Summary
Even in the simple one-factor credit portfolio model that underlies the Basel II regulatory capital rules coming into force in 2007, the exact contributions to credit value-at-risk can only be calculated with Monte-Carlo simulation or with approximation algorithms that often involve numerical integration. As this may require a lot of computational time, there is a need for approximate analytical formulae. In this note, we develop formulae according to two different approaches: the granularity adjustment approach initiated by M. Gordy and T. Wilde, and a semi-asymptotic approach. The application of the formulae is illustrated with a numerical example.

Keywords
One-factor model, capital charge, granularity adjustment, quantile derivative.
1 Introduction

In the past two years, one-factor models\(^1\) for credit portfolio risk have become popular. On the one side, they can rather readily be handled from a computational point of view, and, in particular, allow to avoid lengthy Monte Carlo simulations which in general are needed when dealing with more sophisticated credit risk models. On the other side, they are capable to incorporate simple dependence structures which are to a certain degree sufficient for a rudimentary form of credit risk management.

Often, one-factor models admit a decomposition of the portfolio loss variable into a monotonic function of the factor and a residual. The former part of the decomposition is called systematic risk whereas the latter part is called specific or idiosyncratic risk. Sometimes, the portfolio loss variable converges in some sense to a monotonic function of the factor. This observation can be used as point of departure for analytic approximations of important statistics of the portfolio like quantiles of the portfolio loss variable (value-at-risk, VaR).

Gordy (2003) was the first to suggest this approach which he called granularity adjustment for the one-factor model credit portfolio that underlies the Basel II regulatory capital rules coming into force in 2007 (see BCBS, 2004). Then it was refined by Wilde (2001)\(^2\) and Pykhtin and Dev (2002). Only recently, Martin and Wilde (2002a) observed that the results by Gouriéroux et al. (2000) make feasible an easier and more systematic way to derive the adjustments. In the following (Section 2), we reexamine the granularity adjustment in the one-factor model and develop new formulae for computing adjustments at the transaction level (Corollary 2.4). Additionally, in Section 3 we present a new alternative semi-asymptotic approach to capital charges at transaction level which relies on a limiting procedure applied to a part of the portfolio only. In contrast to the granularity adjustment approach, the semi-asymptotic approach is able to capture fully the effects of exposure concentrations on the risk contributions of single transactions. Section 4 provides a numerical example. We conclude with a short summary in Section 5.

2 The granularity adjustment approach

In order to explain the approach we will follow, we consider two random variables \(L\) and \(X\). \(L\) denotes the portfolio loss whereas \(X\) reflects the value of an economic factor which causes the dependence between the different transactions building up the portfolio. The conditional expectation of \(L\) given \(X\), \(E[L \mid X]\), is considered the systematic part of the

\[^1\]See Frey and McNeil (2004) for an overview of credit modeling methodologies.

\(^2\)The authors thank Tom Wilde for stimulating the writing of this paper and for useful comments on its first version.
portfolio loss. This can be motivated by the decomposition

\[ L = E[L | X] + L - E[L | X] \]  

which leads to

\[ \text{var}[L] = E[\text{var}[L | X]] + \text{var}[E[L | X]] \]

\[ = E[\text{var}[L - E[L | X] | X]] + \text{var}[E[L | X]], \]  

where \( \text{var} \) denotes variance and \( \text{var}[\cdot | X] \) means conditional variance. Under the assumption that conditional on the value of the economic factor \( X \) the elementary transactions in the portfolio are independent, the term \( E[\text{var}[L | X]] \) in (2.2) is likely to converge to zero with a growing number of transactions in the portfolio. Therefore, the specific risk \( L - E[L | X] \) of the portfolio may be considered incremental and small compared to the systematic risk \( E[L | X] \). Note that by the factorization lemma \( E[L | X] \) may be written as \( g(X) \) with some appropriately chosen function \( g \). This becomes interesting when \( g \) turns out to be monotonic since in this case values for some statistics of \( E[L | X] \) like quantiles can be easily computed from the corresponding statistics of \( X \). We fix this as a formal assumption.

**Assumption 2.1** *The conditional expectation of \( L \) given the factor \( X \) can be written as* 

\[ E[L | X] = g(X), \]

*where \( g \) is continuous and strictly increasing or decreasing. The distribution of \( X \) is continuous, i.e. \( P[X = x] = 0 \) for all \( x \).*

For \( \alpha \in (0, 1) \) and any random variable \( Y \), define the \( \alpha \)-quantile of \( Y \) by

\[ q_\alpha(Y) = \inf \{ y \in \mathbb{R} : P[Y \leq y] \geq \alpha \}. \]  

(2.3)

As \( L \) is interpreted as a portfolio loss variable, we are interested in high quantiles of \( L \), i.e. in the case of \( \alpha \) being close to 100% like \( \alpha = 99.9\% \) as in Basel II. Then the value of the quantile can be considered the amount of capital necessary to keep the portfolio holder solvent with a very high probability. In this context, \( q_\alpha(L) \) is also called \emph{value-at-risk} at level \( \alpha \) of the portfolio loss.

