ABSTRACT

We report deep optical integral-field spectroscopy with the Multi-Unit Spectroscopic Explorer (MUSE) at the Very Large Telescope of the luminous radio-quiet quasi-stellar object (QSO) PG 1307+085 ($z = 0.154$) obtained during the commissioning of the instrument. Given the high sensitivity and spatial resolution delivered by MUSE, we are able to resolve the compact ($r_e \sim 1.3$ arcsec) elliptical host galaxy. After careful spectroscopic deblending of the QSO and host galaxy emission, we infer a stellar velocity dispersion of $\sigma_* = 155 \pm 19$ km s$^{-1}$. This places PG 1307+085 local $M_{\text{BH}} - \sigma_*$ relation within the intrinsic scatter but offset towards a higher black hole mass with respect to the mean relation. The observations with MUSE also reveal a large extended narrow-line region (ENLR) around PG 1307+085 reaching out to $\sim 30$ kpc. In addition, we detect a faint bridge of ionized gas towards the most massive galaxy of the galaxy group being just $\sim 20$ arcsec (50 kpc) away. Previous long-slit spectroscopic observations missed most of these extended features due to a miss-aligned slit. The ionized gas kinematics does not show any evidence for gas outflows on kpc scales despite the high QSO luminosity of $L_{\text{bol}} > 10^{46}$ erg s$^{-1}$. Based on the ionized gas distribution, kinematics and metallicity we discuss the origin of the ENLR with respect to its group environments including minor mergers, ram-pressure stripping or filamentary gas accretion as the most likely scenarios. We conclude that PG 1307+085 is a normal elliptical host in terms of the scaling relations, but that the gas is most likely affected by the environment through gravity or ambient pressure. It is possible that the ongoing interaction with the environment, mainly seen in the ionized gas, is also be responsible for driving sufficient gas to feed the black hole at the centre of the galaxy.

1 INTRODUCTION

1.1 Black hole – spheroid relations

An important question in the study of galaxy evolution is the origin of the relations between the mass of the central super-massive black hole (BH) and the properties of the host galaxy spheroid, discovered nearly two decades ago (Kormendy & Richstone 1995; Magorrian et al. 1998; Gebhardt et al. 2000; Ferrarese & Merritt 2000). Mergers or feedback from BHs growing through accretion in active galaxies have been suggested as potential driving forces of the implied BH-galaxy co-evolution (for a recent review see Kormendy & Ho (2013)).

Galaxies hosting active galactic nuclei (AGN) are not only promising candidates for providing direct evidence for such co-evolution, they can also be used to study the scaling relations over cosmic times. Many studies suggest that BH growth precedes spheroid assembly (Treu et al. 2004; Woo et al. 2006; Shields et al. 2006; McLure et al. 2006; Peng et al. 2006a,b; Treu et al. 2007; Salviander et al. 2007; Woo et al. 2008; Gu et al. 2009; Jahnke et al. 2009; Decarli et al. 2010; Merloni et al. 2010; Bennett et al. 2010; Wang et al. 2010; Bennett et al. 2011); however, other studies find no significant evolution with redshift (e.g., Shields et al. 2003; Shen et al. 2008a; Salviander & Shields 2013; Schramm & Silverman 2013; Salviander et al. 2015; Shen et al. 2015; Sun et al. 2015). The likely reason for the disagreement is that the studies...
are differently affected by intrinsic scatter in the relation, selection effects, and observational biases (see e.g., Lauer et al. 2007; Volonteri & Stark 2011; Schulze & Wisotzki 2014). Another issue is that the $M_{BH} - \sigma_*$ relation is not well constrained even for local AGN host galaxies at the high mass end. Especially for the AGN appearing as Quasi- Stellar Objects (QSOs), the bright nuclear point source often outshines its host galaxy. Measurements of the spheroid properties are therefore difficult, in particular the stellar velocity dispersion for which high signal-to-noise (S/N) spectra are needed. Thus, many studies focus on Seyfert galaxies often using aperture spectra which integrates over the central few kpc of the host galaxy (e.g., Greene & Ho 2006; Woo et al. 2006; Treu et al. 2007; Shen et al. 2008a; Woo et al. 2008; Matsuoka et al. 2015). The side effect is that, if present, a significant disc contribution may be included, questioning the definition of the spheroid stellar velocity dispersion in these cases. Bennert et al. (2015) study the effect of different definitions of $\sigma_*$ in the literature for a sample of 66 local Seyfert-1 galaxies and find that it can vary by up to 40 per cent.

Active early-type or elliptical galaxies are therefore ideal targets to constrain the $M_{BH} - \sigma_*$ relation as they lack a disturbing disc component. The colours of early-type QSOs, however, are still bluer than their quiescent counterparts (e.g., Jahnke et al. 2004b; Sánchez et al. 2004; Zakamska et al. 2006; Trump et al. 2013; Matsuoka et al. 2014). This clearly suggests that the phase of BH growth is also accompanied with a significant growth of the spheroid through star formation. Whether AGN feedback is responsible to quench star formation in these systems is still debated. Direct evidence for AGN feedback is provided by the kinematics of the highly-ionized gas on kpc scales, the so-called extended narrow-line region (ENLR). In some cases, broad emission lines components with a line width of >500 km s$^{-1}$ have been found around radio-quiet (e.g., Davis et al. 2012; Liu et al. 2013; Harrison et al. 2014) and radio-loud AGN (e.g., Fu & Stockton 2006; Guillard et al. 2012; Tadhunter et al. 2014), but not all luminous AGN show these prominent kinematic disturbances on kpc scales (e.g., Husemann et al. 2010, 2013). In some cases, the morphology and size of the ENLR rather suggests interactions with neighbouring galaxies (e.g., Villar-Martin et al. 2010; da Silva et al. 2011) or the environmental gas (Husemann et al. 2011) as the origin of the gas reservoir.

In this paper we present, for the first time, deep wide-field optical integral-field spectroscopy for the luminous radio-quiet PG 1307+085 at $z \sim 0.15$ hosted by an undisturbed elliptical galaxy. The main aim of this paper is to recover the optical stellar continuum and measure $\sigma_*$ as well as the systemic redshift of the host galaxy, and to characterize the physical conditions and kinematics of the full 2D distribution of ionized gas around PG 1307+085 to understand the origin of the extended gas.

Throughout the paper we adopt canonical cosmological parameters $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_m = 0.3$, and $\Omega_{\Lambda} = 0.7$.

