magneto-optical effects. We have shown that these states resonantly contribute to the Hall conductivity and are magneto-optically active. These in-gap states lead to peculiar resonant signatures in the frequency dependence of the Faraday and Kerr angles, distinct in character to the contribution of in-gap excitonic states, and can be probed in ellipsometry measurements.

I. INTRODUCTION

Topological insulators (TIs) represent a new class of solids whose band structure can be characterized by a topological invariant As with normal “non-topological” insulators, their bulk has a filled valence band with an empty conduction band separated by a gap. But unlike usual insulators, TIs have very unconventional, symmetry-protected surface states. Interest in TIs has grown considerably since the discovery of two-dimensional (HgTe) and subsequently three-dimensional TIs (Bi₂Se₃, Bi₂Te₃ and other Bismuth based materials). The surface states of three-dimensional TIs are described by a Dirac equation for massless particles, but unlike two-dimensional systems like graphene, there is only one Dirac “cone” (in general, an odd number) – something that can only be realized experimentally like graphene, there is only one Dirac “cone” (in general, an odd number) – something that can only be realized experimentally. As with normal “non-topological” insulators, their bulk has a filled valence band with an empty conduction band separated by a gap. But unlike usual insulators, TIs have very unconventional, symmetry-protected surface states. Interest in TIs has grown considerably since the discovery of two-dimensional (HgTe) and subsequently three-dimensional TIs (Bi₂Se₃, Bi₂Te₃ and other Bismuth based materials). The surface states of three-dimensional TIs are described by a Dirac equation for massless particles, but unlike two-dimensional systems like graphene, there is only one Dirac “cone” (in general, an odd number) – something that can only be realized experimentally like graphene, there is only one Dirac “cone” (in general, an odd number) – something that can only be realized experimentally.

Thus, the surface of a TI is a veritable experimental and theoretical playground for many interesting phenomena including but not limited to both topological superconductivity, which gives rise to exotic Majorana fermions (these could potentially be used as building blocks for quantum computation, and the anomalous half-integer quantum Hall effect (AQHE) (See also Refs. 16 and 17 for a review).

The AQHE occurs when time-reversal symmetry is broken, opening up a gap in the Dirac surface states. Without external magnetic field, this effect can be realized by an exchange field that couples to the spins of the electrons on the surface. The exchange field can be induced either by the proximity effect with an insulating ferromagnet or by the ordering of magnetic impurities introduced to the bulk or surface of a TI. Recently, both methods of inducing an exchange field have been realized experimentally and the AQHE has been experimentally confirmed by transport measurements.

The AQHE is the origin of “image monopole effect” for an electron in the vicinity of a TI surface as well as reflectionless chiral electronic states localized on domain walls which separate regions with the opposite exchange field.

Another way to probe the AQHE is with the magneto-optical Faraday and Kerr effects where the polarization of the transmitted and reflected electromagnetic waves rotates relative to the wave incident on the TI's surface. At low frequencies—when dispersion effects can be neglected—the optics of the TI nanostructures can described macroscopically with an additional axionic term in the Lagrangian \( \Delta L_{\text{AE}} \), which is insensitive to microscopical details and given by

\[
\Delta L_{\text{AE}} = \theta \frac{e^2}{2\pi\hbar} \int d^3r \, \mathbf{E} \cdot \mathbf{B}.
\]

Here \( \theta = 0 \) for ordinary insulators and \( \theta = \pi \) for topological ones. Moreover for thin film TIs, the Faraday angle \( \vartheta_F = \alpha_0 \) and Kerr angle \( \vartheta_K = 1/\alpha_0 \) are predicted to be universal and depend only on the fine structure constant \( \alpha_0 = e^2/\hbar c \approx 1/137 \).

The theoretical investigation of the Faraday and Kerr effect beyond the low frequency regime is important not only because real optical experiments occur at finite frequency but also because single-particle and collective excitations on the surface of TI start to leave their own fingerprint on optical quantities. Particularly, chiral excitons, collective in-gap excitations in the gapped Dirac electron liquid, reveal their chiral nature by prominent resonances seen in the frequency dependence of the Faraday and Kerr angles. Here we consider other in-gap excitations, localized electronic states, which are present due to inevitable impurities occurring in the TI bulk or on its surface. In ordinary semiconductors and semicon-
FIG. 1. (Color online) Here we plot the optical Hall conductivity in units of half the gap (2\(\Delta\) is the magnetically induced gap) taking into account both the effect of localized impurity states (the subject of this paper) and chiral excitons – which can be clearly distinguished – and compare it to the pure, noninteracting optical conductivities (dashed line). The chemical potential is at \(\mu = -\Delta\) and there is a density \(N/S = 0.635a_0^{-2}\) (see Eq. (8)) of Coulomb impurity states with dimensionless coupling to electrons of \(\alpha = 0.3\). The exciton contribution is calculated with dimensionless Coulomb coupling between electron and holes of \(\alpha_c = e^2/\epsilon_0\hbar v_F\). The in-plane component can be gauged by the exchange field – leading to a nonzero magneto-optically active and lead to peculiar resonant states on the magnetically gapped surface of TI are analyzed in Sec. IV, and we conclude with some discussion and a brief summary in Sec. V.