The granularity adjustment approach to the calculation of the \( \alpha \)-quantile \( q_\alpha(L) \) of the portfolio loss is essentially a second order Taylor expansion. Observing that \( L = E[L | X] + h (L - E[L | X]) \) for \( h = 1 \), this can be seen with the following short calculation:

\[ q_\alpha(L) = q_\alpha(E[L | X] + h (L - E[L | X]))\bigg|_{h=1} \]

\[ \approx q_\alpha(E[L | X]) + \frac{\partial q_\alpha}{\partial h}(E[L | X] + h (L - E[L | X]))\bigg|_{h=0} \]

\[ + \frac{1}{2} \frac{\partial^2 q_\alpha}{\partial h^2}(E[L | X] + h (L - E[L | X]))\bigg|_{h=0}. \]  

(2.4)

2
The derivatives of \( q_\alpha (E[L | X] + h (L - E[L | X])) \) with respect to \( h \) can be calculated thanks to results by Gouriéroux et al. (2000) (see Martin and Wilde, 2002b, for the derivatives of arbitrary large orders). This way, we obtain

\[
\frac{\partial q_\alpha}{\partial h} (E[L | X] + h (L - E[L | X])) \bigg|_{h=0} = E[L - E[L | X] | E[L | X] = q_\alpha (E[L | X])]
\]

\[
= 0,
\]

where (2.5) follows from Assumption 2.1, since \( q_\alpha (E[L | X]) = g(q_\alpha (X)) \) if \( g \) is increasing, and \( q_\alpha (E[L | X]) = g(q_{1-\alpha} (X)) \) if \( g \) is decreasing. Under Assumption 2.1, \( E[L | X] \) has a density if \( X \) has a density \( h_X \). If this density of \( E[L | X] \) is denoted by \( \gamma_L \), it can be determined according to

\[
\gamma_L(y) = h_X(g^{-1}(y)) \left| g'(g^{-1}(y)) \right|^{-1}.
\]

With regard to the second derivative in (2.4), we obtain by means of the corresponding result of Gouriéroux et al. (2000)

\[
\frac{\partial^2 q_\alpha}{\partial h^2} (E[L | X] + h (L - E[L | X])) \bigg|_{h=0} = -\frac{\partial \text{var} \{L | X = g^{-1}(x)\}}{\partial x} \bigg|_{x=g(q_\beta(X))}
\]

\[
- \frac{\text{var} \{L | X = q_\beta(X)\}}{\gamma_L(g(q_\beta(X)))} \frac{\partial \gamma_L}{\partial x} \bigg|_{x=g(q_\beta(X))},
\]

with \( \beta = \alpha \), if \( g \) is increasing, and \( \beta = 1 - \alpha \) if \( g \) is decreasing.

In order to be able to carry out numerical calculations by means of (2.4) and (2.7), we have to fix a stochastic model, the one-factor model in our case. Define the indicator variable \( 1_D \) of the event \( D \) by

\[
1_D(\omega) = \begin{cases} 1, & \omega \in D, \\ 0, & \omega \notin D. \end{cases}
\]

We then define the portfolio loss \( L_n \) by

\[
L_n = L_n(u_1, \ldots, u_n) = \sum_{i=1}^{n} u_i 1_{D_i},
\]

\[
D_i = \{ \sqrt{\rho_i} X + \sqrt{1 - \rho_i} \xi_i \leq c_i \},
\]

where \( u_i \geq 0, i = 1, \ldots, n \), denotes the weight or the exposure of asset \( i \) in the portfolio, \( 0 < \rho_i < 1 \) and \( c_i \geq 0, i = 1, \ldots, n \), are constants, and \( X, \xi_1, \ldots, \xi_n \) are independent random variables with continuous distributions. As mentioned above, \( X \) is interpreted as an economic factor that influences all the assets in the portfolio but to different extents.

The so-called asset correlation \( \rho_i \) measures the degree of the \( i \)-th asset’s exposure to the systematic risk expressed by \( X \). The random variables \( \xi_i \) are assumed to model the
idiosyncratic (or specific) risk of the assets. The event \( D_i \) given by (2.9b) can then be interpreted as the event that default occurs with the \( i \)-th asset because its value falls below some critical threshold.

It is easy to show that in this case Assumption 2.1 holds with decreasing \( g = g_n \) where \( g_n(x) \) is given by

\[
g_n(x) = \sum_{i=1}^{n} u_i \Phi \left( \frac{c_i - \sqrt{\rho_i} x}{\sqrt{1 - \rho_i}} \right). \tag{2.10}
\]

(2.9a) implies that

\[
\text{var} [L_n | X = x] = \sum_{i=1}^{n} u_i^2 \left( \frac{c_i - \sqrt{\rho_i} x}{\sqrt{1 - \rho_i}} \right) \left( 1 - \Phi \left( \frac{c_i - \sqrt{\rho_i} x}{\sqrt{1 - \rho_i}} \right) \right). \tag{2.11}
\]

Under the additional assumption that \( \inf_i c_i > -\infty \) and \( \sup_i \rho_i < 1 \), it follows from (2.11) that in case of i.i.d. \( \xi_1, \xi_2, \ldots \) and \( X \) we have

\[
\lim_{n \to \infty} E \left[ \text{var} [L_n | X] \right] = 0 \tag{2.12a}
\]

if and only if\(^3\)

\[
\lim_{n \to \infty} \sum_{i=1}^{n} u_i^2 = 0. \tag{2.12b}
\]

We will see below (Remark 2.3) that small values of \( \sum_{i=1}^{n} u_i^2 \) correspond to the case where the portfolio is well diversified in the sense that there are no essential exposure concentrations.

