1. Introduction

It is well known that titanium beryllide Be\textsubscript{12}Ti is an alternative to metallic beryllium as a material for neutron multipliers in blanket designs of fusion reactors.\textsuperscript{1–3} In particular, Be\textsubscript{12}Ti alloy has a higher melting point and better compatibility with structural materials, better oxidation resistance and resistance to a swelling under neutron irradiation compared with metallic beryllium in the fusion blanket design of a DEMO reactor.\textsuperscript{4–7} As we know, in the DEMO reactor, as functional materials, Be\textsubscript{12}Ti alloys will be used at high temperature and high pressure as well as in a high neutron flux environment where the blanket has a temperature up to 1123 K, a neutron damage dose of an order of 50 dpa and helium accumulation of 20 000 appm.\textsuperscript{8,9} At high temperature, the Be\textsubscript{12}Ti alloy has thermal stress problems, which will produce microcracks and affect the application and lifetime of the Be\textsubscript{12}Ti material, even affecting the performance parameters of fusion reactors. However, thermal stresses are related to the elastic anisotropy and thermodynamic properties of the materials at corresponding temperatures. In addition, pressure is an important role in the mechanical and elastic properties of the materials,\textsuperscript{10,11} it can be produced phase transitions and changes of physical and chemical properties in the materials.\textsuperscript{12,13} From early literature, more research has focused on experimental aspects for Be\textsubscript{12}Ti, especially for the fabrication and tritium release under normal conditions.\textsuperscript{14–17} Although there are a few theoretical calculations for Be–Ti alloys, they mainly focus on hexagonal Be\textsubscript{12}Ti alloy,\textsuperscript{18,19} as for the tetragonal Be\textsubscript{12}Ti, its elastic and thermodynamic properties under high temperature and pressure are missing. Hence, it is necessary to obtain the elastic anisotropy and thermodynamic properties of tetragonal Be\textsubscript{12}Ti alloy at high temperature and high pressure. The first-principles density functional theory method (DFT) is a useful tool for predicting the physical properties of the solid materials, particularly elastic and thermodynamic properties, and it has been widely applied in various materials.\textsuperscript{20–27}

In this present work, the effects of temperature and pressure on the structure, elasticity and thermodynamic properties of tetragonal Be\textsubscript{12}Ti alloys are studied by using the first-principles method and quasi-harmonic approximation (QHA). The calculated results are expected to provide valuable estimation for the experimental and theoretical research of Be\textsubscript{12}Ti intermetallic compound. The rest paper is organized as follows: in Section 2, we have given the theoretical method and the computation details. Some results and discussions are described in Section 3. Finally, the summary of our main results and conclusions is summarized in Section 4.

First-principles calculations of mechanical and thermodynamic properties of tetragonal Be\textsubscript{12}Ti

Xiankun Liu, Qijie Feng, Bin Tang, Jian Zheng, Zhou Zheng, Wei Zhou, Jiting Tian and Jing Wang

The elastic and thermodynamic properties of tetragonal Be\textsubscript{12}Ti under high temperature and pressure are investigated by first-principles calculations based on pseudopotential plane-wave density functional theory (DFT) within the generalized gradient approximation (GGA) and quasi-harmonic approximation (QHA). The calculated lattice parameters and bulk modulus are in good agreement with the available experimental data. The calculated elastic constants of Be\textsubscript{12}Ti increase monotonously with increasing pressure, and the elastic stability criterion and the phonon dispersion calculation show that the Be\textsubscript{12}Ti crystal satisfies the mechanical and dynamic stability under applied pressure (0–100 GPa). The related mechanical properties such as bulk modulus (B), shear modulus (G), Young’s modulus (E), and Poisson’s ratio (ν) are also studied for polycrystalline of Be\textsubscript{12}Ti; the calculated B/G value shows that Be\textsubscript{12}Ti behaves in a brittle manner, and higher pressure can significantly improve the brittleness of Be\textsubscript{12}Ti. The elastic anisotropy is demonstrated by the elastic anisotropy factors. The direction-dependent Young’s modulus and bulk modulus of Be\textsubscript{12}Ti are dealt with in detail under pressure from 0 GPa to 100 GPa. The pressure and temperature dependencies of the relative volume, the bulk modulus, the elastic constants, the heat capacity and the thermal expansion coefficient, as well as the entropy are obtained and discussed using the quasi-harmonic approximation in the ranges of temperature 0–1600 K and pressure 0–100 GPa.
2. Computational methods and details

