ABSTRACT

We report on detection, from observations obtained with the APOGEE spectroscopic survey, of a metal-poor ([Fe/H] = −1.3 dex) field giant star with an extreme Mg-Al abundance ratio ([Mg/Fe] = −0.31 dex; [Al/Fe] = 1.49 dex). Such low Mg/Al ratios are seen only among the second-generation population of globular clusters, and are not present among Galactic disk field stars. The light element abundances of this star, 2M16011638-1201525, suggest that it could have been born in a globular cluster. We explore several origin scenarios, in particular studying the orbit of the star to check the probability of it being kinematically related to known globular clusters. We performed simple orbital integrations assuming the estimated distance of 2M16011638-1201525 and the available six-dimensional phase-space coordinates of 63 globular clusters, looking for close encounters in the past with a minimum distance approach within the tidal radius of each cluster. We found a very low probability that 2M16011638-1201525 was ejected from most globular clusters; however, we note that the best progenitor candidate to host this star is globular cluster ω Centauri (NGC 5139). Our dynamical investigation demonstrates that 2M16011638-1201525 reaches a distance [Zmax] < 3 kpc from the Galactic plane and a minimum and maximum approach to the Galactic center of Rmin < 0.62 kpc and Rmax < 7.26 kpc in an eccentric (e ∼ 0.53) and retrograde orbit. Since the extreme chemical anomaly of 2M16011638-1201525 has also been observed in halo field stars, this object could also be considered a halo contaminant, likely been ejected into the Milky Way disk from the halo. We conclude that, 2M16011638-20152 is also kinematically consistent with the disk but chemically consistent with halo field stars.

1. INTRODUCTION

It is a commonly accepted observational fact that second-generation stars make up a significant fraction of the population of most Galactic globular clusters (GCs, Carretta et al. 2009a,b; Bastian & Lardo 2015), and they display unique inhomogeneities in their abundance of light elements involved in proton-capture processes. The elements C, N, O, F, Na, Al, Mg, and perhaps Si (e.g., Gratton et al. 2012; Mészáros et al. 2015, and references therein) provide useful information about the environment in which they were formed. A fraction of GC populations show a pronounced [Al/Fe] and [Mg/Fe] anti-correlation (e.g., Sneden et al. 2004; Johnson et al. 2005; Marino et al. 2008; Carretta et al. 2009a, 2012; Mészáros et al. 2015), a remarkable characteristic (i.e., a chemical fingerprint) of some particular second generation stars, which are not typically observed in the field, except in some peculiar cases, as described below.

Interestingly, it has been suggested that ∼3% of field stars in the Galaxy show atypical light-element patterns similar to those seen only among the secondary population of Galactic GCs (e.g., Carretta et al. 2010; Martell & Grebel 2010; Martell et al. 2011; Ramírez et al. 2012). They could be explained by the escape of individual stars from those systems (Carretta et al. 2010; Carollo et al. 2013; Fernández Trincado et al. 2013; Carretta 2013; Fernández-Trincado et al. 2015b,c, 2016; Anguiano et al. 2016).

Only a few studies confirm the existence of such stars in the Galactic field, for example: (i) some Aquarius stream stars appear to originate from a globular clus-
2. A PECULIAR GIANT STAR OBSERVED BY APOGEE

The star of interest, 2M16011638-1201525, was found in the Apache Point Observatory Galactic Evolution Experiment (APOGEE, Zasowski et al. 2013; Majewski et al. 2015), a near-infrared spectroscopic survey, part of the Sloan Digital Sky Survey III (SDSS-III; Eisenstein et al. 2011), targeting primarily Milky Way red giants, at a resolution of $R \approx 22,500$, acquired with the APOGEE multi-object spectrograph mounted at the SDSS 2.5m telescope (Gunn et al. 2006). We refer the reader to Holtzman et al. (2015) and Nidever et al. (2015) for detailed information on the data, and the data reduction pipeline.