By (2.12a) and (2.12b), in case of large portfolios the systematic part \( \text{var} [E[L_n | X]] \) of the loss variance \( \text{var} [L_n] \) (cf. (2.2)) is the essential part of the variance. Hence, in this case approximating \( L_n \) by \( E[L_n | X] \) seems reasonable. This observation suggests approximating \( q_a(L_n) \) with the right-hand side of (2.3), where \( E[L_n | X] \) is given by \( g_n(X) \) with \( g_n(x) \) defined by (2.10).

Let us now specify the distributions of \( X, \xi_1, \xi_2, \ldots, \xi_n \) as all being the standard normal distributions. This implies

\[
g_n(x) = \sum_{i=1}^{n} u_i \Phi \left( \frac{c_i - \sqrt{\rho_i} x}{\sqrt{1 - \rho_i}} \right) \tag{2.13a}
\]

and

\[
\text{var} [L_n | X = x] = \sum_{i=1}^{n} u_i^2 \left( \Phi \left( \frac{c_i - \sqrt{\rho_i} x}{\sqrt{1 - \rho_i}} \right) - \Phi \left( \frac{c_i - \sqrt{\rho_i} x}{\sqrt{1 - \rho_i}} \right)^2 \right) \tag{2.13b}
\]

\(^3\)Of course, here we admit an additional dependence of \( u_i \) on \( n \), i.e. \( u_i = u_{i,n} \).
where $\Phi$ denotes the distribution function of the standard normal distribution. Since $g_n$ is decreasing, we obtain from (2.6) and (2.13a) for the density $\gamma_{L_n}$ of $E[L_n | X]$

$$
\gamma_{L_n}(x) = -\frac{\phi(g_n^{-1}(x))}{g_n'(g_n^{-1}(x))}
$$

(2.14a)

and

$$
\frac{\partial \gamma_{L_n}}{\partial x}(x) = \frac{\phi(g_n^{-1}(x)) g_n''(g_n^{-1}(x)) - \phi'(g_n^{-1}(x)) g_n'(g_n^{-1}(x))}{g_n'(g_n^{-1}(x))^3},
$$

(2.14b)

with $\phi(x) = (\sqrt{2\pi})^{-1} e^{-x^2/2}$ denoting the density of the standard normal distribution.

We are now in a position to specialize (2.4) for the case of normally distributed underlying random variables. Plugging in the expressions from (2.13b), (2.14a), and (2.14b) into (2.7) and then the resulting expression for the second derivative of the quantile into (2.4) yields the following formula.

**Proposition 2.2** Let $L_n$ be the portfolio loss variable as defined in (2.9a). Assume that the economic factor $X$ and the idiosyncratic risk factors $\xi_1, \ldots, \xi_n$ are independent and standard normally distributed. Fix a confidence level $\alpha \in (0, 1)$. Then the second order Taylor approximation of the quantile $q_\alpha(L_n)$ in the sense of (2.4) can be calculated according to

$$
q_\alpha(L_n) \approx g_n(q_1-\alpha(X))
+ \left( \sum_{i=1}^{n} u_i^2 \sqrt{1-\rho_i} \phi\left( \frac{c_i-\sqrt{\rho_i}q_1-\alpha(X)}{\sqrt{1-\rho_i}} \right) \left( 1 - 2 \Phi\left( \frac{c_i-\sqrt{\rho_i}q_1-\alpha(X)}{\sqrt{1-\rho_i}} \right) \right) \right.
+ \left( q_1-\alpha(X) + \frac{g_n'(q_1-\alpha(X))}{g_n(q_1-\alpha(X))} \right) \sum_{i=1}^{n} u_i^2 \left( \Phi\left( \frac{c_i-\sqrt{\rho_i}q_1-\alpha(X)}{\sqrt{1-\rho_i}} \right) - \Phi\left( \frac{c_i-\sqrt{\rho_i}q_1-\alpha(X)}{\sqrt{1-\rho_i}} \right)^2 \right) \right)
\times \left( 2 g_n'(q_1-\alpha(X)) \right)^{-1},
$$

(2.15)

with $\phi$ and $\Phi$ denoting the density and the distribution function respectively of the standard normal distribution.