1.2 Previous work on PG 1307+085

The QSO PG 1307+085 was discovered by the Palomar-Green (PG) survey as a UV-excess source at the coordinates $13^309^047^+08^19^438^\prime$ (J2000). A magnitude of $m_B = 15.28$ and a redshift of $z = 0.155$ was reported by the Bright Quasar Survey (BQS) Schmidt & Green 1983. Very Large Array (VLA) observations of the BQS sample by Kellermann et al. (1989) detected only weak radio emission (S$_{1.4GHz} = 3.5$ mJy), consequently classifying PG 1307+085 as a radio-quiet QSO with an R parameter of 0.1 following the definition and classification of Kellermann et al. (1989). As a bright low-redshift QSO, PG 1307+085 has been studied in detail with follow-up observations from X-ray to radio waveband.

The underlying host galaxy was first detected by McLeod & Rieke (1994) in the $H$ band from the ground. They reported a host magnitude of $m_H = 15.25$ mag, a factor of four fainter than the QSO. Observations with the Hubble Space Telescope (HST) (Bahcall et al. 1994; Veilleux et al. 2009; Bentz et al. 2009) and deep adaptive-optics ground-based $H$ band imaging (Guyon et al. 2006) spatially resolved the underlying host galaxy and consistently classified it as an undisturbed elliptical galaxy. From 2D image modelling, Bahcall et al. (1997) and Veilleux et al. (2009) reported an effective radius of $r_e \sim 1.3$ arcsec (3.5 kpc) and a host galaxy magnitude of $m_{R,host} = 17.8$ mag and $m_{N} = 15.21$ mag, respectively, whereas Guyon et al. (2006) inferred a slightly larger ($r_e = 4.7$ arcsec) and brighter ($m_H = 14.71$ mag) host galaxy.

Active early-type or elliptical galaxies are therefore ideal targets to constrain the $M_{BH} - \sigma_*$ relation as they lack a disturbing disc component. The colours of early-type QSOs, however, are still bluer than their quiescent counterparts (e.g., Jahnke et al. 2004b; Sánchez et al. 2004; Zakamska et al. 2006; Trump et al. 2013; Matsuoka et al. 2014). This clearly suggests that the phase of BH growth is also accompanied with a significant growth of the spheroid through star formation. Whether AGN feedback is responsible to quench star formation in these systems is still debated. Direct evidence for AGN feedback is provided by the kinematics of the highly-ionized gas on kpc scales, the so-called extended narrow-line region (ENLR). In some cases, broad emission lines components with a line width of >500 km s$^{-1}$ have been found around radio-quiet (e.g., Davis et al. 2012; Liu et al. 2013; Harrison et al. 2014) and radio-loud AGN (e.g., Fu & Stockton 2006; Guillard et al. 2012; Tadhunter et al. 2014), but not all luminous AGN show these prominent kinematic disturbances on kpc scales (e.g., Husemann et al. 2010, 2013). In some cases, the morphology and size of the ENLR rather suggests interactions with neighbouring galaxies (e.g., Villar-Martin et al. 2010; da Silva et al. 2011) or the environmental gas (Husemann et al. 2011) as the origin of the gas reservoir.

In this paper we present, for the first time, deep wide-field optical integral-field spectroscopy for the luminous radio-quiet PG 1307+085 at $z \sim 0.15$ hosted by an undisturbed elliptical galaxy. The main aim of this paper is to recover the optical stellar continuum and measure $\sigma_*$ as well as the systemic redshift of the host galaxy, and to characterize the physical conditions and kinematics of the full 2D distribution of ionized gas around PG 1307+085 to understand the origin of the extended gas.

Throughout the paper we adopt canonical cosmological parameters $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_m = 0.3$, and $\Omega_{\Lambda} = 0.7$.

2 OBSERVATIONS AND DATA REDUCTION

The QSO PG 1307+085 was observed with the Multi-Unit Spectroscopic Explorer (MUSE, Bacon et al. 2010, 2014) at the VLT on 2014 May 6 as part of the instrument commissioning. MUSE is a novel optical integral-field spectrograph mounted to the Nas-
The MUSE view of QSO PG 1307+085

Figure 1. Single-band F606W image taken with WFPC2 aboard the HST (left panel) and reconstructed false-colour image of the MUSE field (right panel) targeting the QSO PG 1307+085. Several galaxies are part of rich galaxy group extending beyond the HST image that were spectroscopically identified by Prochaska et al. (2011) are labelled on the HST image. The centre of the group is most likely the luminous (~4L∗) elliptical galaxy to the south-east of PG 1307+085. For the MUSE false-colour image we choose two broad continuum bands and a narrow band centred on the redshifted [O ii] λ5007 emission line to highlight the ionized gas distribution around the QSO. Besides the bright [O ii] emission of the nucleus we discovered an extended emission-line region with a size up to ~10 arcsec from the nucleus. The three main structures of the extended emission-line regions are two bright knots to the east and south, respectively, and a low surface brightness tail extending further south of knot 2, which are labelled in the figure accordingly.

3 ANALYSIS

3.1 Reconstructed narrow-band and broad-band images

We extract a 20Å wide narrow-band image centred on the redshifted [O ii] λ5007 line and two broad band images covering the 4750–5250Å and 8000–8500Å pass bands, respectively. The corresponding pseudo RGB image of the field is shown in Fig. 1 (right panel) compared to an archival HST image taken with WFPC2

1 http://www.bhusemann-astro.org/datasets/
camera in the F606W filter (left panel). While the QSO host galaxy has been classified as a round elliptical without any signs of distortion, the MUSE data reveal an extended and complex distribution of ionized gas around the QSO. We identify three prominent structures across the ENLR: (1) a bright knot south-east of the nucleus, (2) a bright knot plus shell-like structure south of the nucleus, and (3) a faint knot about 10 arcsec (26 kpc) south from the nucleus. In addition to PG 1307+085, a few galaxies of the group are also covered by the MUSE FoV. The bright elliptical galaxy is only partially covered at the east edge of the FoV, but we are able to detect a very low surface brightness bridge of ionized gas between this galaxy and the QSO host galaxy.

Figure 2. Rest-frame $g$ and $r$ broad-band images and corresponding PSF and PSF+host galaxy models with residuals. All images are displayed with a common linear scaling. Despite the flat-fielding residuals, the light is significantly more extended compared to a pure point source. Parameters from the best-fitting PSF+host model are given in Table 1.