We turn our attention to the giant star 2M16011638-1201525, with high $[\text{Al/Fe}] = 1.49$ and a strongly depleted $[\text{Mg/Fe}] = -0.31$ (manually confirmed using MOOG$^1$). 2M16011638-1201525 has been identified as part of a sample of $\sim 265$ giant stars originally surveyed spectroscopically by APOGEE in a field centered on $(l, b) = (0, +30)$, having unusual chemical abundances, and a high quality stellar radial velocity. Figure 1 shows a comparison of our results with respect to those derived from 393 giants in 10 GC stars (see Mészáros et al. 2015) and 59 bona fide field nitrogen rich stars giants in the bulge from Schiavon et al. (2016), in particular we show that 2M16011638-1201525 has one of the most extreme combinations of abundances. 2M16011638-1201525 shows a radial velocity (with typical uncertainties of less than 1 km s$^{-1}$) dispersion ($v_{\text{scatter}}$) less than 1 km s$^{-1}$ over 4 visits, which makes it unlikely to be a variable star or a binary star. We also examine variations between 2MASS and DENIS magnitudes and USNO-B catalogs, and find no evidence for photometric variations between those catalogs, i.e., $(K_{\text{2MASS}} - K_{\text{DENIS}}) = -0.016$ mag, and $(R_1 - R_2) = 0.07$ mag.

Figure 1 shows the light-element anomalies of 2M16011638-1201525, in this case for Al and Mg abundances. Such extreme values of Al enhancements and Mg depletions are only observed in second-generation GC stars, are particularly important for understanding how many Galactic field stars could have been deposited by GCs.

In this work, we report the first discovery in APOGEE data of a peculiar giant star in the Milky Way field that stands out in its very low magnesium and high aluminium abundance, as well as other very significant light-element abundance anomalies, such as a greatly enhanced nitrogen to iron ratio ($[N/Fe]>1.0$). This star could be the most convincing evidence yet for a Galactic field star stripped from a GC.

[Fe/H]) of 2M16011638-1201525 were checked using an extended and updated version of iSpec\(^2\) (Blanco-Cuaresma et al. 2014) to work in the spectral regime of APOGEE (~1.51 \(\mu\)m to 1.71\(\mu\)m). For a set of atmospheric parameters, and atomic data, iSpec generates synthetic spectra, computed from the ATLAS atmosphere model, Kurucz (2005), and minimises the difference with the observed spectrum using a least-squares algorithm.

We adopt the iSpec recommended stellar parameters: \(T_{\text{eff}} = 4572 \pm 100\) K, \(\log g = 1.66 \pm 0.1\), and \([\text{Fe/H}] = -1.30 \pm 0.1\), which are entirely consistent with those obtained by ASPCAP pipeline (García Pérez et al. 2015). \(T_{\text{eff}} = 4575 \pm 92\) K, \(\log g = 1.61 \pm 0.11\), and \([\text{Fe/H}] = -1.31 \pm 0.05\). Both sets of model parameters computed with the ATLAS model grid are consistent with those we found using MARCS stellar atmospheres models (Gustafsson et al. 2008; Zamora et al. 2015).

In this work\(^3\), we focus on the abundances of Al, Mg, C, N, and O, which are typical chemical signatures of GCs (Gratton et al. 2012). We did not include sodium in our analysis, which is a typical species to separate GC’s populations, as its lines in our APOGEE spectra contribute different linear and relative abundances for the star studied in this work, and this would lead to unreliable abundance results.

