(Dated: March 9, 2009)

We discovered in simulations of sliding coaxial nanotubes an unanticipated example of dynamical symmetry breaking taking place at the nanoscale. While both nanotubes are perfectly left-right symmetric and nonchiral, a nonzero angular momentum of phonon origin appears spontaneously at a series of critical sliding velocities, in correspondence with large peaks of the sliding friction. The non-linear equations governing this phenomenon resemble the rotational instability of a forced string. However, several new elements, exquisitely “nano” appear here, with the crucial involvement of Umklapp and of sliding nanofriction.

A popular high-school physics demo is a clamped oscillating rope or guitar string. While being imparted a strictly planar vibration at one end, the string initially vibrates, as expected, within the plane. Above a certain amplitude however the plane of vibration spontaneously and unexpectedly begins to turn around, right or left with equal probability \cite{1}. Since all along the string’s Lagrangian (including the external forcing) remains completely left-right symmetric (i.e., nonchiral) this is a prototype example of what may be called 	extit{dynamical chiral symmetry breaking} taking place in the macroscopic world. Dynamical spontaneous symmetry breaking of chiral symmetry is actually rife in nature, including examples such as the Taylor-Couette instability in hydrodynamics \cite{2}, the spontaneous chirality of vibrating cilia in biology \cite{3} and many other macroscopic scale examples.

We discovered, in simulations of the frictional sliding of carbon nanotubes, a nanoscale example of dynamical chiral symmetry breaking in particular in two coaxial nanotubes, one forced to slide inside the other. While both nanotubes are perfectly left-right symmetric and nonchiral, angular momentum strikingly jumps to nonzero values in correspondence to some sliding velocities, coinciding with large phonon-related peaks of the sliding friction. The theory of this phenomenon yields non-linear equations that differ from the string problem by newer elements that are exquisitely nano, now involving Umklapp and of sliding nanofriction.

We conducted classical molecular dynamics simulations of an inner, infinite and termination-free, (5,5) armchair single-wall carbon nanotube sliding at speed \( v \) inside a coaxial (10,10) nanotube, as in Fig. 1a. Standard empirical potentials were used for the intratube and intertube interactions. Details of simulation are given in Ref. \textsuperscript{4}. Temperature was controlled, usually at \( T = 300 \) K, by an algorithm designed to preserve angular momentum \textsuperscript{5}. As noted earlier by Tangney et al. \textsuperscript{6}, the tube-tube sliding friction is not hydrodynamical, in fact not even monotonic with \( v \), but develops sharp peaks and onsets at selected speeds. We found sharp frictional peaks near \( v = 450 \) m/s, \( 570 \) m/s, \( 720 \) m/s, and an important threshold onset near \( 780 \) m/s, shown in Fig. 1b. These peaks are known to generally arise out of parametric excitation of outer nanotube ‘breathing’ phonon modes, classified by an angular momentum index \( n \) (for tangential quantization around the tube axis). Our peak positions differ from earlier ones \textsuperscript{8} due to our lack of tube terminations (implying mode uniformity along the

\end{figure}
tube), and also to our different inter-tube potentials. As noted earlier [6], the non-monotonic $F-v$ characteristics implies a “negative differential friction”, whereby an increasing applied force $F$ yields an inner-tube velocity that grows by jumps and plateaus, rather than smoothly.

The surprise comes from analysing, at the frictional peaks, the two parts of angular momentum $J$ around the tube axis $y$: its center-of-mass (rigid body rotation with angular velocity $\omega$) and shape-rotation (“pseudo-rotational”) parts $J = J_{CM} + J_{\text{pseudo}}$, with $J_{CM} = \sum_i m_i \langle \mathbf{r}_i \times (\mathbf{\Omega} \times \mathbf{r}_i) \rangle_y$, and $J_{\text{pseudo}} = \sum_i m_i \langle \mathbf{\Omega} \times \mathbf{r}_i \rangle_y$. Generally zero at generic $v$ due to lack of nanotube chirality, $J_{\text{pseudo}} = -J_{CM} = 0$, $J_{\text{pseudo}}$ jumps to nonzero values at the frictional peaks and past the threshold, where $J_{\text{pseudo}} = -J_{CM} \neq 0$ (total $J$ is clearly conserved), see Fig. [1b]. Simulations at lower temperatures (not shown) reveal other smaller frictional peaks, but the main findings of the present paper, including chirality breaking, are still present, and indeed even stronger.