3.2 QSO-host deblending

Even at good seeing conditions, the bright QSO significantly contaminates a large area due to the wings of the PSF and the high contrast ratio between unresolved and extended emission. Here we take advantage of the broad Balmer lines of the QSO to measure the PSF (e.g. Jahnke et al. 2004a). Our iterative algorithm to deblend the point-like emission of the QSO and the extended host galaxy emission is described in detail in Husemann et al. (2013, 2014), we here just briefly outline the process.

First, we measure a PSF from broad emission lines by mapping the intensity in the line wings above the adjacent continuum flux. Since the PSF is smoothly changing as a function of wavelength, we determine the PSF from the broad Hγ, Hβ, HeI, and Hα lines. Then we reconstruct a PSF cube by normalizing all PSFs to one at the brightest pixel and interpolate the intensity maps with a two-order polynomial function along wavelength. An almost pure QSO cube is produced by multiplying the normalized PSF cube with QSO spectrum from the brightest spaxel2. However, there is some host galaxy contamination even in the QSO spectrum that we need to subtract to avoid significant over-subtraction. Since the radial surface brightness distribution of the host galaxy is necessarily more extended than the PSF, we co-add the residual spectra around the brightest spaxel after the QSO subtraction to obtain a best guess on the host galaxy spectrum. We re-scale this host galaxy spectrum in total flux so that it matches the expected host galaxy surface brightness at that brightest spaxel. In an iterative scheme we subsequently subtract the re-scaled host spectrum from the original QSO spectrum in each iteration to clean it from the host contamination. The process converges after a few iterations and we stop after ten in this particular case. To estimate the radial surface brightness profile of the host galaxy, we extracted rest-frame $g$ and $r$-band images from the initial data as well as the corresponding PSFs from the PSF cube. Then we used GALFIT (Peng et al. 2002, 2010) to model the 2D surface brightness as a superposition of a point source and a Sersič profile. We fixed the Sersič index to $n = 4$ because the host galaxy is known to be an elliptical galaxy from higher resolution HST observations (Bahcall et al. 1994; Veilleux et al. 2009). In Fig. 2 we show the model and residual of a PSF model only and a PSF+Sersič model for the $g$-band (left panel) and $r$ band (right panel) images, respectively. Our best-fitting parameters for both bands are given in Table 1.

MUSE is not designed to be a broad-band imager and the systematic uncertainty of the flat-fielding across the field is strongly limited by the preliminary calibration plan during the commissioning run. Thus, it is not possible to obtain very precise measurements on the host galaxy morphological parameter. However, the residuals of the PSF-only model are significant and highlight that the un-

The MUSE view of QSO PG 1307+085

Figure 3. The total, pure QSO and the host galaxy spectrum containing spatially resolved emission within an aperture of 3.2 arcsec radius. The QSO exceeds the host galaxy light by a factor \(~10\) at 5250 Å (rest frame). No significant broad emission-line residuals appear in the host galaxy spectra, but strong narrow-emission lines are clearly present from the surrounding kpc-scale ENLR as seen in the narrow-band image shown in Fig. 1.

Figure 4. Host galaxy continuum spectrum within an aperture of 2 arcsec in radius. The spectrum is slightly smoothed from a spectral resolution of 2.5 to 3.0 Å with a Gaussian kernel. We model the spectrum as a super-position of single stellar population spectra (Vazdekis et al. 2010) generated from the MILES stellar library (Sánchez-Blázquez et al. 2006), adopting a Gaussian kernel for the LOSVD which is shown as the red line. The modelling was performed independently on the entire spectrum up to the wavelength of H α (upper panel), covering a wavelength region centred around the G band stellar absorption feature (lower left panel) and the Mg b+Fe stellar absorption features (lower right panel). All measurements agree within the error bars, but the full spectral fitting is considered more robust as template mismatches are minimized.

3.3 Stellar continuum and velocity dispersion

In Fig. 4 we show the host galaxy spectrum extracted from an aperture of 2 arcsec in radius to capture all the light within the effective radius given a 1 arcsec seeing. We slightly degrade the spectral resolution from 2.5 Å Full Width Half Maximum (FWHM), estimated from the width of the sky lines, to 3.0 Å FWHM. This allows us to model the spectrum with stellar population synthesis spectra from the Medium-resolution Isaac newton telescope Library of Empirical Spectra (MILES) (Sánchez-Blázquez et al. 2006). The intrinsic rest-frame spectral resolution of the spectra is 2.51 Å (Falcón-Barroso et al. 2011) corresponding to 2.89 Å at the redshift of the QSO. The slight spectral smoothing also increased the S/N of the spectrum from S/N=8 to S/N=10 per pixel. Strong stellar absorption features are visible in the spectrum in particular the prominent G band at 4300 Å, Mg b triplet at 5175 Å, various adjacent Fe lines as well as the NaD line at 5892 Å. The continuum shows a small low frequency spectral shape deviation due to systematic uncertainties in the QSO host deblending. Those systematics are caused by (1) uncertainties to correct the positional shifts due to differential atmospheric refraction, and (2) the uncertainties in the broad-line PSF measurements and subsequent interpolation with wavelength.

Here, we use our own software PyParadise (Husemann, Choudhury & Walcher in prep.) which is an extended Python version of paradise (Walcher et al. 2015) to perform stellar population spectral synthesis to fit the stellar continuum. The algorithm is insensitive to the global continuum shape as it first divides the spectrum and all template spectra by a running mean after linearly interpolating masked wavelength regions. A detailed description of the algorithm is presented in Walcher et al. (2015) which we summarize below. The main improvements for PyParadise are that (1) a Markov-Chain-Monte-Carlo (MCMC) algorithm is used to find the parameters and associated errors for the line-of-sight velocity distribution (LOSVD), and (2) that only the high S/N template library spectra are resampled during the fitting while the input spectrum remains unchanged to preserve its noise properties.
In the initial iteration, a single stellar population spectrum is drawn from the library and the best-fitting LOSVD, in terms of redshift $z$ and velocity dispersion $\sigma_z$, is estimated by means of a MCMC algorithm (PyMC, Patil et al. 2010) in which the spectrum is smoothed with corresponding Gaussian kernels. Here, we parametrize the LOSVD only by a single Gaussian and avoid to model higher moments given the relatively low S/N of the stellar continuum. In order to match the spectral resolution of the data and the template spectra, we smooth the template spectra, after redshifting to the initial redshift guess $z_{\text{guess}}$, to match the spectral resolution of the data. For the priors we assume a flat probability distribution within $||c(z - z_{\text{guess}})|| < 500$ km s$^{-1}$ and $50$ km s$^{-1} < \sigma_z < 400$ km s$^{-1}$. From the posterior distribution we select the most likely LOSVD and apply it to all normalized spectra of the template library and use a non-negative linear least square algorithm to determine the best-fitting linear coefficients. In all following iterations, this two step process is repeated but the initial spectrum is replaced by a linear combination of the template library based on best-fitting linear coefficients of the previous iteration without applying the LOSVD. The LOSVD parameters and linear coefficient of the templates converge quickly and here we stop after five iterations.