APOGEE spectra has three main windows to determine aluminium abundances: 1.6718\(\mu\)m, 1.6750\(\mu\)m, and 1.6763\(\mu\)m. We did not analyze the line at 1.6718\(\mu\)m because it is poorly fitted in the core and this may be an indicator of NLTE or saturation effects (Hawkins et al. 2016). The selected lines at 1.6750\(\mu\)m and 1.6763\(\mu\)m shown an offset of ±0.5 dex (see Fig. 2) between the two best-fit abundances, i.e., the derived line-to-line abundance is \(A(1.6750\mu m) = 6.81\) and \(A(1.6763\mu m) = 6.31\). It is important to note that this discrepancy does not affect the discussion and conclusions of this work, i.e., the line-to-line and relative abundance indicates that the star is Al-rich. For 2M16011638-1201525 we have done a manual inspection of the best MOOG (v. Jan2016, Sneden 1973) fitted synthesis of Al, Mg, C, N, and O lines, using atomic and molecular species, the most recent OH line list by Brooke et al. (2016), and Solar abundances values from Asplund et al. (2005). The best MOOG fitted synthesis of Al and Mg lines for 2M16011638-1201525 are shown in Figure 2. For our manual analysis we adopted the best fit of atmospheric stellar param-

| [Mg/Fe] | -0.04 | -0.31 | -0.43 |
| [Al/Fe] | 1.06 | 1.49 | 1.28 |

Note—The Solar reference abundances are from Asplund et al. (2005).

We consider axisymmetric and non-axisymmetric Galactic models including a prolate bar and spiral arms structures. The relevant parameters employed in the bar and the spiral arms are the same as those explained in Moreno et al. (2014); Robin et al. (2012).

We employed the kinematical parameters of 2M16011638-1201525 and those associated with the Galactic model, and consider their corresponding uncertainties as 1σ variations in a Gaussian Monte Carlo sampling. The adopted Solar motion with its uncertainties is \((U,V,W)_\odot = (-11.1\pm1.2, 12.24\pm2.1, 7.25\pm0.6)\) km s\(^{-1}\) (e.g., Schönrich et al. 2010; Brunthaler et al. 2011). In each computed orbit we obtain the following orbital parameters: maximum distance from the Galactic plane, \(Z_{\text{max}}\); maximum and minimum Galactocentric radii, \(r_{\text{max}}\) and \(r_{\text{min}}\); and the orbital eccentricity defined as \(e = (r_{\text{max}} - r_{\text{min}})/(r_{\text{max}} + r_{\text{min}})\).

To estimate the effect of axisymmetric and non-axisymmetric components of the Galactic potential in the computed orbital parameters, we considered the following four configurations of the Galactic potential:

(i) Model 1: the axisymmetric model, which is the direct scaling of the Allen & Santillan (1991) model.
Models 2, 3 and 4 the computed orbital parameters of in both, Model 2 and Model 3. We have found that in dialogue for this star).

Unfortunately improvements in distance and proper motions are not available from TGAS (Gaia Collaboration 2016) catalogue.

In these models the orbits of the star are integrated over 2 Gyr, with $10^3$ orbits in Model 1 and $10^5$ orbits in both, Model 2 and Model 3. We have found that in Models 2, 3 and 4 the computed orbital parameters of 2M16011638-1201525 are very similar, thus not depending sensitively on the assumed model of the Galactic bar.

For the orbital computation of 2M16011638-1201525, we also tested the set of distances and proper motions given in Table 2; small variations in these observables do not lead to substantial difference in the orbital parameters and does not affect the overall conclusions of this work.

We chose to use the accurate ($<1$ km s$^{-1}$) radial velocity from APOGEE. We adopted the spectro-photometric estimated distance from Hayden et al. (2014) based on Bayesian methods developed for APOGEE data, which is in good agreement with the distance measurements from RAVE survey (see Table 2). We have adopted absolute proper motions from the UCAC4 catalogue (Fourth U.S. Naval Observatory CCD Astrograph Catalogue Zacharias et al. 2013), because the error in proper motion (with uncertainties $<2$ mas yr$^{-1}$) is smaller compared to other catalogues (see Table 2), and is less affected by potential systematic uncertainties (Vickers et al. 2016). We note that the small uncertainties on the proper motions are good enough to estimate the space-velocity vector accurately, i.e., $(U_{\text{LSR}}, V_{\text{LSR}}, W_{\text{LSR}})^7 = (93.9 \pm 10.9, -246.1 \pm 68.9, 21.7 \pm 19.9)$ km s$^{-1}$.