II. LOCALIZED IN-GAP STATES

The single-particle Hamiltonian for Dirac electrons interacting with charged impurities scattered over the surface of a TI is given by

\[
H_0 = v_F |\mathbf{p} \times \mathbf{\sigma}|_z + \Delta \sigma_z - \sum_i \frac{Z_i e^2}{4\pi |\mathbf{r} - \mathbf{r}_i|}. \tag{2}
\]

Here \(\mathbf{p}\) is the momentum operator; \(\mathbf{\sigma}\) is the vector of Pauli matrices with components \(\sigma_i\); \(v_F\) is Fermi velocity of Dirac electrons; \(\mathbf{r}_i\) is position of \(i\)th impurity and \(Z_i\) is its charge; \(\epsilon\) is the effective dielectric permittivity on the surface of the TI. And \(\Delta\) parametrizes the out-of-plane component of exchange field which gaps the surface spectrum. In the absence of impurities the spectrum is 

\[
\epsilon_p = \pm\sqrt{(v_F p)^2 + \Delta^2} (+ \text{ for the conduction band; } - \text{ for the valence band; separated by a gap } 2|\Delta|). \tag{3}
\]

The wave functions of Dirac states can be presented as \(|\mathbf{p}\pm\rangle = e^{i\mathbf{p}\cdot\mathbf{r}/\hbar} |\varphi_{\mathbf{p}\pm}\rangle\), where the spinor part is given by

\[
|\varphi_{\mathbf{p}\pm}\rangle = \frac{1}{\sqrt{2\varphi_p(\epsilon_\uparrow + \Delta\pm \epsilon_p)}} \left( \begin{pmatrix} \alpha_\uparrow \\
\alpha_\downarrow \end{pmatrix} \right)^{(\Delta\pm \epsilon_p)/i\hbar v_F}\tag{4}
\]

with \(\theta_{\mathbf{p}}\) is the polar angle of the wave vector \(\mathbf{p}\).

If impurities are dilute enough—the case we consider below—they can be considered independently. The dimensionless effective structure constant \(\alpha = Ze^2/h\sqrt{\hbar v_F\epsilon}\) measures their coupling to Dirac states. Further, we assume positively charged impurities \(\alpha > 0\) and generalization to \(\alpha < 0\) is straightforward. Each Coulomb impurity creates numerous localized states with energies labeled by the radial quantum number \(n = 0, 1, 2, \ldots\) and total angular momentum quantum number \(j = \pm 1/2, \pm 3/2, \ldots\)

\[
\epsilon_{n_j} = \frac{\Delta(n + \gamma)}{\sqrt{(n + \gamma)^2 + \alpha^2}}, \tag{5}
\]

where \(\gamma = \sqrt{\frac{\alpha^2}{\Delta^2} - 1}\). The wave functions of the localized states take the form

\[
|\Psi_{n_j}\rangle = \frac{1}{\sqrt{2\pi}} \left( \begin{pmatrix} F_{n_j}^+(r)e^{i(j-1/2)\theta_r} \\
F_{n_j}^-(r)e^{i(j+1/2)\theta_r} \end{pmatrix} \right), \tag{6}
\]

where \(\theta_r\) is polar angle in the real space and functions \(F_{n_j}^\pm(r)\) are given by

\[
F_{n_j}^\pm(r) = \frac{(-1)^n \lambda^{3/2}}{\Delta\Gamma(1 + 2\gamma)} \sqrt{\frac{\Gamma(1 + 2\gamma + n)(\Delta \pm \epsilon_{n_j})}{(\Delta\alpha/\lambda)\alpha n!}} \times (2\alpha r)^{-1/2} e^{-\lambda r/2} [F(-n, 1 + 2\gamma; 2\alpha r) + \hbar v_F n F(1 - n, 1 + 2\gamma; 2\alpha r)]. \tag{7}
\]

where \(\lambda = \sqrt{\frac{\Delta^2 - \epsilon_{n_j}^2}{\hbar v_F}}\) and \(F(a, b; z) = 1 + \frac{a}{b} z + \frac{a(a+1)}{b(b+1)}\frac{z^2}{2!} + \ldots\) is the confluent hypergeometric function.
FIG. 2. (Color online) Energies of the first six states localized on a charged impurity. The vertical line represents the $\alpha$ we consider for our numerical results.