The best-fitting spectra are shown in Fig. 4 based on the library of single stellar population models presented by Vazdekis et al. (2010) from the MILES stellar library for a universal Kroupa initial mass function. We perform an independent modelling of three different wavelength regions; (i) the entire spectrum up to H $\alpha$ (upper panel), (ii) the wavelength region centred on the $G$ band (lower left panel) and (iii) the wavelength region centred on Mg b+Fe absorption lines (lower right panel). The best-fitting parameters for the $z$ and $\sigma_z$ agree within the $1\sigma$ error bars inferred from the all-most symmetric posterior distribution as the 16% and 83% percentiles. We consider the model of the full wavelength range to be more robust as the simultaneous fitting of significantly more feature reduces the systematic errors caused by template mismatch. Our best-fitting parameters for the LOSVD are $c_z = 46318^{+13}_{-13}$ km s$^{-1}$ ($z = 0.1544 \pm 0.0001$) and $\sigma_z = 155^{+12}_{-10}$ km s$^{-1}$. Thus, we obtain a very reliable measurement of the systemic redshift which is import to interpret the ionized gas kinematics.

### 3.4 QSO spectrum and BH mass estimate

The QSO spectrum is shown in Fig. 5 after subtracting the host galaxy contribution. We model the spectrum as a super-position of a continuum and emission lines components following the scheme of Shen et al. (2008b). We assume a power-law function as the primary continuum with two different slopes in the blue and red part of the rest-frame optical spectrum (e.g. Vanden Berk et al. 2001). Due to the various broad lines and FeII bands we can only infer the continuum flux at three rest-frame wavelengths: 4200Å, 5650Å, and 7400Å. Based on the best-fitting power-law we infer a continuum flux density at 5100 (rest-frame) of $f_{5100} = 21.5 \times 10^{-16}$ erg s$^{-1}$ cm$^{-2}$ s$^{-1}$ which corresponds to a continuum luminosity of $L_{5100} = 8 \times 10^{44}$ erg s$^{-1}$. An additional pseudo-continuum is produced by the FeII bands that we model with the broadened FeII template spectrum of I Zw 1 provided by Boroson & Green (1992). The width of the smoothing kernel is empirically constrained to minimize the residuals for the prominent FeII band at 5100Å–5450Å.

We model all the emission lines above the continuum with multiple Gaussian components (see Fig. 5). Two broad Gaussian components are necessary to model the broad H $\gamma$ and H $\beta$
and H \( \alpha \) line shape, respectively, whereas one broad component is sufficient for the broad He \( \text{II} \) \( \lambda 4685 \) \AA\ line. Prominent narrow lines are also seen in H \( \gamma \), \([\text{O}\text{II}]\) \( \lambda 3742 \), He \( \text{II} \) \( \lambda 4685 \), H \( \beta \), \([\text{O}\text{III}]\) \( \lambda 4960, 5007, [\text{O}\text{I}] \) \( \lambda 6300 \) \AA, H \( \alpha \), \([\text{N}\text{II}]\) \( \lambda 6548, 6583 \) \AA, and \([\text{S}\text{II}]\) \( \lambda 6717, 6730 \) \AA. All of the narrow lines except \([\text{O}\text{I}]\) and \([\text{S}\text{II}]\) appear asymmetric with a blue wing, so that we model those narrow lines with two Gaussian components. Such a broad asymmetric wing is a common feature in the spectra of luminous QSOs (e.g. Mullaney et al. 2013) and considered to be a genuine signature of AGN-driven outflows at least in the circumnuclear region. The best-fitting parameters for these two narrow-line components are listed in Table 2. In contrast to the broad lines, we force the redshift and intrinsic velocity dispersion of the two narrow-line kinematic components to be the same. This greatly reduces the number of free parameters and leads to a more robust fit.

The broader component of the narrow lines has a velocity dispersion of about \( \sim 300 \) km s\(^{-1}\) compared to \( \sim 100 \) km s\(^{-1}\) for the other components. The broader component is blue-shifted by about 60 km s\(^{-1}\). The velocity dispersion of the bluer component and its blue-shift with respect to the narrower component are smaller than the average value of luminous AGN as inferred by Mullaney et al. (2013). We discuss the physical conditions of this ionized gas together with the extended emission in the next section. One difficulty in their interpretation is that the fluxes of the narrow H \( \beta \) and H \( \alpha \) line are unreliable due to the systematic error in the model of the complex broad Balmer line shapes that are compensated by a skewed flux ratio of the two narrow line components.

We measure a broad H \( \beta \) line width of FWHM\(_{H\beta}\) = 4250 \pm 30 km s\(^{-1}\) and \( \sigma_{H\beta} = 2347 \pm 21 \) km s\(^{-1}\). Those errors correspond only to the random uncertainties given the S/N of the spectrum, but not the systematic uncertainties due to line blending. The FWHM is in good agreement with the measurements of Kaspi et al. (2000) and Shen et al. (2011), but 1000 km s\(^{-1}\) narrower than reported by Marziani et al. (2003) and Peterson et al. (2004). Oh et al. (2013) reported a line dispersion of \( \sigma_{H\beta} = 1885 \pm 10 \) km s\(^{-1}\) which is 460 km s\(^{-1}\) narrower than our measurements. It is unclear whether this is attributed to time variability in the line shape or systematic uncertainties of the H \( \beta \) line. We find very different results based on the same spectra.