4. POSSIBLE ORIGINS

A possible scenario producing very extreme Mg-Al-N nucleosynthesis could be an association with an intermediate mass ($\sim 3 - 6 \ M_\odot$) AGB star (see Ventura et al. 2011; Schiavon et al. 2016) in a binary companion. A future work will be dedicated to investigate in more detail other mechanisms, including binary stellar mergers or pollution of the interstellar matter (ISM) by a previous generation of massive stars.

In the following subsections we will analyze other scenarios that could have led this peculiar star to its current phase space location in the Galaxy.

4.1. A dwarf spheroidal (dSph) galaxy interloper?

Lind et al. (2015) argue that stars with low [Mg/Fe]-ratios are commonly found in dwarf spheroidal galaxies. However, [Al/Fe] enhancement is not expected in these systems (see Koch & McWilliam 2008). Therefore, given the high Al enhancement and strongly depleted Mg observed in 2M16011638-1201525, we conclude that it seems unlikely that a merged and disrupted dwarf spheroidal galaxy could have hosted 2M16011638-1201525.

4.2. A globular cluster escapee?

In order to study the ejection scenario of 2M16011638-1201525 from a not entirely disrupted GC into the Milky Way disk, we performed a kinematical analysis using Model 2 over a 2 Gyrs period. It is based on $3 \times 10^3$ Monte Carlo cluster and 2M16011638-1201525 orbits for a sample of 63 Galactic GC with good proper motion measurements (see Moreno et al. 2014).

We assumed that 2M16011638-1201525 could have been ejected from a given GC, with a relative velocity below a certain threshold ($V_{rel} < 200 \text{ km s}^{-1}$), which may be possible in the interaction of black holes and/or binary systems (see Fernández-Trincado et al. 2015b). Then, we computed the cumulative probability distribution (see Figure 3) for the relative velocity ($V_{rel}$), which is defined as the relative velocity during each close encounter, occurring at times $t < 2 \text{ Gyr}$ and within a distance less than or equal to the tidal radius of the GC ($|\delta r < r_t$; Moreno et al. 2014). If a close past encounter is probable, then the GC could be identified as a possible progenitor of 2M16011638-1201525.

Our results suggest that our hypothesis of 2M16011638-1201525 being ejected from a given GC is negligible for 59 of them, and very small (< 0.5%) for four GC in our sample (see Figure 2): NGC 5139 ($\omega$ Cen), NGC 104 (47 Tucanae), NGC 4372, NGC 4833.

Other parameters also disfavor the proposes hypothesis: 2M16011638-1201525 is metal-poor, $[\text{Fe/H}] = -1.30$ dex, with orbital parameters that reach a distance $|Z_{max}| \sim 3 \text{ kpc}$ from the Galactic plane (see Figure 4), which are not consistent with the metallicity (Harris 1996) and orbital properties (Moreno et al. 2014) for three of the four clusters mentioned above: NGC 104 ($[\text{Fe/H}] = -0.72$ dex, $|Z_{max}| \sim 3.13 \text{ kpc}$), NGC 4372 ($[\text{Fe/H}] = -2.17$ dex, $|Z_{max}| \sim 1.57 \text{ kpc}$) and NGC 4833 ($[\text{Fe/H}] = -1.85$ dex, $|Z_{max}| \sim 1.54 \text{ kpc}$). Both NGC 4372 and NGC 4833, are more metal-poor than 2M16011638-1201525, while NGC 104 is more metal-rich and particularly with a more Mg-rich population, (see Carretta et al. 2013) than 2M16011638-1201525, which makes these 3 clusters an unlikely origin for the star.