It should be noted that the state with the lowest energy (which we refer to as the “lowest state”) to differentiate it from the many-body ground state) is well separated from excited states which lay in the continuum of delocalized electronic states as seen in Fig. 2. Thus, we focus on the lowest state with energy $\epsilon_0 = \epsilon_{0.12} = \Delta \sqrt{1 - 4\alpha^2}$ and wave functions given by Eq. (5) with $j = 1/2$ and

$$F_{1/2}^\pm(r) = \frac{2\alpha}{h\nu_F} \sqrt{\frac{2\Delta(\Delta \pm \epsilon_0)}{\Gamma(1 + 2\gamma)}} \left( \frac{4\alpha}{h\nu_F} \right)^{\gamma - 1/2} e^{-2\alpha \frac{\Delta r}{2\nu_F}},$$

with a effective radius

$$a_0 = \sqrt{\langle r^2 \rangle} = \frac{h\nu_F}{\Delta} \sqrt{3 - 4\alpha^2 + 3\sqrt{1 - 4\alpha^2}}$$

$$\sim \sqrt{\frac{3}{8} \frac{h\nu_F}{\Delta} \frac{1}{\alpha} + O(\alpha)}.$$  \hfill (9)

For $\alpha \geq 0.5$, the $j = 1/2$ bound states become unstable and classically these bound electrons collapse into the “nucleus”; this has been extensively discussed in the case of Dirac fermions in graphene.\cite{BES09}

We are interested in the resonant contribution of the localized states, so we approximate the delocalized scattering states by the nonperturbed delocalized ones as written in Eq. (3).\cite{BES09}

\section{III. OPTICAL CONDUCTIVITIES}

The electromagnetic response on the surface of a TI is described by the optical conductivity tensor. For non-interacting electrons, this tensor can be written in the Kubo-Greenwood formulation as

$$\sigma_{\mu\nu}(\omega) = \frac{\hbar e^2}{i\mathcal{S}} \sum_{\alpha_\beta} f_\alpha - f_\beta \frac{\langle \alpha | j_\mu | \beta \rangle \langle \beta | j_\nu | \alpha \rangle}{\hbar \omega + \epsilon_\alpha - \epsilon_\beta + i\delta}.$$  \hfill (10)

Here $\omega$ is the frequency of the incident electromagnetic wave, $S$ is the surface area, and $j = v_F [\sigma \times \mathbf{z}]$ is the single-particle current operator. The sum is over all single-particle states $\alpha$, including valence band, conduction band, and localized states with their corresponding energies $\epsilon_\alpha$ and occupation numbers $f_\alpha$. The conductivity can be broken up into transitions between (1) surface bands, denoted by $\sigma^{\text{cv}}$, (2) a surface band and the localized states, denoted by $\sigma^{\text{imp}}$, and (3) localized states, denoted by $\sigma^{\text{imp-imp}}$. One can separate each of these contributions to the conductivity tensor as $\sigma = \sigma^{\text{cv}} + \sigma^{\text{imp}} + \sigma^{\text{imp-imp}}$. In this paper, the impurities contribute independently; this works well when the sample is dilute enough, i.e. given $N$ impurities, $(N/S)a_0^2 \ll 1$.

The contribution between bands can be presented as

$$\sigma_{\mu\nu}^{\text{cv}}(\omega) = -i\hbar e^2 \sum_{\mu_\gamma,\nu_\gamma} \frac{f_{\mu,\gamma} - f_{\mu,\gamma'}}{\omega - \epsilon_{\mu,\gamma} + \epsilon_{\mu,\gamma'} + i\delta} \left[ \langle \varphi_{\mu,\gamma} | j_\mu | \varphi_{\mu,\gamma'} \rangle \langle \varphi_{\mu',\gamma'} | j_\nu | \varphi_{\mu',\gamma} \rangle \right].$$  \hfill (11)

This quantity was evaluated previously and is given by\cite{JAD93}

$$\text{Re}[\sigma_{\mu\nu}^{\text{cv}}(\omega)] = \frac{e^2}{h} \left[ 1 + \left( \frac{2\Delta}{\hbar \omega} \right)^2 \right] \Theta(h\omega - 2|\mu|),$$

$$\text{Im}[\sigma_{\mu\nu}^{\text{cv}}(\omega)] = \frac{e^2 \Delta}{4\hbar} \log \left( \frac{h\omega - 2|\mu|}{h\omega + 2|\mu|} \right),$$

assuming $|\mu| \geq \Delta$ (if $|\mu| < \Delta$, let $\mu \to \Delta$ in these expressions).