A reverberation time-lag of \( \tau = 105^{+36}_{-26} \) light days for PG 1307+085 was initially reported by Peterson et al. (2004) for the broad H \( \beta \) line, but significantly revised to \( \tau = 188^{+5}_{-3} \) light days by Zu et al. (2011). The corresponding virial product \( VP = c \sigma_{\text{blue}}/G = 120^{+49}_{-34} \times 10^{8} M_{\odot} \) for the broad H \( \beta \) line dispersion as measured by Peterson et al. (2004) combined with a virial factor of \( f = 4.47^{+1.4}_{-1.2} \) (Woo et al. 2015) leads to a reverberation-based BH mass of \( M_{\text{BH}} = 5.3^{+1.9}_{-1.1} \times 10^{8} M_{\odot} \). We infer a broader H \( \beta \) line dispersion from the analysis of the MUSE spectrum, we also compute a single-epoch virial BH mass replacing the reverberation-mapped BLR size with the size-luminosity relation of Bentz et al. (2013). This yields a BH mass of \( M_{\text{BH}} = 4.9 \times 10^{8} M_{\odot} \) which is well within the uncertainties of the reverberation-based BH mass. We therefore refer to the reverberation-mapped BH throughout the paper.

Assuming a mean bolometric correction factor of ten for the continuum luminosity at 5100\( \AA \) following Richards et al. (2006), we obtain a bolometric luminosity of \( \log (L_{\text{bol}}/\text{erg s}^{-1}) = 45.9 \). This corresponds to an Eddington ratio of \( \lambda = L_{\text{bol}}/L_{\text{Edd}} = 0.3 \) for PG 1307+085.

---

**Figure 6.** Co-added spectra and best-fitting emission-line models for several prominent emission-line regions indicated in the narrow-band [O\text{III}] image on the top. Two spectral windows covering the H \( \beta \) and [O\text{III}] \( \lambda \lambda 4960, 5007 \) (left panels) and the H \( \alpha \), [N\text{II}] \( \lambda 6548, 6583 \), and [S\text{II}] \( \lambda \lambda 6717, 6730 \) (right panels) are shown. The two “bridge” spectra suffer more strongly from the sky line residuals given the low surface brightness of the emission lines.
3.5 Physical conditions across the ENLR

In Fig. 6 we present the co-added QSO-subtracted spectra for the host galaxy, the three knots across the ENLR, and the bridge split up into two regions. Several narrow emission lines are visible in the spectra. Besides the strong lines [O I] $\lambda\lambda$4960,5007, H $\beta$, [N II] $\lambda\lambda$6548,6583, and H $\alpha$, we detect fainter lines such as the [O III] $\lambda\lambda$4363, H $\gamma$, He II $\lambda$4635, [S II] $\lambda\lambda$6713, 6730, and [Ar III] $\lambda$7135 only in the two brightest knots. We model the lines above a local continuum level with Gaussians profiles that are all coupled in their radial velocity and intrinsic velocity dispersion. The obtained line fluxes and kinematic parameters are listed in Table 2; 3$\sigma$ upper limits are given for the undetected lines based on the noise in the continuum.

From the H $\alpha$/H $\beta$ line ratio we infer the line of sight extinction $E(B-V)$ adopting a theoretical Balmer decrement of H $\alpha$/H $\beta\sim$2.85 for case B recombination and a Milky Way like extinction curve (Cardelli et al. 1989). Subsequently, we correct the observed line fluxes for extinction and use the $\alpha$-models with four different metallicities 0.5 $Z_\odot$, 1$Z_\odot$, 2$Z_\odot$, and 3$Z_\odot$ to estimate the electron temperature ($T_e$) following the prescription of Osterbrock & Ferland (2006) as implemented in the PyNeb package (Luridiana et al. 2015). We obtain values of $n_e$ $\sim$ 1000 cm$^{-2}$ and $T_e$ $\sim$ 14000 K for the two brightest knots of the ENLR as well as $n_e$ $\sim$ 1000 cm$^{-2}$ and $T_e$ $\sim$ 25000 K for the unresolved emission of the QSO. Our measurements for knot 1 are consistent with the results from the long-slit spectrum aligned along that region as reported by Oh et al. (2013), but with significantly smaller error bars. The measured temperatures and densities are typical conditions for the nucleus (e.g. Vaona et al. 2012) and for the ENLR on kpc scales (e.g. Bennett et al. 2006a,b), respectively.

The total ionized gas mass is mainly set by the amount of ionized hydrogen. This can be easily inferred from the photons emitted by the Balmer recombination lines. Following Osterbrock & Ferland (2006) the ionized gas mass can be approximated from the
The MUSE view of QSO PG 1307+085

Table 2. Emission-line fluxes and physical conditions for the narrow-emission lines in the QSO and extended region spectra

1 Emission-line fluxes are given in units of 10^{-16} erg s^{-1} cm^{-2}
2 Emission-line surface brightness is given in units of 10^{-19} erg s^{-1} cm^{-2} arcsec^{-2}

H α luminosity as

M_{ion} = \frac{1.4 \times 10^{10} \times E_{Hα}}{n_e < 10^{14} \text{ erg s}^{-1}} (L_{Hα} / 10^{14} \text{ erg s}^{-1})

where n_p is the proton mass, n_e is the electron density and h is the Planck constant. Here, we compute the ionized gas mass separately for each region based on the attenuation correct H α luminosity and electron density. If the attenuation or electron density is not measurable for a given region, we adopt E(B − V) = 0.1 and n_e = 70 cm^{-2}, which are representative values from all other regions. Adding the ionized gas mass of all regions we infer a total ionized gas mass of the ENLR of approximately M_{ion} ~ 2.5 \times 10^7 M_{⊙} which is uncertain at an order or magnitude level.

The two brightest knots of the ENLR show a large number of lines that we can detect with high confidence. In Fig. 7 we show twelve different line ratio plots including the well-known [O III] λ5007/β vs. [N II] λ6583/α BPT diagram (Baldwin et al. 1981; Veilleux & Osterbrock 1987). Except for the line ratios in the bridge, all regions clearly indicate photoionization by the AGN (e.g. Kewley et al. 2006; Stasinska et al. 2006). The [O III] λ5007/β vs. [N II] λ6583/α diagram and [Ar III] λ7135/β vs. [N II] λ6583/α BPT diagram (Baldwin et al. 1981) and [Ar III] λ7135/β vs. [O III] λ5007 spectrum (Baldwin et al. 1981) only show a single gas density of n = 100 cm^{-3} as implied by the [S II] doublet ratio. Except for the [Ar III] λ7135/β vs. [O III] λ5007 spectrum (Baldwin et al. 1981) and [Ar III] λ7135/β vs. [O III] λ5007, all line ratios are even lower than predicted by this “best-fitting” model. Since Argon and Helium are not depleated on to dust, Argon is a good metallicity indicator independent of the assumed dust composition but depends on ionization parameter.