In present work, all calculations are performed by first-principles based on VASP software package,\textsuperscript{28} which is based on density functional theory (DFT). We describe the interaction between core ions and valence electrons using PAW pseudopotentials\textsuperscript{29,30} and the exchange-correlation function are treated by the generalized gradient approximation (GGA) within Perdew–Burke–Ernzerhof (PBE). The plane wave cut-off energy was taken as 550 eV. Pseudo atomic calculations of Be\textsubscript{12}Ti are performed for Be 2s\textsuperscript{2} and Ti 3s\textsuperscript{2}3p\textsuperscript{6}3d\textsuperscript{2}4s\textsuperscript{2}. For the Brillouin-zone sampling, we use the 8\textsuperscript{th} Monkhorst–Pack mesh for k-space integration, where the self-consistent convergence of the total energy is set to 1.0 \times 10\textsuperscript{-6} eV per atom, the maximum ionic force on the atom is below 0.0001 eV Å\textsuperscript{-1}. These all parameters including k-point convergence test have been carefully tested.

In order to obtain the equilibrium volume and bulk modulus of, the E–V results obtained from the first calculation will be fitted by the following Birch–Murnaghan EOS:\textsuperscript{29}

\[
E(V) = E_0 - \frac{9}{16}B_0 \left[ \left( 4 - B'_0 \right) \frac{V_0^3}{V^3} - \left( 14 - 3B'_0 \right) \frac{V_0^{7/3}}{V^{7/3}} \right] + \left[ 16 - 3B'_0 \right] \frac{V_0^{5/3}}{V^{5/3}}
\]

where \(E_0\) is the equilibrium energy at \(P = 0\), the \(B_0\) is the bulk modulus, \(B'_0\) is the pressure derivative on bulk modulus. As for elastic properties, here we have used stress–strain approach based on the Hooke’s law to calculate the elasticity, in which the elastic stiffness tensor \([C_{ij}]\) can be expressed as\textsuperscript{32}

\[
\{\delta_{ij}\} = [C_{ij}]\{\varepsilon_{ij}\}
\]

where \(\{\delta_{ij}\}\) and \(\{\varepsilon_{ij}\}\) are stress and strain tensors respectively. For tetragonal Be\textsubscript{12}Ti crystal, there are six independent components (\(C_{11}, C_{12}, C_{13}, C_{22}, C_{23}, C_{44}\) and \(C_{66}\)). Based on above \(C_{ij}\) values, other elastic parameters for example bulk modulus \(B\) and shear modulus \(G\) and Young’s modulus \(E\) can be obtained by Voigt–Reuss–Hill approximation from elastic constants in ref. 33 and 34.