The localized states on the Coulomb impurity are labeled by $\lambda = (r, n, j)$, and their matrix elements can be presented in the following form

$$\langle \mathbf{p} | j_\mu | \lambda \rangle = \int d^2x \langle \varphi_{\mathbf{p} \pm} | j_\mu | \Psi_{\mathbf{k} - \mathbf{r}, n, j} \rangle \frac{e^{i\mathbf{p} \cdot \mathbf{r}}}{\hbar}$$

$$= e^{i\mathbf{p} \cdot \mathbf{r}} \langle \varphi_{\mathbf{p} \pm} | j_\mu | \Psi_{\mathbf{p}, n, j} \rangle,$$

where $|\Psi_{\mathbf{p}, n, j} \rangle$ is the Fourier transform of $|\Psi_{\mathbf{k}, n, j} \rangle$. The expression for $\sigma_{\mu\nu}^{\text{imp}}$ can be further split

$$\sigma_{\mu\nu}^{\text{imp}} = \sigma_{\mu\nu}^{\text{imp}+} + \sigma_{\mu\nu}^{\text{imp}-}.$$  \hfill (18)

Here $\sigma_{\mu\nu}^{\text{imp}+}$ ($\sigma_{\mu\nu}^{\text{imp}-}$) denotes the contribution due to excitations from localized states to the conduction band (from valence band to localized states), which is nonzero if the localized state is filled (empty). They can be both be presented in the form

$$\sigma_{\mu\nu}^{\text{imp}+} = \frac{N\hbar e^2}{i\mathcal{S}} \sum_{\mathbf{p} \lambda} \sum_{\mathbf{p} \pm} \frac{f_{\mathbf{p} \pm} - f_{\mathbf{p} \pm}}{\epsilon_{\mathbf{p} \pm} + i\delta} \left[ \frac{\langle \mathbf{p} | j_\mu | \mathbf{p} \pm \rangle}{h\omega + \epsilon_{\mathbf{p}} + i\delta} + \frac{\langle \mathbf{p} \pm | j_\mu | \mathbf{p} \rangle}{h\omega + \epsilon_{\mathbf{p}} + i\delta} \right].$$  \hfill (19)
Here we have summed over all Coulomb impurities. The phase factor in Eq. (17) depends on the position of the impurity and is canceled in the product of matrix elements in Eq. (19). Integrating the matrix elements over the angle of $\mathbf{p}$ and changing variables from $p$ to $\epsilon_p \equiv \epsilon$, while taking into account the occupation of the bands, we obtain

$$
\sigma_{xx}^{\text{imp}}(\epsilon) = \frac{i N \hbar e^2}{S} \sum_{\epsilon \leq \mu} \int_{\max(|\mu|, \Delta)}^{\infty} \frac{d \epsilon}{(2\pi \hbar v_F)^2} \frac{\epsilon de}{\epsilon + \epsilon_\lambda} 
$$

$$
\sigma_{xy}^{\text{imp}}(\epsilon) = \frac{N \hbar e^2}{S} \sum_{\epsilon \leq \mu} \int_{\max(|\mu|, \Delta)}^{\infty} \frac{d \epsilon}{(2\pi \hbar v_F)^2} \frac{\epsilon de}{\epsilon + \epsilon_\lambda} 
$$

$$
\times \left[ \frac{1}{\hbar \omega + \epsilon - \epsilon_\lambda + i\delta} + \frac{1}{\hbar \omega + \epsilon + i\delta} \right],
$$

where

$$
M_{xx}^{\lambda \pm}(\epsilon) = \int_0^{2\pi} d\theta_p |\langle \mathbf{p} \pm |j_\lambda \rangle|^2,
$$

$$
M_{xy}^{\lambda \pm}(\epsilon) = i \int_0^{2\pi} d\theta_p \langle \mathbf{p} \pm |j_\epsilon \rangle \langle \lambda |j_\lambda |\mathbf{p} \pm \rangle,
$$

and used the fact that these are real functions.

To evaluate these, we use Eq. (17). In position space, the bound state $|\lambda\rangle$ is of the form shown in Eq. (5) (centered around $r_j$), so the Fourier transform takes the corresponding form

$$
|\Psi_p;j_\lambda\rangle = \sqrt{2\pi} \left( \hat{F}^{+}_{nj}(p)e^{i\delta_p(j-1/2)} + \hat{F}^{-}_{nj}(p)e^{i\delta_p(j+1/2)} \right)
$$

where $\hat{F}^{\pm}_{nj}(p) = \int_0^{\infty} dr r \hat{F}^{\pm}_{nj}(r)J_{\frac{1}{2}}(pr/\hbar)$ are Hankel transforms of their real-space counterparts (which can be analytically evaluated given Eq. (7)).