In our case, He II λ5865 implies a high ionization parameter independent of metallicity while the low [Ar III] λ7135/β γ line ratio indicates significantly lower metallicities than in the majority of AGN.

We can definitely rule out shock or shock+precursor ionization because the high [O III] /H β line ratio would require high excitation by fast shocks with v_s > 500 km s^{-1} (Allen et al. 2008). This is inconsistent with the observed quiescent kinematics of the gas (see next section) across the ENLR.

3.6 Ionized gas kinematics

To roughly quantify the ionization properties of the gas, we compare all line ratios for knots 1 and 2 with dusty radiation pressure dominated photoionization model (Groves et al. 2004) in Fig. 7 for four metallicities (0.5Z⊙, 1Z⊙, 2Z⊙ and 4Z⊙), three power-law slopes of the ionizing AGN continuum (α = 1.2, 1.4, 1.7), and a single gas density of n = 100 cm^{-3} as implied by the [S II] doublet ratio. Except for the [Ar III] λ7135/β vs. [O III] λ5007 spectrum (Baldwin et al. 1981) and [Ar III] λ7135/β vs. [O III] λ5007, all line ratios are even lower than predicted by this “best-fitting” model. Since Argon and Helium are not depleated on to dust, Argon is a good metallicity indicator independent of the assumed dust composition but depends on ionization parameter.

In our case, He II λ5865 implies a high ionization parameter independent of metallicity while the low [Ar III] λ7135/β γ line ratio indicates significantly lower metallicities than in the majority of AGN.

We can definitely rule out shock or shock+precursor ionization because the high [O III] /H β line ratio would require high excitation by fast shocks with v_s > 500 km s^{-1} (Allen et al. 2008). This is inconsistent with the observed quiescent kinematics of the gas (see next section) across the ENLR.

3.6 Ionized gas kinematics

In addition to the line measurements from the co-added spectra for the specific regions, we reconstruct the kinematics of the ENLR from the bright [O III] λλ4960, 5007 lines across the field. We model the doublet line independently for each spaxel as a single pair of Gaussians that are coupled in redshift and velocity dispersion with a fixed flux ratio of [O III] λ5007/[O III] λ4960 = 3 in the QSO-subtracted data cube. The best-fitting [O III] λ5007 surface brightness, radial velocity (systemic velocity subtracted) and velocity dispersion maps are shown in Fig. 8. Although the [O III] λ5007 in the QSO spectrum exhibits a strong blue-shifted component with
a line width of \( \sim 650 \text{ km s}^{-1} \) (FWHM), we detect mainly narrow lines with \(< 120 \text{ km s}^{-1} \) (FWHM) across the entire region.

An increased line dispersion is apparently seen in the region between knot 1 and knot 2. The increase in velocity dispersion is not physical, but rather a combined artefact of beam smearing and fitting only a single Gaussian component. We noticed that this feature in this region appear double peaked because the emission lines of knot 1 and knot 2 are offset by about 50 km/s in velocity space and both components contribute with an almost equal surface brightness to the overall line shape. The same superposition also happens in the host galaxy region which is contaminated by emission from knot 1 due to beam smearing. The spectral resolution of MUSE is not sufficient to reliably decompose those lines in their respective components. Whether the same mechanism also happens in the host galaxy region which is contaminated by emission from knot 1 due to beam smearing. The line-of-sight radial velocity variation shows a low amplitude of \(< 200 \text{ km s}^{-1} \) in general. Interestingly, we find a smooth velocity gradient from red-shifted to significantly blue-shifted with respect to the systemic velocity from the location of the host galaxy through knot 2 towards knot 3. This velocity gradient has the largest velocity amplitude of 200 km s\(^{-1}\). We consider this gradient physical and unconnected to instrumental effects as beam smearing would only smooth out the gradient. From the data alone we cannot distinguish between gas approaching and escaping from the host galaxy.

The S/N in the bridge between PG 1307+085 and the massive galaxy at the group centre is too low for analysing individual spaxels. However, the radial velocity measured from the two binned regions along the bridge (see Table 2) reveals that the gas is more blue-shifted closer to the massive companion by \(\sim 260 \text{ km s}^{-1}\).

This is consistent in sign and amplitude with the redshift difference between two galaxies. It confirms that the ionized gas bridge is not just a superposition, but physically connects the ionized gas between the two galaxies.

4 DISCUSSION

4.1 The BH mass - \( \sigma \) relation

With the unique sensitivity, spatial resolution and image quality of MUSE, we are able to measure a robust \( \sigma \) for the faint host galaxy underneath the luminous QSO PG 1307+085. Here we compare our measurements with the \( M_{\text{BH}}-\sigma \) relation of local quiescent galaxies (McConnell & Ma 2013, 72 objects), where BH masses are derived directly from dynamical measurements, as well as reverberation-mapped AGN (Woo et al. 2015, 29 objects). We also show the best-fitting relation derived by Kormendy & Ho (2013) (51 objects; pseudo bulges and mergers excluded) and by Graham et al. (2011) (64 objects; all morphologies). As can be seen from Figure 9, PG 1307+085 is consistent with the local relation within its intrinsic scatter taking the errors of our measurements into account. However, it is slightly offset towards a higher BH mass with respect to the mean relation.

An offset of \( \Delta M_{\text{BH}}(\@ z = 0.15) = 0.24 \text{ dex} \) is suggested by the reported redshift evolution of Woo et al. (2006). The nominal offset from the mean relation we measure for PG 1307+085 is about 0.3 dex and would be in line with the predicted offset. For a single object it is, however, still within the intrinsic scatter of the relation. Certainly, the offset from the relation of quiescent galaxies is smaller than in some extreme AGN host galaxies (Husemann et al. 2011; Trakhtenbrot et al. 2015) and can be accounted for by the uncertainties in the \( M_{\text{BH}} \) and \( \sigma \) estimation. Thus, we consider...
measuring $\sigma_*$ at a physical size matched to the spheroid component. Furthermore, the reliability of the measurements decreases with increasing AGN luminosity and contrast ratio, thus limiting this technique to AGN with $L_{\text{bol}} \lesssim 10^{45}$ erg s$^{-1}$. To probe more luminous AGN, deep off-axis spectroscopy a few arcsec away from the QSO has been obtained to reduce the contrast between QSO and host galaxy emission (Hughes et al. 2000; Wolf & Sheinis 2008; Wold et al. 2010). While $\sigma_*$ can be reliably derived from these off-axis spectra (Wolf & Sheinis 2008), an uncertain aperture correction needs to be applied to infer comparable measurements representative for the spheroidal component.