Our chemodynamical results show that among the more probable GC candidates associated with 2M16011638-1201525, NGC 5139 could be a possible progenitor system. This cluster is metal-poor, $[\text{Fe/H}] = -1.53$ dex (Harris 1996), and has an orbit that reaches a distance $|Z_{max}| \sim 1.69 \text{ kpc}$ from the Galactic plane (Moreno et al. 2014). Additionally, NGC 5139 shows enrichment levels spanning from $\sim 1.8$ dex to $\sim 0.5$ dex (e.g., Villanova et al. 2014, and references therein), and atypical light-element abundances with a pronounced Mg-Al anti-correlation (e.g., Norris & Da Costa 1995) like that seen in 2M16011638-1201525. From Figure 3, we conclude that this star could have been radially ejected in any direction from NGC 5139 (blue dashed line in Figure 3). 2M16011638-1201525 has a velocity greater than the cluster’s escape velocity, i.e., $V_{rel} > 60.4 \text{ km s}^{-1}$ (see Fernández-Trincado et al. 2015b, and references therein), reaching a total energy ($E$) and angular momentum ($L_z$) from the ejection process slightly similar to that of NGC 5139. We note that 2M16011638-1201525 is moving on a retrograde orbit, and have specific angular momenta, $L_z = -307 \text{ km s}^{-1}\text{kpc}$, similar to that of NGC 5139, i.e., $L_z = -342.5 \text{ km s}^{-1}\text{kpc}$ (see Moreno et al. 2014); this result could strengthen the association of this star with NGC 5139.

We emphasize that there is evidence which suggests NGC 5139 as a dominant contributor of retrograde stars, and of stars with chemical anomalies generally found only within GCs (Altmann et al. 2005; Majewski et al. 2012; Fernández-Trincado et al. 2015c). These stellar debris and the newly discovered star strongly suggest that NGC 5139 was not formed on its present orbit, and has been affected by frequent passages through the disk (e.g., Meza et al. 2005). Hence many of the claimed stellar debris to be part of NGC 5139 follow orbital properties ($R_{min}$, $R_{max}$, $Z_{max}$) slightly different from the host system.

We also highlight that 2M16011638-1201525 has halo-like radial velocity based on the kinematics predicted by the revised version of the Besançon Galaxy model (Robin et al. 2014), implying that this star could be interpreted also as a "halo interloper" especially given a retrograde motion, and a peculiar chemical fingerprint that is consistent with the "GC" halo population.

Figure 3. Cumulative probability distribution of the relative velocities ($V_{rel}$) during close encounters between 2M16011638-1201525 and Galactics GC from Moreno et al. (2014). The vertical dashed line shows the velocity threshold (200 km s$^{-1}$) adopted in this work.
4.3. A Galactic bulge interloper?

Schiavon et al. (2016) have recently discovered a new stellar population in the Galactic bulge (called the N-rich population), which clearly shows atypical light-element patterns, particularly with elevated nitrogen abundance $[\text{N/Fe}] > 1.0$ dex. Such abundances are very different from what is seen in the normal stellar population of the Galactic bulge in the same spatial region (i.e., $|b| < 16^\circ$, $-20^\circ < l < 20^\circ$, and 5 kpc $< d_{\odot} < 11$ kpc).

We consider a possible scenario where 2M16011638-1201525 could be associated with this new stellar population, since this star shows similar nitrogen enhancement as those of the Schiavon's sample, i.e., 2M16011638-1201525 has elevated nitrogen abundance, $[\text{N/Fe}]=1.46$ dex (see Table 1), like the N-rich population. Interestingly, our orbital solutions show that 2M16011638-1201525 passes through the Galactic bulge at its closest approach to the Galactic center $R_{\text{min}} \sim 0.62$ kpc, and reaches a maximum distance from the Galactic center at $R_{\text{max}} < 7.26$ kpc (see orbit projection in Figure 4), in an eccentric orbit $e = 0.53$. Given its peculiar chemical fingerprint and orbital elements within the Galactic disk, this star could be interpreted as a N-rich bulge interloper. It is interesting to note that there are a handful of N-rich stars from Schiavon's sample with intermediate Al abundance and Mg enhancement (see fig. 1) making it difficult to link chemically this population with 2M16011638-1201525 which fall outside the main group of field stars, and within the locus of second-generation GC population. However, there is also one star from Schiavon's sample that has Al enhancement and a strongly depleted Mg abundance and is likely within the Al-Mg tail of the N-rich population. On the other hand, one might expect N-rich contaminants with extreme Al-Mg abundance ratio. However, given the kinematic and chemical properties of 2M16011638-1201525, a GC-like second-generation seems more probable.