In terms of these objects, we can evaluate the integrated matrix elements

$$
M_{xx}^{\lambda \pm}(\epsilon) = \frac{(2\pi v_F)^2}{2\epsilon} \left[ (\epsilon - \Delta)|\hat{F}^{+}_{nj}(p)|^2 + (\epsilon + \Delta)|\hat{F}^{-}_{nj}(p)|^2 \right]
$$

$$
M_{xy}^{\lambda \pm}(\epsilon) = \frac{(2\pi v_F)^2}{2\epsilon} \left[ (\epsilon - \Delta)|\hat{F}^{+}_{nj}(p)|^2 - (\epsilon + \Delta)|\hat{F}^{-}_{nj}(p)|^2 \right]
$$

with $p = \sqrt{\epsilon^2 - \Delta^2}/v_F$.

Considering just the lowest state with $n = 0$ and $j = 1/2$ (labeled with $\lambda = 0$), we obtain

$$
M_{xx}^{\pm}(\epsilon) + M_{xy}^{\pm}(\epsilon) = \frac{2^\gamma(2\pi v_F)^2}{4\alpha^2} \left( \frac{\hbar v_F}{\Delta} \right)^2 \frac{\Gamma(\gamma + 3/2)}{\Gamma(2\gamma + 1)} \frac{2}{\epsilon^\Delta} 2\text{F}1(2\gamma + 1/2, a \epsilon; \epsilon^\Delta \Delta^2)\epsilon^\Delta \Delta^2)
$$

$$
M_{xx}^{\pm}(\epsilon) - M_{xy}^{\pm}(\epsilon) = \frac{2^\gamma(2\pi v_F)^2}{64\alpha^4} \left( \frac{\hbar v_F}{\Delta} \right)^2 \frac{\Gamma(\gamma + 3/2)}{\Gamma(2\gamma + 1)} \frac{2}{\epsilon^\Delta} 2\text{F}1(\gamma + 2, a \epsilon; \epsilon^\Delta \Delta^2)\epsilon^\Delta \Delta^2)
$$

where $a = (2\gamma + 3)/4$ and $2\text{F}1(a; b; c; x) = 1 + ab x + \frac{a(a+1)b(b+1)
}{c(c+1)} x^2 + \cdots$.

If two bound states are at different positions, then by our diluteness assumption (insignificant wave function overlap) transitions between them will not contribute to the conductivity significantly. However, if the chemical potential is in between two bound states that live at the same position (e.g., the ground and excited states of a single impurity), then transitions between those states can contribute to the conductivity; this contribution is given by

$$
\sigma_{xx}^{\text{imp-imp}} = \frac{N \hbar e^2}{iS} \sum_{\epsilon_{m,j} \leq \mu} \sum_{\epsilon_{m,j'} \geq \mu} \frac{(\Phi_{m,j}^{n})^2 \delta_{j+1,j'} + (\Phi_{m,j'}^{n})^2 \delta_{j,j'+1}}{\epsilon_{m,j} - \epsilon_{m,j'}}
$$

$$
\times \left[ \frac{1}{\hbar \omega + \epsilon_{m,j} - \epsilon_{m,j'} + i\delta} + \frac{1}{\hbar \omega + \epsilon_{m,j'} - \epsilon_{m,j} + i\delta} \right],
$$

\( \text{(30)} \)
and

\[
\sigma_{xy}^{\text{imp-imp}} = N \frac{\hbar e^2}{g} \sum_{\epsilon_{n_j} < \mu} \frac{(\Phi_{m_j}^{n_j})^2 \delta_{j, j'} - (\Phi_{m_j}^{n_j})^2 \delta_{j, j'})}{\epsilon_{n_j} - \epsilon_{m_j'}} \times \left[ \frac{1}{\hbar \omega + \epsilon_{n_j} - \epsilon_{m_j'} + i \delta} - \frac{1}{\hbar \omega + \epsilon_{m_j'} - \epsilon_{n_j} + i \delta} \right],
\]

where we have defined

\[
\Phi_{m_j}^{n_j} \equiv v_F^2 \int_0^\infty r dr F_{m_j'}^{n_j}(r) F_{n_j}(r).
\]

The integral in Eq. (32) can be calculated analytically for the functions given in Eq. (9); the result is in terms of Appell hypergeometric functions and can be calculated with the use of an integral identity. Notice that transitions can only occur between states that only differ by a quantum of angular momentum as expected from the form of the single-particle current operator. For our calculations we do not consider these transitions since the higher excited states merge with the continuum - leading to at most a decreasing and smoothing of the threshold.