Cross-section snapshots at intervals of 50 fs, at $v = 820$ m/s of Fig. [2] show a large pentagonal distortion of the outer tube, corresponding to an $n = 5$ breathing mode. A vertex of the pentagon moves clockwise (or counter-clockwise with 50-50 probability in different simulations) with angular velocity $\Omega_w/5$, where $\Omega_w = 2\pi v/a$ is the “washboard” frequency associated with the sliding speed $v$ and $a = 2.46$ Å is the intertungsten periodicity. The pentagon rotation signals a non-vanishing $J_{\text{pseudo}} > 0$. Since the total $J = 0$, the center-of-mass acquires an equal and opposite counter-rotation $J_{CM} = -J_{\text{pseudo}} < 0$, as demonstrated by the red atom marker in Fig. [2].

Theory - The mechanism underlying symmetry breaking is the tube non-linearity, reminiscent of the string instability [1]. The non-linear motion of a string forced to vibrate along a transverse direction $x$ at frequency $\Omega$ is described by

$$\ddot{X} = -[\omega_{k,T}^2 + K(|X|^2 + |Y|^2)]X + F \cos(\Omega t)$$

$$\ddot{Y} = -[\omega_{k,T}^2 + K(|X|^2 + |Y|^2)]Y,$$

where $\omega_{k,T} = k\sqrt{\mu/M}$ is the bare transverse frequency with wavevector $k$ ($\mu$ is the Lamé constant and $M$ the mass density), $X, Y$ are two orthogonal linear polarizations, and $F$ is the forcing amplitude. The nonlinearity $K > 0$ accounts for the increase of the transverse frequency at large amplitudes, where the larger overall elongation leads to an effective string tension increase. Due to $K > 0$ there is a critical frequency $\Omega_{cr} = \sqrt{\omega_{k,T}^2 + (KF^2/16)^{1/3}}$ beyond which the string, although forced along $x$, spontaneously develops both $X$ and $Y$ modes, an elliptical polarization resulting from a purely linear forcing, with a spontaneous dynamical chirality breaking. The critical amplitude of the $X$-mode beyond which the elliptical polarization sets in is $(2F/K)^{1/3}$ (this will be demonstrated in Fig. [3] below). In the nanotube case, the sliding inner tube excites phonon modes of the outer one, uniformly along the tube in our termination-free case. The outer (10,10) nanotube has, among others, doubly-degenerate modes with angular momentum $n = \pm2, \pm3, \pm4$, etc.

Let $u_x(\theta)$ and $u_z(\theta)$ be displacements in the $x$ (tangential) and $z$ (radial) directions at angular position $\theta$ on the outer tube circumference, and $u_{n,x,\pm}$ and $u_{n,z,\pm}$ their respective n-mode amplitudes, travelling clockwise (+) and counter-clockwise (−). Suzuura and Ando (SA) [9] described these modes at the quadratic level in a continuum model. Third- and fourth-order energy terms in $u$ mix the different $n$-modes in all possible ways compatible with conservation of angular momentum. The main nonlinear terms $\propto \int dx (\frac{\partial u_x}{\partial z} + \frac{\partial u_z}{\partial x})(\frac{\partial u_x}{\partial x} - \frac{\partial u_z}{\partial z})$ to third order, and $\propto \int dx (\frac{\partial u_x}{\partial z} - \frac{\partial u_z}{\partial x})^4$ to fourth order turn out to be as crucial as in the string.