3. Results and discussion

3.1. Crystal structure and stability

The crystal structure of Be\textsubscript{12}Ti in this study belongs to the tetragonal with space group 14/mmm,\textsuperscript{26} in its unit cell, the Be atoms occupy Wyckoff position 8f (0.25, 0.25, 0.25), 8i (0.35, 0, 0), 8j (0.28, 0.5, 0) and Ti atoms occupy 2a (0, 0, 0), respectively (see Fig. 1). In order to determine the equilibrium structure of Be\textsubscript{12}Ti, we first carried out the structural optimization calculation under different pressure (pressure range of 0–100 GPa), obtained the corresponding energy \(E\) and volume \(V\). Then, fitted above the \(E\) and \(V\) to the Birch–Murnaghan equation of state (EOS)\textsuperscript{29} to get the bulk modulus \(B_0\) and its pressure derivative \(B'_0\) at 0 K and 0 GPa. Fitted energy \(E\)–volume \(V\) relations of Be\textsubscript{12}Ti are shown in Fig. 2, and the fitting results of the bulk \(B_0\) and its derivative \(B'_0\) and equilibrium lattice constants are given in Table 1. It can be seen from Table 1 that the calculated lattice constants \((a\ and\ c)\) and bulk modulus \((B_0)\) are very close to the previous experimental data\textsuperscript{35,36} even the experimental values were obtained in the 273 K environment, while pressure derivative \((B'_0)\) has not yet been compared with the experimental data. Nevertheless, this work is a significant attempt to predict the characteristics of tetragonal Be\textsubscript{12}Ti alloys. It can provide reference data for further research on the properties of Be\textsubscript{12}Ti alloy.

Usually, the pressure can deform the material and even cause the phase transition of the material. But for different materials, the effect of pressure on the structure parameters is different. For tetragonal Be\textsubscript{12}Ti, there are differences in lattice constants and volume changes \((a/a_0, c/c_0, V/V_0)\) under external pressure. Fig. 3 shows the variation of \(a/a_0, c/c_0, V/V_0\) with pressure in the range of 0 to 100 GPa, where \(a_0, c_0\) and \(V_0\) denote the equilibrium structural parameters and cell volume at \(T = 0\) K and \(P = 0\) GPa, respectively. It can be seen that with increasing pressure, the equilibrium ratios \(a/a_0, c/c_0\) and \(V/V_0\) decrease smoothly, but \(V/V_0\) decrease quickly than \(c/c_0\) and \(a/a_0\) and \(c/c_0\) decreases slightly faster than \(a/a_0\), indicating that the

![Fig. 1](image-url)  
Crystal structure of the tetragonal Be\textsubscript{12}Ti.
compression along the $a$-axis is slightly smaller than that along the $c$-axis. This suggests that the lattice constant $c$ is more sensitive to external pressure than $a$. Nevertheless, change value of the $a/c$ is not large and it remains almost constant in the range of pressure from 0 to 100 GPa.

### 3.2. Elastic properties

The elastic property is important parameter which is related to many physical properties of the solid materials, including specific heat, Debye temperature, thermal expansion, Grüneisen parameter and melting point. Some mechanical properties and dynamical behaviors of the materials can be obtained by its elastic constants. For tetragonal $\text{Be}_{12}\text{Ti}$, there are six independent elastic constants $C_{11}$, $C_{12}$, $C_{13}$, $C_{33}$, $C_{44}$ and $C_{66}$. In the Fig. 4(a) and (b), we presented the elastic constants and its increasing rate with pressure of $\text{Be}_{12}\text{Ti}$ under various pressures. From Fig. 4(a), we can see that all elastic constants increase with applied pressure up to 100 GPa for $\text{Be}_{12}\text{Ti}$. The increasing rate of each elastic constant with pressure is derived from the slope of the corresponding linear fitted curve, as shown in Fig. 4(b). Among them, the variation of $C_{11}$ is the most sensitive at 4.62, while $C_{13}$ has the least increasing rate at 0.67. According to calculated elastic constants and mentioned formulas in ref. 34, we have calculated the mechanical properties of $\text{Be}_{12}\text{Ti}$ under various pressure, such as bulk modulus $B$, shear modulus $G$, Young’s modulus $E$, and Poisson’s ration $\nu$, which are listed with other theoretical data in Table 2. It is obvious from Table 2 that the Voigt–Reuss–Hill approximations bulk modulus $B_h$ (114.27 GPa) at 0 GPa is very close to the value $B_0$ (121.0 GPa) obtained with above Birch–Murnaghan EOS\textsuperscript{13} and experimental data.\textsuperscript{36} It indicates that our calculations are reliable and calculation method is correct. On the other hand, the bulk modulus $B$ and shear modulus $G$ can represent the resistance to volume change and shape change, respectively. The Young’s modulus is related to the stiffness of materials. From Table 2, we also found that the bulk modulus $B$ and shear modulus $G$ and Young’s modulus $E$ increase with growing pressures till 40 GPa, indicating that the increase of resistance ability to volume and shape, and the stiffness of $\text{Be}_{12}\text{Ti}$ is getting harder and harder, and the $\text{Be}_{12}\text{Ti}$ becomes more and more difficult to compress as pressure increases. At the same time the value of $B$ is greater than $G$, implies the principal parameter limiting the stability of tetragonal $\text{Be}_{12}\text{Ti}$ is the shear modulus.\textsuperscript{37}