A direct decomposition the stellar continuum of the host galaxy underneath very luminous QSOs with deep optical IFU observations was previously attempted with VIMOS for HE 1029−1401 (Husemann et al. 2010). Although HE 1029−1401 is much closer with a redshift of $z = 0.086$ but has a similar luminosity as PG 1307+085, the achieved S/N in the host spectrum was significantly lower than what we obtained with MUSE for PG 1307+085. This can be clearly attributed to the superior sensitivity, spatial resolution/sampling, and image quality of MUSE compared to VIMOS. These capabilities allow direct measurements of $\sigma_*$ with MUSE even in a high contrast regime that has not been accessible to any other techniques so far.

Figure 9. $M_{\text{BH}}$−$\sigma$ relation for a sample of quiescent local galaxies (black points; McConnell & Ma 2013) and reverberation-mapped AGN (green symbols; Woo et al. 2015). For comparison we also plot the relation of Kormendy & Ho (2013) as a dashed line and Graham et al. (2011) as a dotted line. The position of PG1307+085 is shown as a red square point adopting the reverberation-mapped BH mass inferred by Peterson et al. (2004).

the offset insignificant given the systematic uncertainties for a single object. In case that the offset is real, it is possible that either PG 1307+085 is moving further away from the relation given the substantial BH growth compared to the low star formation in the spheroid implied by the FIR colours, or that the spheroid growth will eventually catch up the BH growth to move it back towards the relations.

Given that we only consider a measurement for a single object, we refrain from discussing any further physical interpretation here. Instead, we highlight the efficiency and potential of measuring $\sigma_*$ of luminous QSOs with MUSE in the context of previous studies. PG 1307+085 is the third most massive BH and most luminous AGN among the reverberation-mapped AGN with $\sigma_*$ measurements discussed by Woo et al. (2015). Measurements of $\sigma_*$ for luminous QSOs are difficult because of the high AGN-to-host/spheroid contrast ratio. Different techniques have been used to tackle this problem. Since the contrast ratio is much weaker in the NIR. NIR observations, in particular with adaptive optics (AO), can much better resolve the stellar continuum against AGN contribution. Stellar velocity dispersions have been obtained for about a dozen QSOs at $z < 0.1$ (Dasyra et al. 2007; Watson et al. 2008; Woo et al. 2010, 2013). However, AO-assisted NIR observations for higher redshift QSOs ($z > 0.1$) are time consuming and may suffer from a low S/N (Grier et al. 2013) caused by the combination of weak absorption lines, surface brightness dimming, instrument sensitivity and atmospheric transmission.

In the rest-frame optical regime, the QSO and host galaxy contribution can be separated in high S/N single-aperture spectra by directly modelling them with template spectra for each component (Shen et al. 2008a, 2015). While a large sample can be studied with this technique, the fixed aperture size prevents such studies from

4.2 The nature of the large extended emission line region

4.2.1 Ionized gas shells driven by AGN outflows?

A number of recent studies report kpc-scale high-velocity outflows to be common around luminous AGN with line widths of about 1000 km s$^{-1}$ (e.g., Cano-Díaz et al. 2012; Liu et al. 2013, 2014; Harrison et al. 2014). Those outflows have been interpreted as spherically symmetric radiation pressure dominated winds (Liu et al. 2013) and are possibly common for AGN with $L_{\text{bol}} > 2 \times 10^{45}$ erg s$^{-1}$ (Zamorska & Greene 2014). However, not all QSOs above this luminosity threshold exhibit such powerful superbubble-like outflows (e.g., Husemann et al. 2010, 2013). The ionized gas kinematics of the ENLR around PG 1307+085 exhibits only small line widths with a velocity dispersion of $<50$ km s$^{-1}$ in all the bright extended knots without any asymmetric component. This confidently rules out the AGN-driven super-bubble scenario at least for this particular QSO.

Although PG 1307+085 is classified as radio-quiet QSO with $R < 0.1$ (Kellermann et al. 1989) and a relatively low radio-power ($L_{\text{radio}} < 2 \times 10^{21}$ W Hz$^{-1}$), it is still possible that a small-scale ($<1$ kpc) radio jet is accelerating gas through jet-cloud interactions. Some evidence that there is an outflow at least in the circumnuclear region of PG 1307+085 comes from the asymmetric [O III] line (e.g., Mullaney et al. 2013). A deep 4.8 GHz high-resolution map obtained with the VLA was presented by Leipski et al. (2006). They reported tentative but inconclusive evidence for a small-scale one-sided radio jet with a size of 1 arcsec towards the south-west direction. The jet is certainly much smaller than the ENLR in size and cannot be the driver of its morphology. Especially, it would not be able to explain the bright ENLR knot to the east almost 90° away from the putative jet axis. On the other hand, the direction of the radio jet is consistent with the orientation of the velocity gradient close to the QSO position where we also find a peak on ionized gas velocity dispersion.

To summarize, we cannot rule out that there is an AGN outflow on scales of $\leq 1$ arcsec, potentially driven by a radio jet of the same size. This picture is in agreement with the correlation be-
between [O III] asymmetry and radio luminosity discussed by Mul- 
laney et al. (2013), because the low velocity dispersion of the blue-
shifted [O III] component is consistent with the low \( R \) parameter and radio power. Another possibility is that there was a past out-
flow event, either driven by the AGN or radio jet. Such an event could have lifted gas further out in the halo of the galaxy (without accelerating the gas to escape velocity) from which the ENLR has formed.

4.2.2 Galaxy interactions and tidal debris?
Galaxy interactions, in particular major mergers, have been thought as a common channel to trigger luminous AGN (e.g. Sanders et al. 1988; Hopkins et al. 2005). While a fraction of AGN are known to reside in ongoing major mergers, systematic studies of QSO hosts have shown that major mergers cannot be the dominant mecha-
nisms for fueling AGN (e.g., Cisternas et al. 2011; Villforth et al. 2014) at least for moderate luminosities. However, it is particularly difficult to identify the faint morphological disturbances and tidal features in advanced mergers or major merger remnants, which can only be seen in very deep exposures (e.g., Bennert et al. 2008; Duc et al. 2015). Indeed, large ENLRs have been observed that are clearly associated with ongoing galaxy interaction (e.g., Villar-
Martin et al. 2010; da Silva et al. 2011).