**Remark 2.3 (Herfindahl index)** Consider the following special case of (2.15):

$$
\rho_i = \rho, \quad \text{and} \quad c_i = c, \quad i = 1, \ldots, n, \quad \sum_{i=1}^{n} u_i = 1.
$$

Here the $u_i$ have to be interpreted as the relative weights of the assets in the portfolio.
\[ q_\alpha(L_n) \approx \Phi\left( \frac{c-\sqrt{\rho}q_{1-\alpha}(X)}{\sqrt{1-\rho}} \right) - \left( 2 \sqrt{\frac{\rho}{1-\rho}} \phi\left( \frac{c-\sqrt{\rho}q_{1-\alpha}(X)}{\sqrt{1-\rho}} \right) \right) - \sum_{i=1}^{n} u_i^2 
\times \left( \sqrt{\frac{\rho}{1-\rho}} \phi\left( \frac{c-\sqrt{\rho}q_{1-\alpha}(X)}{\sqrt{1-\rho}} \right) \right) \] 
\[ + \Phi\left( \frac{c-\sqrt{\rho}q_{1-\alpha}(X)}{\sqrt{1-\rho}} \right) \Phi\left( \frac{\sqrt{\rho}q_{1-\alpha}(X)-c}{\sqrt{1-\rho}} \right) \] 

(2.16)

The case \( u_i = 1/n \) for all \( i \) is particularly important as it describes a completely homogeneous portfolio without concentrations. If the \( u_i \) are not all equal, \( \left( \sum_{i=1}^{n} u_i^2 \right)^{-1} \) is approximately the equivalent portfolio size that would render the portfolio completely homogeneous. Assume that the \( i \)-th asset has absolute exposure \( v_i \). Then its relative weight \( u_i \) is given by

\[ u_i = \frac{v_i}{\sum_{j=1}^{n} v_j} \]

In this case the above introduced equivalent portfolio size reads \( \frac{\left( \sum_{j=1}^{n} v_j \right)^2}{\sum_{j=1}^{n} v_j^2} \). This quantity is known as Herfindahl index. Gordy (2003) suggested the Herfindahl index as a key constituent for constructing equivalent homogeneous portfolios. (2.16) yields strong support for this suggestion.

Recall that in Proposition 2.2 not only \( q_\alpha(L_n) = q_\alpha(L_n(u_1, \ldots, u_n)) \) is a function of the weights \( u_1, \ldots, u_n \) but that also the function \( g_n \) depends on \( u_1, \ldots, u_n \) via (2.13a). A closer inspection of (2.15) reveals that the right-hand side of the equation (as function of the weight vector \( (u_1, \ldots, u_n) \)) is positively homogeneous of order 1. By Euler’s theorem on the representation of homogeneous functions as a weighted sum of the partial derivatives, we can obtain canonical approximate capital charges on transaction or sub-portfolio level which add up to the approximate value-at-risk (cf. Litterman, 1996; Tasche, 1999). The capital charges will thus be approximations to the terms \( u_j \frac{\partial q_\alpha(L_n)}{\partial u_j}, j = 1, \ldots, n \).

These approximate capital charges do not enjoy the portfolio invariance which is the great advantage of the asymptotic capital charges suggested by Gordy (2003). Portfolio invariance in Gordy’s sense means that the capital charges of the single assets depend upon the characteristics of the assets under consideration only but not upon the portfolio composition. In particular, when dealing with portfolio invariant capital charges, it does not really matter whether an asset takes on 50% of the total portfolio exposure or 0.05% only, because the capital charge would increase only linearly. However, in order to capture exposure concentration effects, the capital charge of an asset should grow more than linearly with the exposure as soon as the relative weight of the asset in the portfolio exceeds some critical value. Therefore, as portfolio invariance has the effect to entail capital charges which are not sensitive to concentrations in the portfolio, the partial derivatives approach has got its own attractiveness.
Corollary 2.4 The partial derivative with respect to $u_j$ of the approximate quantile $q_\alpha(L_n) = q_\alpha(L_n(u_1, \ldots, u_n))$ as provided by the right-hand side of (2.15) is given by

$$
\frac{\partial q_\alpha(L_n)}{\partial u_j} \approx \Phi \left( \frac{c_j - \sqrt{\rho_j} q_{1-\alpha}(X)}{\sqrt{1 - \rho_j}} \right) + (2 g'_n(q_{1-\alpha}(X))^2)^{-1} \left( 2 u_j A_j g'_n(q_{1-\alpha}(X)) - B_j \sum_{i=1}^n u_i^2 A_i \right) + \left( E_j - \frac{2 B_j g''_n(q_{1-\alpha}(X))}{g'_n(q_{1-\alpha}(X))} \right) \sum_{i=1}^n u_i^2 D_i \tag{2.17}
$$

with

$$
A_i = \sqrt{\frac{\rho_i}{1 - \rho_i}} \phi \left( \frac{c_i - \sqrt{\rho_i} q_{1-\alpha}(X)}{\sqrt{1 - \rho_i}} \right) \left( 1 - 2 \Phi \left( \frac{c_i - \sqrt{\rho_i} q_{1-\alpha}(X)}{\sqrt{1 - \rho_i}} \right) \right),
$$

$$
B_i = -\phi \left( \frac{c_i - \sqrt{\rho_i} q_{1-\alpha}(X)}{\sqrt{1 - \rho_i}} \right) \sqrt{\frac{\rho_i}{1 - \rho_i}},
$$

$$
D_i = \Phi \left( \frac{c_i - \sqrt{\rho_i} q_{1-\alpha}(X)}{\sqrt{1 - \rho_i}} \right) - \Phi \left( \frac{\sqrt{\rho_i} q_{1-\alpha}(X) - c_i}{\sqrt{1 - \rho_i}} \right)^2,
$$

$$
E_i = \phi \left( \frac{c_i - \sqrt{\rho_i} q_{1-\alpha}(X)}{\sqrt{1 - \rho_i}} \right) \frac{\rho_i}{1 - \rho_i} \sqrt{\frac{\rho_i}{1 - \rho_i}} \sqrt{\frac{\rho_i}{1 - \rho_i}}.
$$