5. CONCLUSIONS

We made use of high resolution, near-IR spectra from the SDSS-III/APOGEE survey, and we have discovered the existence of a star within the Milky Way disk with light-element anomalies associated with one of the most extreme combination of Mg and Al anticorrelation seen only in the second generation GC populations. Our orbital computations based on reliable six-dimensional phase space coordinates of this peculiar giant star, 2M16011638-1201525, show that it travels through the Milky Way in a coplanar, eccentric orbit relatively close to the Galactic plane, which suggests that this star has been dynamically ejected into the Milky Way disk from the halo.

A more exotic explanation of such peculiar chemistry in a disk-like orbit star is that it could be chemically linked with the $\omega$ Cen progenitor system, from which it might have been ejected. However, $\omega$ Cen is a very complex and unusual stellar system in the Milky Way and its origin is still not well understood (globular cluster or dwarf spheroidal galaxy?). Other GC progenitor candidates might be examined with more detail in the near future, given the upcoming and more accurate six-dimensional phase-space data set that will be produced by the Gaia space mission.

The authors wish to thank the referee for constructive comments that significantly improved the presentation of this paper.

We thank UNAM-PAPIIT grants IN 105916 and IN 114114. J.G.F.-T is currently supported by Centre National d’Etudes Spatiales (CNES) through PhD grant 0101973 and the Région de Franche-Comté and by the French Programme National de Cosmologie et Galaxies (PNCG).

E.M, L.A.M.M, B.P, and A.P.V acknowledge support from UNAM/PAPIIT grant IN105916. D.A.G.H was funded by the Ramón y Cajal fellowship number RYC-2013-14182.

D.A.G.H and O.Z. acknowledge support provided by the Spanish Ministry of Economy and Competitiveness (MINECO) under grant AYA-2014-58082-P. S.R.M. and C. S. acknowledge support from NSF grants AST-1312863 and AST-1211585, respectively. A.M. acknowledges support from Proyecto Interno UNAB DI-677-15/N.

D.G., and R.M. gratefully acknowledge support from the Chilean BASAL Centro de Excelencia en Astrofísica y Tecnologías Afines (CATA) grant PFB-06/2007.

Szabolcs Mészáros has been supported by the János Bolyai Research Scholarship of the Hungarian Academy of Sciences.

This research made use of GravPot16 (Fortran version), a community-developed core under the git version-control system on GitHub. Monte Carlo simulations were executed on computers from the Instituto de Astronomía-UNAM, México.

Funding for SDSS-III has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Science Foundation, and the U.S. Department of Energy Office of Science. The SDSS-III web site is http://www.sdss3.org/.

SDSS-III is managed by the Astrophysical Research Consortium for the Participating Institutions of the SDSS-III Collaboration including the University of Arizona, the Brazilian Participation Group, Brookhaven...
Figure 4. Left: Maximum distance $|Z_{\text{max}}|$ from the Galactic plane as function of the orbital eccentricity for 2M16011638-1201525, and 63 GC from Moreno et al. (2014). The open star symbol refers to NGC 5139. The horizontal black dashed line represent 3 kpc, the higher limit for the thick disc proposed by (Carollo et al. 2010). Right: Meridional orbit of 2M16011638-1201525 computed with the Model 3 (black line), and Model 4 (red dashed line).