$n = 5$ excitation - The 10-atom linear structure of the sliding (5,5) inner tube stimulates at all speeds $v$ the outer tube with a deformation corresponding to a linearly polarized, $k_y = 0$, $n = 5$ mode with a washboard frequency $\Omega_w = 2\pi v/a$. Away from resonance, $\Omega_w < \omega_5$, the excitation amplitude of the $n = 5$ outer tube mode is small, and linear. Near and above resonance, however, the amplitude grows, and nonlinearities become dominant. Starting from the SA model [9] including non-linearities, after some approximations (mainly $u_{n,x,\pm} \approx (i/n)\rangle u_{z,n,\pm}$ as appropriate from linear eigenvector analysis, neglecting small mode-mixing third-order terms while keeping large fourth-order contributions which generate terms such as $|u_{z,5,\pm}|^2/4|u_{z,5,\pm}|$, we arrive at equations for the $n = \pm5$ phonon amplitudes of the suggestive form

$$\ddot{X} = -[\omega_5^2 + Q + (P/4)(|X|^2 + |Y|^2)]X + 4F \cos(\Omega_w t)$$

$$\ddot{Y} = -[\omega_5^2 - Q + (P/4)(|X|^2 + |Y|^2)]Y,$$
through a "reciprocal lattice vector" of the inner tube, process coupling two outer tube modes with the string is the "nano" important difference between Eqs. (2) and those of the upwards the frequency as the amplitude increases. The orthogonal standing waves, characterize the radial displacement of Eqs. (2). Here the dynamics, still chiral, becomes more complex than that of the pure "n = 5" mode. In Fig. 3a solutions of Eqs. (2) are shown as shaded thick lines, with parameters $P = (1728/50)a/MR^4$, $Q$, and $F$ which were fit to the bulk modulus of the nanotube ($\alpha = 15000 \text{ A}^2/\text{ps}^2$), the intrinsic phonon frequencies and the splitting for $n = 5 (Q = 50.5/\text{ps})$, as well as the energy corrugation ($F = 5 \text{ A}^2/\text{ps}^2$) of the inter-tube potential. The model agrees fairly well with hard simulation results, including a crossing of $X$ and $Y$ amplitudes at around $v = 815 \text{ m/s}$, which only occurs due to Umklapp. A feature predicted by the model is a hysteric behaviour with respect to increasing and decreasing $v$. The hysteresis is not seen in simulations both at 300 K and at 50 K. We suspect that frictional Joule heating could be sufficient to remove it. Also, our model being mean-field in character, it does not allow for fluctuations. The simulations of course do, and indeed occasional reversals of the sign of $J_{\text{CM}}$ are observed when $|J_{\text{CM}}|$ is very small; these reversals are suppressed, most likely by inertia, when $|J_{\text{CM}}|$ is large.

$^2 + 3 = 5$" excitation - Consider now the main frictional peak labelled "$^2 + 3$" in Fig. 1b, around $v \approx 570 \text{ m/s}$. This corresponds, as shown by Fig. 1 to a mixed-resonance involving three modes, $n = 2, 3,$ and 5 simultaneously (see Fourier spectrum in Fig. 1b). The inset in Fig. 2 shows that the cross-section snapshot of both tubes in this region of $v$, where frictional excitation is huge, is mostly elliptical, indicating a dominant $n = 2$ deformation (see also the large $n = 2$ peak in the Fourier spectrum of Fig. 1b), with a slight triangular ($n = 3$) deformation. Our anharmonic continuum model nicely explains these results, the Umklapp terms (present in nanotubes but not in the string) playing a crucial role. In this region of $v$ we can truncate the full hierarchy of coupled equations to 6 equations involving the relevant Fourier modes $u_{z/\pm,n}$ with $n = 2, 3, 5$. To give a flavor of the full theory [10], we report here the equation of motion for mode $u_{z,5}$ obtained under the linear approximation $u_{z,5} \approx (i/5)u_{z,5}$ [10],

$$\ddot{u}_{z,5} = -\gamma \dot{u}_{z,5} - Qu_{z,5}^* - (\omega_z^2 + \sum_{m=2,3,5} B_m |u_{z,m}|^2)u_{z,5} - A^{\text{dir}}u_{z,2}u_{z,3} + A^{\text{umkl}}u_{z,2}^*u_{z,3}^* + 2F \cos(\Omega_w t),$$