In the case of PG 1307+085, neither the HST images (Bah-
call et al. 1994; Veilleux et al. 2009), nor the deep AO-assisted ground-based image (Guyon et al. 2006) reveal any detectable sub-
structure at the location of the bright knots in the ENLR. However, the amount of ionized gas in these regions is small (\( \sim 10^7 M_\odot \)) and given the hard radiation field, the total gas mass is not likely to be more than an order of magnitude larger. Thus, we cannot rule out that the ENLR corresponds to tidal features of a merging event. However, the likelihood of a recent major merger is low given that PG1307+085 is known to be FIR faint (Netzer et al. 2007), implying a lower star formation rate – at least in the last 100 Myr (Hayward et al. 2014) – than in other QSOs of similar luminosity. While the time delay between the peak of star formation and the AGN phase during the merger of a few 100 Myr could provide an explanation (e.g., Wild et al. 2010), a minor merger scenario is more likely, considering the low gas mass and the lower metallicity gas. In particular knot 2 and the diffuse extension towards knot 3 with the strong velocity gradient may be a kinematic signature of the tidal debris from a minor companion.

Such a minor merger scenario cannot explain the bright knots 1 and 2 in the ENLR morphology at the same time because they are oriented almost exactly 90° with respect to their specific QSO line-
of-sights. It is notable that knot 1 is positioned along the axis be-
tween the massive galaxy at the galaxy group’s centre and the QSO which are connected by a very faint bridge of ionized gas. Thus, the ENLR may be linked to the vivid group environment leading to gravitational interaction with several major or minor galaxies over short periods of time.

4.2.3 Illumination or interactions with the inter-group medium?
Another possibility for the origin of the ENLR morphology around PG 1307+085 is an ongoing interaction of the host galaxy with the diffuse inter-group medium (IGM). The systemic redshift of the host galaxy differs from the redshift of the central group galaxy by \( \sim 350 \text{ km s}^{-1} \) implying that it moves with significant speed through the IGM. Ionized gas tails behind galaxies due to ram-pressure stripping of their gas are well-known phenomena in groups and clusters (e.g. Chung et al. 2007; Fumagalli et al. 2014) and large filamentary structures of gas have been observed in cool-core clusters (e.g. Tremblay et al. 2015, and reference therein). Thus, it is possible that either ram pressure is pushing the remaining gas out of the QSO host or that the galaxy has hit a higher density IGM cloud/filament and is piling up the gas.

In particular the (likely) low gas-phase metallicity together with the strong velocity gradient towards the south-west direction suggest an ongoing mixing of the gas with the surrounding IGM. The velocity gradient shows that the radial velocity of the most dis-
tant ionized gas clouds converges to the systematic velocity of the group. This would be common for both gas inflow and outflow sce-
arios because the gas will be confined by the ambient gas pressure anyway at large distances from the QSO. The gas phase metallicity cannot be used to discriminate between the two scenarios as it will be mixed with the IGM in both cases. Such a mixing is observed in the large ENLRs around powerful radio-loud AGN (e.g. Fu & Stockton 2006) where the radio jet is likely driving a shock front through the IGM.

While luminous AGN with low NLR gas-phase metallicites are rare (e.g. Groves et al. 2006), another QSO, HE 2158–0107, with very similar characteristics has been studied by Husemann et al. (2011). Similar to PG 1307+085, the ionized gas around that QSO exhibits a low [N II]/H \( \alpha \) ratio, implying low metallicities, and a large ENLR extending \( \gtrsim 30 \) kpc beyond the host galaxy. It is unclear whether the QSO is linked to a galaxy group such as PG 1307+085, but it is possible that the origin of the ENLR for both objects is the same. HE 2158–0107 appears to be more strongly offset from the \( M_{\text{BH}}–\text{spheroid} \) relations towards higher BH masses. This may point either to a different formation mech-
anism or a different evolutionary phase in the process that is also responsible for producing their large ENLR. Currently, a detailed systematic study of ENLR around early-type/elliptical QSOs hosts is missing to test how common group interactions are among this specific population and what role those interactions have for the overall evolution of those galaxies.

5 SUMMARY
In this article we present deep optical integral-field spectroscopy with MUSE of the luminous radio-quiet QSO PG 1307+085. The combination of high spatial resolution and a wide FoV obtained with MUSE is essential to simultaneously characterize the large-
scale distribution and properties of the warm ionized gas and the compact elliptical host galaxy underneath the bright QSO. We study the properties of this luminous QSO in unprecedented detail. Our findings can be summarized as follows:

(i) We resolve the underlying host galaxy and measure a stel-
ar velocity dispersion of \( \sigma = 155 \pm 19 \text{ km s}^{-1} \). This places PG 1307+085 still within the scatter of the local \( M_{\text{BH}}–\sigma \) relation based on the reverberation-mapped BH mass, but slightly offset by \( \sim 0.3 \text{ dex} \) towards a higher BH with respect to the mean relation. It is unclear whether PG 1307+085 continues to move away from the mean relation or that the spheroid growth will eventually overtake the BH growth again moving the system back towards the relation.

(ii) We detect an ENLR with a complex morphology that ex-
teas at least out to \( \gtrsim 30 \) kpc from the QSO. In addition, we also reach a very low surface brightness detection limit to identify an ionized gas bridge between PG 1307+085 and a more massive
The MUSE view of QSO PG 1307+085

Acknowledgements

We thank the referee for very instructive comments and suggestions that improved the clarity of the manuscript. We would like to thank Brent Groves and Stefanie Komossa for their help and valuable discussions about AGN photoionization models and their interpretation. These observations would not have been possible with enthusiasm and support of the staff at Paranal and the entire MUSE team, in particular Roland Bacon as the PI of the instrument. We thank Jakob Walcher for the continuous support for the development of PyParadise. The AGN Fe template spectrum of I Zw 1 was kindly provided by Todd Boroson. VNB acknowledges assistance from the National Science Foundation (NSF) Research at Undergraduate Institutions (RUI) grant AST-1312926 and support for program number HST-AR-12625.11-A, provided by NASA through a grant from the Space Telescope Science Institute, particularly Roland Bacon as the PI of the instrument.