For the calculation of the frequency dependent conductivities shown in Fig. 3, we use the dimensionless parameters \(\alpha = 0.3\), \((N/S) a_0^2 = 0.035\). Also, we use four values of the chemical potential corresponding to four different occupation situations, illustrated in Fig. 3a. In-gap states correspond to resonance features in Figs. 3b and 3c which are well below the threshold of \(2\max(\Delta, |\mu|)\). If the in-gap states are empty, an additional peak appears at \(\epsilon_0 + \max\{\Delta, |\mu|\}\). If they are occupied, it appears at frequency \(\max\{\Delta, |\mu|\} - \epsilon_0\). The shape of the resonance weakly depends on the value of chemical potential and its height disappears at \(|\mu|/\Delta| \gg 1\). Thus, the main role of the chemical potential, if it is outside the gap, is shifting of resonant frequencies, and in the next section on the magneto-optical effects of a topological insulator film, we exclusively consider the chemical potential to be situated inside the gap.

It should be noted that in the above calculation we neglected the Drude contribution, which appears if the chemical potential lies outside the gap. The Drude contribution dominates transport but it is not as important for the optical conductivity at frequencies \(\omega \gg 1/r\). We further assume that we have only one localized state: the lowest bound state in Eq. (7). The excited in-gap states violate diluteness criterion: electrons can hop between these states due to significant wave function overlap; hence, these states will merge with continuum of delocalized states.

\section{IV. FARADAY AND KERR EFFECTS}

We consider the Faraday and Kerr effects at normal incidence and in a thin film geometry. These conditions correspond to resonance features in Figs. 3b and 3c which are well below the threshold of \(2\max(\Delta, |\mu|)\). When electromagnetic waves excite electrons from the valence to the conduction band, the lower frequency features occur when electromagnetic waves excite electrons from the valence to the bound states \((\mu \leq -\Delta)\) or when electromagnetic waves excite electrons from the bound state to the conduction band \((\mu \geq \Delta)\).
are the most favorable for observing the effects of surface states on the optics. While the Faraday and Kerr effects are quite insensitive to oblique incidence, they considerably decrease (especially the Kerr effect) in the presence of a mismatch of dielectric constants on the TI film surfaces and due to longitudinal conductivity. This mismatch can be neglected only if the film thickness is considerably smaller than optical wavelength in it, \(d \ll \lambda/\epsilon_{\text{TI}}\). In real samples, the bulk contributes considerably to the longitudinal conductivity, which could be reduced in TI films. Further, we assume that the direction of the exchange field (sign of \(\Delta\)) is the same on each surface of the TI; in the opposite case, the effects of both plates on the optics cancel one another.

In experiments, the incident wave is usually linearly polarized \(\mathbf{E} = E_0 \hat{\mathbf{x}}\). For calculational purposes, it is convenient to present the incident wave as combination of two circularly polarized waves and calculate their reflection \(r_{\pm} = |r_{\pm}| e^{i\Phi_{\pm}}\) and transmission \(t_{\pm} = |t_{\pm}| e^{i\Phi_{\pm}}\) amplitudes. In this basis, the reflected and transmitted waves are respectively \(\mathbf{E}_r = E_0 (r_+ e_+ + r_- e_-)\) and \(\mathbf{E}_t = E_0 (t_+ e_+ + t_- e_-)\) where \(e_{\pm} = \hat{x} \pm i \hat{y}\) represent the two directions of circular polarization. The transmittance through the film is given by \(T = (|t_+|^2 + |t_-|^2)/2\); the transmitted wave’s polarization rotates through an angle \(\Phi_t = (\Phi_+ - \Phi_-)/2\) (the Faraday angle) and has ellipticity \(\Phi_e = (|t_+| - |t_-|)/(|t_+| + |t_-|)\); and the reflected wave’s polarization rotates through an angle \(\Phi_k = (\Phi_+ - \Phi_-)/2\) (the Kerr angle) and has ellipticity \(\Phi_{ke} = (|r_+| - |r_-|)/(|r_+| + |r_-|)\).

The amplitudes of the reflected and transmitted waves can be found from Maxwell’s equation taking into account the electric currents excited by the incident electromagnetic wave. They are given by

\[
t_{\pm} = \frac{e^2/\hbar}{\epsilon^2/\hbar + \alpha_0 \sigma_{\text{tot}}/\hbar}, \quad r_{\pm} = -\frac{\alpha_0 \sigma_{\text{tot}}^{\text{tot}}}{e^2/\hbar + \alpha_0 \sigma_{\text{tot}}^{\text{tot}}}, \tag{33}
\]

where \(\sigma_{\text{tot}}^{\text{tot}} = \sigma_{xx}^{\text{tot}} \pm i \sigma_{xy}^{\text{tot}}\), \(e^2/\hbar\) is the quantum of conductance, and \(\alpha_0 \approx 1/137\) is the fine structure constant. Additionally, both sides of the thin film contribute to the optical conductivity, so \(\sigma_{\text{tot}}^{\text{tot}} = 2\sigma_{\text{tot}}\). If we expand in the fine structure constant, we have \(\Phi_t \sim 2\alpha \text{Re} \sigma_{xy}/(e^2/\hbar), \delta_{\text{K}} \sim 2\alpha \text{Im} \sigma_{xy}/(e^2/\hbar),\) and \(T \sim 1 - 4\alpha \text{Re} \sigma_{xx}/(e^2/\hbar)\). Thus, these quantities track the respective optical conductivities quite well.