For a tetragonal crystal, the traditional mechanical stability conditions under isotropic pressure are given by the following equations:\textsuperscript{38}

$$
\tilde{C}_{11} > 0, \tilde{C}_{33} > 0, \tilde{C}_{44} > 0, \tilde{C}_{66} > 0, \tilde{C}_{11} - \tilde{C}_{12} > 0, (\tilde{C}_{33} + \tilde{C}_{11} - 2\tilde{C}_{12}) > 0, (2\tilde{C}_{11} + 2\tilde{C}_{12} + \tilde{C}_{33} + 4\tilde{C}_{13}) > 0
$$

(3)

where $\tilde{C}_{aa} = C_{aa} - P (a = 1, 3, 4, 6), \tilde{C}_{12} = C_{12} + P, \tilde{C}_{13} = C_{13} + P$. It is evident that from calculated results the elastic constants of $\text{Be}_{12}\text{Ti}$ satisfy all of these conditions above at pressure up to 100 GPa, which indicates that tetragonal structure $\text{Be}_{12}\text{Ti}$ under applies pressure is elastic stable. In order to determine the

| Phase      | $a$ (Å) | $c$ (Å) | $V_0$ (Å³) | $B_0$ (GPa) | $B'_0$ (GPa) |
|------------|---------|---------|------------|-------------|--------------|
| $\text{Be}_{12}\text{Ti}$ | 7.25    | 4.17    | 223.097    | 121.0       | 3.46         |
| Experimental ($T = 273$ K) | 7.35\textsuperscript{a} | 4.19\textsuperscript{a} | 226.354 | 117\textsuperscript{b} | —          |

\textsuperscript{a} Ref. 35. \textsuperscript{b} Ref. 36.
Dynamic stability under the pressure considered, we also calculate the phonon dispersion based on linear response (DFPT) for the $2 \times 2 \times 2$ supercell with 104 atoms at 0, 20, 40, 60 GPa and 100 GPa in Fig. 5 where no imaginary frequencies in the whole Brillouin zone of Be$_{12}$Ti and do not show any anomaly for all the phonon modes, confirming that Be$_{12}$Ti with tetragonal structure is at least stable dynamically up to 100 GPa. Meanwhile, we found that the acoustic and optical modes become more compact and frequency range increase as the pressure increasing, when the pressure reaches 100 GPa, the phonon spectrum intervals between acoustic and optical modes have disappeared.