Proposition 2.2 and Corollary 2.4 provide a way for the simultaneous determination of economic capital charges in a top-down approach. First, by means of Proposition 2.2 an approximation for the portfolio value-at-risk is calculated. Then, by means of Corollary 2.4 approximations for the partial derivatives of the portfolio value-at-risk can be found. The derivatives are related to the capital charges via

$$
\text{Capital charge of asset } j = u_j \frac{\partial q_\alpha(L_n)}{\partial u_j}. \tag{2.18}
$$

However, there is a caveat in using this approach. Its accuracy is subject to the validity of (2.12b) which will be questionable if there are very large exposures in the portfolio. In this case, the semi-asymptotic approach we will explain in Section 3 might be more appropriate.

3 The semi-asymptotic approach

We consider here a special case of (2.9a) where $\rho_1 = \tau$, $c_1 = a$ but $\rho_i = \rho$ and $c_i = c$ for $i > 1$, and $\sum_{i=1}^n u_i = 1$. Additionally, we assume that $u_1 = u$ is a constant for all $n$ but that $u_2, u_3, \ldots$ fulfills (2.12b).
In this case, the portfolio loss can be represented by

$$L_n(u, u_2, \ldots, u_n) = u 1_{\{\sqrt{\tau} X + \sqrt{1-\tau} \xi \leq a\}} + (1-u) \sum_{i=2}^{n} u_i 1_{\{\sqrt{\rho} X + \sqrt{1-\rho} \xi_i \leq c\}}$$  \hspace{1cm} (3.1)$$

with $\sum_{i=2}^{n} u_i = 1$. Transition to the limit for $n \to \infty$ in (3.1) in the sense of (2.12b) leads to the *semi-asymptotic* percentage loss function

$$L(u) = u 1_D + (1-u) Y$$  \hspace{1cm} (3.2)$$

with $D = \{\sqrt{\tau} X + \sqrt{1-\tau} \xi \leq a\}$ and $Y = P[\xi \leq \frac{c-\sqrt{\tau} x}{\sqrt{1-\rho}}]$. Note that the transition from (3.1) to (3.2) is *semi*-asymptotic only as we keep the first term on the right-hand side of (3.1) unchanged such that it reappears in (3.2). Of course, a natural choice for $\tau$ might be $\tau = \rho$, the mean portfolio asset correlation.

**Definition 3.1** The quantity

$$u P[D \mid L(u) = q_\alpha(L(u))]$$

is called semi-asymptotic capital charge (at level $\alpha$) of the loan with exposure $u$ (as percentage of total portfolio exposure) and default event $D$ as in (3.1).

The capital charges we suggest in Definition 3.1 have to be calculated separately, i.e. for each asset an own model of type (3.2) has to be regarded. This corresponds to a bottom-up approach since the total capital requirement for the portfolio must be determined by adding up all the capital charges of the assets. Note that the capital charges of Definition 3.1 are not portfolio invariant in the sense of Gordy (2003). However, in contrast to the portfolio invariant charges, the semi-asymptotic charges take into account concentration effects. In particular, their dependence on the exposure $u$ is not merely linear since also the factor $P[D \mid L(u) = q_\alpha(L(u))]$ depends on $u$. Definition 3.1 is in line with the general definition of VaR contributions (cf. Litterman, 1996; Tasche, 1999) since (3.2) can be considered a two-assets portfolio model.

In the following, we will assume that the conditional distribution functions $F_0$ and $F_1$ of $Y$ given $1_D = 0$ and $1_D = 1$ respectively have densities which are continuous and concentrated on the interval $(0,1)$. Call these densities $f_0$ and $f_1$, i.e.

$$P[Y \leq y \mid 1_D = i] = F_i(y) = \int_{-\infty}^{y} f_i(t) \, dt, \quad y \in \mathbb{R}, \ i = 0, 1.$$  \hspace{1cm} (3.3)$$