where the last term represents the washboard forcing (due to inner tube sliding), while the $Q$-term is the previously discussed Umklapp term $-5 - 5$. (Similar equations hold for the modes $n = 2, 3$, except that the $Q$-term and the explicit forcing are missing.) The physics of the $B_m$-terms is an effective increase of the bare frequency $\omega_z$ due to the excitation of modes $m = 2, 3, 5$, via fourth-order non-linearities. $A^{\text{dir}}$ and $A^{\text{umkl}}$ represent the effect
of third-order non-linearities, whereby a combined excitation of modes 2 and 3 can lead, by angular momentum conservation, to a term influencing mode 5 either in a direct way, via $2+3 = 5$, or through Umklapp, via $-2-3 = -5 = 5$. The stationary solutions of the nonlinear coupled equations for $u_{x/n} = 2, 3, 5$, obtained numerically, reveal a rather simple structure, namely, $u_{x/n}(t) = u_{x/n} + e^{i\Omega w t}$, $u_{x/n}(t) = u_{x/n} + e^{i\Omega t}$, and $u_{x/n}(t) = u_{x/n} + e^{i\Omega t}$, with $\Omega_2 + \Omega_3 = \Omega_4$: in words, mode 4 oscillates with the driving washboard frequency $\Omega_w$, while modes 2 and 3 “feel” an indirect driving from mode 5 and oscillate at frequencies $\Omega_2$ and $\Omega_3$ (renormalized by tube-tube coupling and anharmonicity) in such a way as to realize a perfect “resonance” with the driving frequency (see Fourier spectra Fig. 4).

As simulations show, the amplitudes of $X_n = u_{x/n} + u^*_{x/n}$ and $Y_n = u_{x/n} - u^*_{x/n}$ (in qualitative agreement between model and simulation) are equal to each other for both $n = 2$ and $n = 3$, implying $u_{x/2,3} = 0$. That means, in full agreement with the model, a full chirality for both modes, with waves travelling totally clock-wise (or counter-clock-wise, with equal probability). The $n = 5$ $X$ and $Y$ amplitudes are, on the contrary, unequal and much smaller than $n = 2$ and 3. The continuum model actually predicts – in striking agreement with the simulation – that the $n = 5$ mode rotates opposite to the chirality of modes 2 and 3 (i.e., counter-clockwise, $|u_{x,5,-}| > |u_{x,5,+}|$, for the case shown here), an effect entirely due to Umklapp terms 10.

So far we have explained the two main features labelled A in Fig. 4. The features labelled B appear to represent a replica, where single outer tube $n = 3, 5$ excitations replace the double tube ones $n = 3, 5$. For example, in the spectrum for 455 m/s (Fig. 11), the $n = 3$ mode is at 1.14 THz, the outer tube value, different from the joint $n = 3$ mode where both tubes vibrate together. Analogously, the $n = 5$ mode is excited at 720 m/s. Here, however, the friction is so small that the excited angular momentum is essentially invisible. The two regions labelled C, finally, are irrelevant to the present context and will be discussed elsewhere 11.

In summary we have described a spontaneous breaking of chiral symmetry occurring in nanoscale friction. Our very large speeds and termination-free conditions differ strongly from experimental conditions where nanotube sliding was observed so far 11. Attempts at observing this chirality breaking could nonetheless be of considerable interest, considering in addition the possibility to examine the effect of electronic frictional dragging 12 an avenue which seems worth considering. Although the modes that play a major role in electron-phonon coupling 13, and nanotube superconductivity 14 are different, breathing modes excitation was recently demonstrated by STM tips 13. The physical understanding obtained for our microscopic nonlinear dynamical system might also serve as a prototype for phenomena in the field of nanomotors. Examples of spontaneous chiral symmetry breaking that are relevant to the dynamics of nanomotors have been described in rotaxanes 10, where a series of chemical reactions can give rise to a biased Brownian motion of a small ring around a larger one in either direction. Our example represents a first idealized case where the origin of nanoscale chiral symmetry breaking is strictly physical.

This research was partially supported by PRIN 2006022847, and by CNR/ESF/EUROCORES/FANAS/AFRI. We thank D. Ceresoli for an illuminating suggestion.