Poisson’s ratio $\nu$ can be used to estimate the ductility and brittleness of the materials. As for Be$_{12}$Ti, its Poisson’s ratio value has been listed in Table 2, we can see that from Table 2 all Poisson’s ratio values are less than 1/3 under applied pressure, which means that the Be$_{12}$Ti is brittle in nature. Meanwhile, according to the Pugh’s criterion, the ratio of the bulk modulus to the shear modules $B/G$ can be used to predict the whether a material will behave in a brittle or ductile manner. A high $B/G$ ratio is associated with ductility, whereas a low value corresponds to a brittle material, the critical value between them is around 1.75. If $B/G$ is less than 1.75, then brittle behavior is predicted; otherwise, the material behaves in a ductile manner. In this study, calculated $B/G$ values for tetragonal Be$_{12}$Ti as a function of pressure are shown in Table 2 and Fig. 6. It is noted that the value of $B/G$ is 0.90 at 0 K and 0 GPa, showing that tetragonal Be$_{12}$Ti has a brittle nature under these conditions. When applied pressure increases from 0 GPa to 100 GPa, $B/G$ monotonously increases from 0.90 to 1.09, which is always remaining smaller than 1.75. This trend is markedly different from ref. 17. This indicates that Be$_{12}$Ti will also behave in a brittle manner at pressure up to 100 GPa, but it has a tendency towards the development of ductility, indicating that the external pressure can improve the brittleness of tetragonal Be$_{12}$Ti alloys.

### 3.3. Elastic anisotropy

Anisotropic behavior has an important implication in engineering science as well as crystal physics since it is highly related with the possibility to induce microcracks in

materials. By means of elastic anisotropy, we can know more information about the material. Such as phase transformation, precipitation, dislocation dynamics, and micro-cracks formation. Usually, the elastic anisotropy can be represented by three elastic factors, which are shear anisotropic factors \(A_1, A_2\) and \(A_3\) of different crystallographic planes and universal anisotropic index \(A^U\) and the percentage of anisotropy in compression and shear \(A_p\) and \(A_s\). In this work, we have calculated above three type anisotropy of tetragonal \(\text{Be}_12\text{Ti}\) under applied pressure and listed in Table 3, the detail calculation equations as follows.

Fig. 5 Phonon dispersion curves for tetragonal \(\text{Be}_12\text{Ti}\) at 0 GPa (a), 20 GPa (b), 40 GPa (c), 60 GPa (d) and 100 GPa (e).

3.4. Thermodynamic properties

We have used the quasi-harmonic approximation (QHA) to investigate the thermodynamic properties of tetragonal Be$_{12}$Ti in the temperature range 0–1600 K and pressure range 0–100 GPa, which has been successfully applied to several materials, the detail calculation method are presented in ref. 46 and are not described here. To obtain the equilibrium volume and bulk modulus of Be$_{12}$Ti at different temperature, we have calculated the Helmholtz free energy $F(V, T)$ dependence of the volume $V$, the equilibrium volume and the bulk modulus are obtained by above the formula (1) Birch–Murnaghan EOS. They are shown in Fig. 9 and 10, respectively. From Fig. 9, we can see that the free energy value decreases gradually and its change range in the same temperature interval (such as 200 K) enhances as increase of temperature. If we connected the minimum values of free energy using one line we can obviously find that the equilibrium volume of Be$_{12}$Ti expands with the increasing of temperature. Also, clearly, the bulk modulus decreases with the increase of temperature from 0 K to 1600 K, and when the temperature is near 270 K, the calculated result of bulk modulus are close to the experimental data.

The investigation on the heat capacity of crystal is an old topic of the condensed matter physics, because as one variation of the thermal properties, the heat capacity of a substance not only provides essential insight into its vibrational properties but is also mandatory for many applications. According to the laws of thermodynamics, there are two kinds of heat capacities in a material, namely heat capacity at constant volume $C_v$ and heat capacity at constant pressure $C_p$, the $C_v$ and $C_p$ can be calculated from ref. 46. Fig. 11 shows the variation of $C_v$ and $C_p$ with temperature at 0 GPa. One can easily see that $C_v$ and $C_p$ increases with the increase of temperature, and when temperature lower than 300 K, they are almost equal, while the temperature is higher than 300 K, $C_p$ is always larger than $C_v$, but the discrepancy between them becomes significant as the temperature enhances. Meanwhile, the constant volume $C_v$ at various pressure is calculated and displayed in Fig. 12. It is obvious that the $C_v$ at different pressure has a similar trend if compared with the $C_v$ at 0 GPa. That is while $T < 400$ K $C_v$ increases rapidly with temperature at a given pressure and decreases with increasing pressure at a given temperature. Namely, the variation of $C_v$ is dependent on both temperature and pressure at low temperature. At the same
Fig. 8  Directional dependence of the Bulk modulus for Be$_{12}$Ti under 0 GPa (a) and 40 GPa (b). The corresponding projections in different crystal planes (XY plane, and XZ plane, and YZ plane) of Bulk modulus are also shown in (c) and (d).