In this case, the distribution function and the density of $L(u)$ are given by

$$P[L(u) \leq z] = p F_1 \left( \frac{z-u}{1-u} \right) + (1-p) F_0 \left( \frac{z}{1-u} \right)$$  \hspace{1cm} (3.4a)$$
\[
\frac{\partial P[L(u) \leq z]}{\partial z} = (1 - u)^{-1} \left( p f_1\left( \frac{z - u}{1 - u} \right) + (1 - p) f_0\left( \frac{z}{1 - u} \right) \right) \tag{3.4b}
\]
respectively, where \( p = P[D] \) is the default probability of the loan under consideration. By means of (3.4a) and (3.4b), the quantile \( q_\alpha(L(u)) \) can be numerically computed. For the conditional probability which is part of Definition 3.1, we obtain
\[
P[D | L(u) = z] = \frac{p f_1\left( \frac{z - u}{1 - u} \right)}{p f_1\left( \frac{z - u}{1 - u} \right) + (1 - p) f_0\left( \frac{z}{1 - u} \right)}. \tag{3.5}
\]
If, similarly to the situation of (2.13a), we assume that \( X \) and \( \xi \) are independent and both standard normally distributed, we obtain for the conditional densities in (3.3)
\[
f_1(z) = \begin{cases} 
\frac{f(z)}{p} \Phi \left( \sqrt{1 - \tau}^{-1} \left( \Phi^{-1}(p) + \sqrt{\tau} \left( \frac{\sqrt{1 - \rho} \Phi^{-1}(z) - c}{\sqrt{\rho}} \right) \right) \right), & z \in (0, 1) \\
0, & \text{otherwise}
\end{cases} \tag{3.6a}
\]
and
\[
f_0(z) = \begin{cases} 
\frac{f(z)}{1 - p} \Phi \left( - \sqrt{1 - \tau}^{-1} \left( \Phi^{-1}(p) + \sqrt{\tau} \left( \frac{\sqrt{1 - \rho} \Phi^{-1}(z) - c}{\sqrt{\rho}} \right) \right) \right), & z \in (0, 1) \\
0, & \text{otherwise}
\end{cases} \tag{3.6b}
\]
with
\[
f(z) = \begin{cases} 
\sqrt{\rho}/(1 - \rho) \exp \left( 1/2 \left( \Phi^{-1}(z)^2 - \left( \frac{\sqrt{1 - \rho} \Phi^{-1}(z) - c}{\sqrt{\rho}} \right)^2 \right) \right), & z \in (0, 1) \\
0, & \text{otherwise}
\end{cases} \tag{3.6c}
\]
Note that \( p = \Phi(a) \) in (3.6a) and (3.6b). Denote by \( \Phi_2(\cdot, \cdot; \theta) \) the distribution function of the bivariate standard normal distribution with correlation \( \theta \). Then, for the conditional distribution functions corresponding to (3.6a) and (3.6b), we have
\[
F_1(z) = \begin{cases} 
1 - p^{-1} \Phi_2(a, \frac{c - \sqrt{1 - \rho} \Phi^{-1}(z)}{\sqrt{\rho}}; \sqrt{\tau}), & z \in (0, 1) \\
0, & \text{otherwise}
\end{cases} \tag{3.7a}
\]
and
\[
F_0(z) = \begin{cases} 
(1 - p)^{-1} \Phi_2(-a, \frac{c - \sqrt{1 - \rho} \Phi^{-1}(z)}{\sqrt{\rho}}; \sqrt{\tau}), & z \in (0, 1) \\
0, & \text{otherwise}
\end{cases} \tag{3.7b}
\]
Unfortunately, the capital charges from Definition 3.1 do not yield reasonable values in all cases. Indeed, considering the relation of the default probability \( p \) and the confidence level \( \alpha \), we easily arrive at the following result.
Proposition 3.2 For \( L(u) \) defined by (3.2) with \( F_1(0) = 0 \), we have

\[
\lim_{u \to 1} q_\alpha(L(u)) = \begin{cases} 
1, & p > 1 - \alpha \\
0, & p \leq 1 - \alpha.
\end{cases}
\]

The proof of Proposition 3.2 is presented in Appendix A. Under slightly stronger assumptions than in Proposition 3.2, the limiting behavior of \( q_\alpha(L(u)) \) is inherited by \( P[D \mid L(u) = q_\alpha(L(u))] \).

Proposition 3.3 Assume that the densities in (3.3) are positive in \((0,1)\). Then for \( L(u) \) defined by (3.2), we have

\[
\lim_{u \to 1} P[D \mid L(u) = q_\alpha(L(u))] = \begin{cases} 
1, & p > 1 - \alpha \\
0, & p < 1 - \alpha.
\end{cases}
\]

The proof of Proposition 3.3 is also given in Appendix A. In addition, Remark A.2 explains why there is no statement on the case \( \alpha = 1 - p \) in Proposition 3.3.

By Proposition 3.3 we see that in case \( p < 1 - \alpha \) it would be worthwhile to concentrate all the exposure to one loan. This is another appearance of a well-known deficiency of value-at-risk. Under value-at-risk portfolio risk measurement, putting all the risk into an event with very small probability can quite drastically reduce capital charges. In order to avoid this phenomenon, other risk measures like Expected Shortfall (cf. Acerbi and Tasche, 2002) have to be used. For Expected Shortfall, in Definition 3.1 the conditional probability \( P[D \mid L(u) = q_\alpha(L(u))] \) has to be replaced by \( P[D \mid L(u) \geq q_\alpha(L(u))] \). See Tasche and Theiler (2004) for details of this approach.

4 Numerical example

For the purpose of illustrating the previous sections, we consider a numerical example in the framework of Section 3. This means that there is a portfolio driven by systematic risk only (the variable \( Y \) in (3.2)) which is enlarged with an additional loan (the indicator \( 1_D \) in (3.2)).