For the numerical calculations, we have used the following parameters, in addition to the dimensionless parameters taken previously \((\alpha = 0.3\) and \((N/S) a_0^2 = 0.035\)), we take the parameters for Bi$_2$Se$_3$ for the gap to be the maximum achievable by magnetic doping: \(\Delta = 25\) meV and Fermi velocity \(v_F = 6.2 \times 10^5\) m/s. With these numbers, our density is \(N/S = 38 \mu\text{m}^{-2}\) and \(a_0 = 30\) nm. It should be noted that \(N/S\) is not the total concentration of impurities, but the concentration of impurity states with a definite energy \(e_0\) inside the gap. The generalization to the realistic case is discussed in the Conclusions.

The dependence of transmittance on frequency is presented in Fig. 4. As one can easily see, the in-gap states lead to absorption below the threshold (i.e. when \(\hbar \omega > 2|\mu|\)), but it is small, not impeding the observation of transmission. The decrease can be understood from the relation of the longitudinal conductivity to transmission, and hence why even magneto-optically inactive states affect transmission.

The Faraday and Kerr angles’ dependence on frequency is presented in Figs. 5a and 5c respectively. As with transmittance, the largest feature is at the threshold. Since the Faraday angle strongly depends on the real part of the Hall conductivity, we see that it matches it and has a similar resonant structure. The Kerr angle is more sensitive to the real part of the longitudinal conductivity though and we see corresponding features at these points — decreasing the Kerr angle from its large \(90^\circ\) rotation at zero frequency when the frequency is on resonance with the localized state. In both cases, the effect due to impurities is similar in nature to the resonant feature at threshold \(\omega = 2\Delta\).

Lastly, we show the frequency dependence of ellipticities of transmitted and reflected waves in Figs. 5b and 5d respectively. Again, we see features when the incident electromagnetic wave is on resonance with the impurity state. The ellipticity of the transmitted wave follows the imaginary part of the Hall conductivity, and the reflected wave again is quite sensitive to resonant effects. Thus, in-gap states can be probed effectively with ellipsometry.

V. CONCLUSIONS

We have shown that in-gap localized states dominate both the absorption and magneto-optics for TI films with magnetically gapped surfaces. In particular, they lead to peculiar resonances in the frequency dependencies of the Faraday and Kerr effects. In ordinary semiconductors...
in-gap states dominate absorption but they are not optically active unless time-reversal symmetry is externally broken, for example, by magnetic field. In the system considered in this paper, the surface spectrum does not respect time-reversal symmetry due to the gap induced by exchange field. Hence, we can conclude that the effect we observe is insensitive to details such as electron-hole asymmetry, hexagonal corrections to the Dirac spectrum, or to the profile of impurity potential which we assumed to be the Coulomb potential. We also assumed that all Coulomb impurities have the same charge and are located on the surface of TI; they can also be in the bulk of the TI, and their coupling to the electronic Dirac states will depend on their distance to the surface. If they are dilute enough, they will also contribute to the optical conductivity, which can be represented as

$$\sigma_{\mu
u}^{\text{imp}}(\omega) = \int_{-|\Delta|}^{|\Delta|} d\epsilon_0 P(\epsilon_0) \sigma_{\mu
u}^{\text{imp}}(\omega, \epsilon_0),$$  \hspace{1cm} (34)$$

where $\sigma_{\mu
u}^{\text{imp}}(\omega, \epsilon_0)$ is the contribution of a single impurity bound state with energy $\epsilon_0$ and $P(\epsilon_0)$ is concentration of the corresponding states. The finite distribution of levels, originating from different coupling of impurities with Dirac states, can make the calculated resonance features shallower and considerably wider. Additionally, there are variations of the chemical potential $\delta \mu$ which correspond to electron and hole puddles for $\delta \mu > 2|\Delta|$. For $\delta \mu < 2|\Delta|$, the variations can lead variation of occupation numbers of impurity states in different regions which does not qualitatively modify our results. In order for our results to qualitatively still make sense, we require the variations in chemical potential $\delta \mu < 2|\Delta|$.