Fig. 9  Dependence of the Helmholtz free energy $F(V, T)$ on crystal volume at various temperatures and the locus of the minimum of the free energy for Be$_{12}$Ti.

Fig. 10  Temperature dependence of the bulk modulus for Be$_{12}$Ti.
time at sufficiently low temperatures \(T < 400 \text{ K}\), \(C_v\) is approximately proportional to \(T^4\). However, the anharmonic effect on \(C_v\) is suppressed at higher temperature, the heat capacity \(C_v\) approaches to a constant Dulong–Petit limit \(3nN_A K_B (≈ 324.53 \text{ J mol}^{-1} \text{K}^{-1})\), where \(n = 13\) is number of atoms for Be\(_{12}\)Ti unit cell, \(N_A\) is the Avogadro number and \(K_B\) is the Boltzmann’s constant. At intermediate temperatures, the temperature dependence of \(C_v\) is governed by the details of vibrations of the atoms. It indicates that the atomic interaction occurs at low temperature in Be\(_{12}\)Ti alloys. The effects of temperature on heat capacity are more significant than that of the pressure for Be\(_{12}\)Ti, and the \(C_v\) is more sensitive to the temperature than that of the pressure. Here, we also plotted the change of entropy with temperature at various pressure in Fig. 13 for Be\(_{12}\)Ti. It can be seen that the entropy increase quickly as increasing temperature and decreases with increasing of pressure. It’s consistent with common sense, because the entropy of a crystal is generated by lattice vibrations and electronic excitation, and as the temperature goes up, the lattice vibrations of the crystal increases and the electrons are more likely to be excited.

The dependence of the thermal expansion \(\alpha\) with temperature \(T\) and pressure \(P\) is illustrated in Fig. 14. It is similar to the heat capacity, when the temperature \(T\) is below 400 K, \(\alpha\) rises sharply with temperature, the propensity of increment becomes gently and gradually approaches to a liner increase at high temperature. For comparison, the experimental values of thermal expansion for tetragonal Be\(_{12}\)Ti from ref. 50 are also presented in Fig. 14. The comparison demonstrates that our calculated results are in excellent agreement with the experimental data in the temperature range 300–800 K. This further indicates that the above calculation method and model for tetragonal Be\(_{12}\)Ti are reliable and effective. Unfortunately, the experimental data are only in the range of 300–800 K, and more experimental values under high temperature are expected to be compared in the future.
4. Conclusions

In this work, the structure, elastic anisotropy and thermodynamic properties of tetragonal Be$_{12}$Ti at different temperature and pressure are investigated using the pseudo-potential plane-wave method in combination with the quasi-harmonic approximation. The calculated equilibrium structure parameters and bulk modulus are good agreement with the available experimental data and other theoretical results. The calculated elastic constants $C_{ij}$ and interrelated quantities $G, E, \nu$ show that Be$_{12}$Ti alloy possesses brittle nature at ambient conditions and Be$_{12}$Ti exhibits no pronounced elastic anisotropy by the 3D surface of Young’s modulus. The higher the temperature, cell compression for Be$_{12}$Ti at a given pressure is more difficult. Phonon dispersions has been carried out, shows that the Be$_{12}$Ti crystal is dynamic stability up to 100 GPa. Under the QHA method, the thermodynamic properties of Be$_{12}$Ti are obtained successfully. The pressure and temperature dependence of heat capacity and thermal expansion are also predicted in the present work.