The portfolio modeled by \( Y \) has a quite moderate credit standing which is expressed by its expected loss \( E[Y] = 0.025 = \Phi(c) \). However, we assume that the additional loan enjoys a quite high credit-worthiness as we set \( p = P[D] = 0.002 = \Phi(a) \). The asset correlation \( \rho \) of the portfolio with the systematic factor and the asset correlation \( \tau \) of the additional loan with the systematic factor are chosen according to the current Basel II proposal for corporate loan portfolios (BCBS, 2004), namely \( \rho = 0.154 \) and \( \tau = 0.229 \).
In order to draw Figure 1, the risk of the portfolio loss variable \( L(u) \), as defined by (3.2), is regarded as a function of the relative weight \( u \) of the new loan in the portfolio. Risk then is calculated as true Value-at-Risk (VaR) at level 99.9\% (i.e. \( q_{0.999}(L(u)) \)), as the granularity adjustment approximation to \( q_{0.999}(L(u)) \) according to (2.4), and in the manner\(^4\) of the Basel II Accord (cf. BCBS, 2004). The values of VaR are computed by solving numerically for \( z \) the equation

\[
P[L(u) \leq z] = \alpha, \tag{4.1}
\]

with \( P[L(u) \leq z] \) given by (3.4a), (3.7a), and (3.7b). The granularity adjustment approximation is computed by applying (2.15) to (3.1) and taking the limit with \( n \to \infty \). The Basel II risk weight function can be interpreted as the first order version of (2.4) which yields the straight line

\[
u \mapsto u \Phi \left( \frac{a - \sqrt{\tau} q_{1-\alpha}(X)}{\sqrt{1-\tau}} \right) + (1-u) \Phi \left( \frac{c - \sqrt{\rho} q_{1-\alpha}(X)}{\sqrt{1-\rho}} \right). \tag{4.2}
\]

Note that for (4.2) we make use of a stylized version of the Basel II risk weight function as we chose arbitrarily the correlation \( \rho \). The Basel I risk weight function is a constant at 8\% that should not be compared to the afore-mentioned functions since it was defined without recourse to mathematical methods. For that reason it has been omitted from Figure 1.

From Figure 1, we see that, up to a level of 2\% relative weight of the new loan, both the granularity adjustment approach and the Basel II approach yield precise approximations to the true portfolio VaR. Beyond that level the approximations lose quality very fast. Of course, this observation does not surprise since both the granularity adjustment approach and the Basel II are based on the assumption that there is no concentration in the portfolio. Intuitively, this condition should be violated when the concentration of the additional loan increases too much.

Figure 2 illustrates the relative contribution of the new loan to the risk of the portfolio loss variable \( L(u) \). The contribution is considered a function of the relative weight \( u \) of the new loan in the portfolio and calculated according to four different methods. The first method relates to the relative contribution to true portfolio VaR, defined as the ratio of the contribution to VaR according to Definition 3.1 and portfolio VaR, i.e. the function

\[
u \mapsto \frac{u P[D \mid L(u) = q_{\alpha}(L(u))]}{q_{\alpha}(L(u))}, \tag{4.3}
\]

where the conditional probability has to be evaluated by means of (3.5), (3.6a), and (3.6b). Secondly, the relative contribution is calculated as the fraction with the granularity adjustment contribution according to Corollary 2.4 applied to (3.1) (with \( n \to \infty \)) in the

\(^4\)Actually, the regulatory capital requirements according to Basel II are to be calculated as *unexpected losses*, i.e. as differences of quantiles and loss expectations. In this example, risk is calculated as the quantile only, i.e. as sum of expected and unexpected loss in the Basel II sense.
Figure 1: Portfolio risk as function of the relative weight of the additional loan in the setting of Section 3. Comparison of true Value-at-Risk (VaR), granularity adjustment approximation to VaR (GA VaR), and the risk weights according to the Basel II Accord.

The numerator and the granularity adjustment approximation to VaR as for Figure 1 in the denominator. Moreover, curves are drawn for the Basel II approach, i.e. the function

\[ u \mapsto \frac{u \Phi\left(\frac{a - \sqrt{\tau} q_{1-o}(X)}{\sqrt{1-\tau}}\right)}{u \Phi\left(\frac{a - \sqrt{\tau} q_{1-o}(X)}{\sqrt{1-\tau}}\right) + (1 - u) \Phi\left(\frac{c - \sqrt{\tau} q_{1-o}(X)}{\sqrt{1-\rho}}\right)}, \quad (4.4) \]

and the Basel I approach. The latter approach just entails the diagonal as risk contribution curve since it corresponds to purely volume-oriented capital allocation.

Note that in Figure 2 the true VaR curve intersects the diagonal (Basel I curve) just at the relative weight \( u^* \) that corresponds to the minimum risk portfolio \( L(u^*) \). Whereas the granularity adjustment curve yields, up to a relative risk weight of 2% of the additional loan, a satisfying approximation to the true contribution curve, the Basel II curve loses reliability much earlier. Both these approximation curves are completely situated below the diagonal. This fact could yield the misleading impression that an arbitrarily high exposure to the additional loan still improves the risk of portfolio. However, as the true VaR curve in Figure 2 shows, the diversification effect from pooling with the new loan stops at 7% relative weight. From Figure 1 we see that beyond 7% relative weight of the additional loan the portfolio risk grows dramatically.
Figure 2: Relative risk contribution of new loan as function of the relative weight of the new loan in the setting of Section 3. Comparison of contribution to true Value-at-Risk (VaR), contribution to granularity adjustment approximation to VaR (GA VaR), and the contributions according to the Basel II and Basel I Accords.