There have been multiple optical experiments probing topological insulators which measure the Kerr and Faraday effects. Jenkins et al. studied the Kerr and reflectivity for a fixed frequency and varying the magnetic field. Time-domain spectroscopy has been utilized on strained HgTe. The large Kerr effect and thickness independent Drude peaks have also been observed. Additionally, the quantized Faraday angle has been seen with passivated Bi$_2$Se$_3$ in a terahertz experiment as well as observation of a shifted Dirac cone. Time-domain

FIG. 5. (Color online) The measurable optical quantities of the (a) Faraday angle, (b) ellipticity of the transmitted wave, (c) Kerr Angle, and (d) ellipticity of the reflected wave for Bi$_2$Se$_3$ in the case of a filled valence band with an unoccupied bound state ($\mu = -\Delta$) and an occupied bound state ($\mu = \Delta$). As expected, the features correspond to the features in the optical conductivities.
spectrum was also used in BSTS to see both the surface state and a bulk impurity band. And recently the same technique was used on (Bi$_1$-xIn$_x$)$_2$Se$_3$ to observe a topological phase transition as $x$ is varied. At present, all observed features originate from the bulk physics, but recently new ultrathin magnetically gapped TI films have been grown and for these samples all conditions necessary for the observation of magneto-optical effects are satisfied.

In these ultrathin films, the tunneling between opposite surfaces can become important. The tunneling splits the bands and 'splits' the threshold, leading to features similar to impurity states.

Resonant features from localized in-gap states and from chiral excitons appear below the threshold $|\Delta|$, but their shapes have completely different characters. The localized impurity states are single-particle excitations while excitons are two-particle excitations. Continuous transitions from valence band to a localized state (or from the localized state to conduction band) contribute to optical conductivity, hence the additional peak can be interpreted as a splitting of the threshold $|\Delta| \rightarrow |\Delta| + \epsilon_0$ (or $|\Delta| - \epsilon_0$ if the state is occupied). On the other hand, excitons lead to a sharp feature in the two-particle spectrum, corresponding to their dispersion law $E_{\text{exc}}(q)$. Since only excitons with zero momentum are optically active, they lead to features of a single, resonant shape in the magneto-optic.

To conclude, we have investigated the role of localized in-gap states on the surface of a topological insulator in the magneto-optical Faraday and Kerr effects. These in-gap states resonantly contribute to both the longitudinal and Hall conductivities which in turn leads to peculiar resonances in the frequency dependence of the Faraday and Kerr angles as well as to the ellipticities of transmitted and reflected waves. These resonant features that we have predicted can be directly measured by optical experiments. In fact, their specific shape of these resonant features allows them to be easily separated from other in-gap excitations.

When a charge impurity sits on the surface of a material, we expect some dielectric screening, and if we consider a thin film of that material as we do in this paper, the potential will be modified due to induced charge accumulation on the surfaces. As can be found in any book on Electromagnetism, the effect will appear as though there are image charges and lead to a potential

\[
\phi_{\text{exact}}(r) = \frac{2}{\epsilon + 1} \frac{Ze}{r} + \frac{4e}{\epsilon^2 - 1} \sum_{n=1}^{\infty} \left( \frac{\epsilon - 1}{\epsilon + 1} \right)^{2n} \frac{Ze}{\sqrt{r^2 + (2dn)^2}}.
\]

This potential supports localized bound states for certain values of \(\alpha\), and one can match both the wave function's extent and energy with the appropriate Coulomb state in order to obtain a reasonable approximation to how this affects the optics (which will not differ wildly from what we have elaborated on here). The bulk dielectric constant for Bi$_2$Se$_3$ is \(\epsilon \sim 100\), quite large.

The relevant integral is

\[
\int_{0}^{\infty} dr \, e^{-br} r^{\gamma-1} \mathcal{F}(\alpha_1; \beta_1; a_1 r) \mathcal{F}(\alpha_2; \beta_2; a_2 r) = \frac{\Gamma(\gamma)}{b^{\gamma}} F_2(\gamma; \alpha_1, \alpha_2; \beta_1, \beta_2; \frac{a_1}{b^{\gamma}}, \frac{a_2}{b^{\gamma}}),
\]

where \(F_2\) is the Appell hypergeometric function defined by the series

\[
F_2(\gamma; \alpha_1, \alpha_2; \beta_1, \beta_2; x_1, x_2) = \sum_{n,m=0}^{\infty} \frac{\gamma_{n+m}(\alpha_1)_n(\alpha_2)_m}{(\beta_1)_n(\beta_2)_m} \frac{x_1^n x_2^m}{n! m!}
\]

with \((a)_n = a(a+1) \cdots (a+n-1)\) being the Pochhammer symbol.