5 Conclusions

In the present paper we have extended the granularity approach introduced by Gordy (2003) in a way that takes care of the exact weights of the assets in the portfolio. By calculating the partial derivatives of the resulting approximate portfolio loss quantile and multiplying the results with the asset weights, we can arrive at an approximate capital charge for every asset in the portfolio. In addition, we have introduced the semi-asymptotic approach to one-factor portfolio loss modeling. This approach provides an alternative way to capital charges that accounts for concentrations. By a numerical comparison of these both approaches we have shown that the granularity approach to risk contributions may come up with misleading results if there is a non-negligible concentration in the portfolio. However, also the semi-asymptotic approach yields counter-intuitive results if the probability of default of the loan under consideration is very small. In order to avoid this drawback which is caused by the very nature of value-at-risk, sounder risk measures like Expected Shortfall have to be used.
The proofs of Propositions 3.2 and 3.3 are based on the following simple inequalities for $q_\alpha(L(u))$.

**Lemma A.1** Assume $F_1(0) = 0$. Then for $L(u)$ defined by (3.2), we have

$$q_\alpha(L(u)) \begin{cases} \leq 1 - u, & \text{if } \alpha \leq 1 - p, \\ > u, & \text{if } \alpha > 1 - p. \end{cases}$$

**Proof.** In case $\alpha \leq 1 - p$ we obtain by means of (3.4a)

$$P[L(u) \leq 1 - u] = (1 - p) F_0\left(1 - \frac{u}{1 - u}\right) + p F_1\left(1 - \frac{2u}{1 - u}\right) \geq 1 - p \geq \alpha. \quad (A.1)$$

By the definition of quantiles (see (2.3)), (A.1) implies the first part of the assertion. Assume now $\alpha > 1 - p$. Analogously to (A.1), then we calculate

$$P[L(u) \leq u] = (1 - p) F_0\left(\frac{u}{1 - u}\right) + p F_1(0) \leq 1 - p < \alpha. \quad (A.2)$$

Again by the definition of quantiles, (A.2) yields $q_\alpha(L(u)) > u$ as stated above. □

**Proof of Proposition 3.2** In case $\alpha \leq 1 - p$, Lemma A.1 implies

$$\limsup_{u \to 1} q_\alpha(L(u)) \leq 0, \quad (A.3a)$$

in case $\alpha > 1 - p$ we deduce from Lemma A.1

$$\liminf_{u \to 1} q_\alpha(L(u)) \geq 1. \quad (A.3b)$$

Since $0 \leq q_\alpha(L(u)) \leq 1$, (A.3a) and (A.3b) imply the assertion. □

**Proof of Proposition 3.3** By Lemma A.1 in case $\alpha \leq 1 - p$ we have $q_\alpha(L(u)) \leq 1/2$ for $u > 1/2$ and hence $q_\alpha(L(u)) - u < 0$. This implies

$$f_1\left(\frac{q_\alpha(L(u)) - u}{1 - u}\right) = 0 \quad (A.4)$$

for $u > 1/2$. A closer inspection of the proof of Lemma A.1 reveals that in case $\alpha < 1 - p$ even $0 < q_\alpha(L(u)) < 1 - u$ obtains if $f_0$ is positive. This observation implies $f_0\left(\frac{q_\alpha(L(u))}{1 - u}\right) > 0$. Hence, $\lim_{u \to 1} P[D \mid L(u) = q_\alpha(L(u))] = 0$ follows from (A.3a) and (A.4). Assume now $\alpha > 1 - p$. Then by the positivity assumption on $f_1$, Lemma A.1 implies $1 > q_\alpha(L(u)) > u$. Since $u/(1 - u) > 1$ for $u > 1/2$ we may deduce that

$$f_0\left(\frac{q_\alpha(L(u))}{1 - u}\right) = 0 \quad \text{and} \quad f_1\left(\frac{q_\alpha(L(u)) - u}{1 - u}\right) > 0. \quad (A.5)$$

This implies $P[D \mid L(u) = q_\alpha(L(u))] = 1$ for $u$ enough close to 1. □
Remark A.2 By inspection of the proof of Proposition 3.3 one can observe that
\[ q_{1-p}(L(u)) = 1 - u, \quad u > 1/2. \] (A.6)
As a consequence, \( f_1\left(\frac{q_{1-p}(L(u)) - u}{1-u}\right) \) and \( f_0\left(\frac{q_{1-p}(L(u)) - u}{1-u}\right) \) may equal zero at the same time. Hence, in case \( \alpha = 1 - p \) according to (3.3) the conditional probability \( P[D \mid L(u) = q_{1-p}(L(u))] \) may be undefined for \( u > 1/2 \). For this reason, Proposition 3.3 does not provide a limit statement for the case \( \alpha = 1 - p \).
