Abstract

AIM: To identify and characterize the function of nonmuscle myosin II (NMM II) isoforms in primary rat hepatic stellate cells (HSCs).

METHODS: Primary HSCs were isolated from male Sprague-Dawley rats by pronase/collagenase digestion. Total RNA and protein were harvested from quiescent and culture-activated HSCs. NMM II isoform (II-A, II-B and II-C) gene and protein expression were measured by RealTime polymerase chain reaction and Western blot analyses respectively. NMM II protein localization was visualized in vitro using immunocytochemical analysis. For in vivo assessment, liver tissue was harvested from bile duct-ligated (BDL) rats and NMM II isoform expression determined by immunohistochemistry. Using a selective myosin II inhibitor and siRNA-mediated knockdown of each isoform, NMM II functionality in primary rat HSCs was determined by contraction and migration assays.

RESULTS: NMM II-A and II-B mRNA expression was increased in culture-activated HSCs (Day 14) with significant increases seen in all pair-wise comparisons (II-A: 12.67 ± 0.99 (quiescent) vs 17.36 ± 0.78 (Day 14), P < 0.05; II-B: 4.94 ± 0.62 (quiescent) vs 13.90 ± 0.85 (Day 14), P < 0.001). Protein expression exhibited similar expression patterns (II-A: 1.87 ± 2.50 (quiescent) vs 58.64 ± 8.76 (Day 14), P < 0.05; II-B: 1.17 ± 1.93 (quiescent) vs 103.71 ± 21.73 (Day 14), P < 0.05). No significant differences were observed in NMM II-C mRNA and protein expression between quiescent and activated HSCs. In culture-activated HSCs, NMM II-A and II-B merged with F-actin at the cellular periphery and throughout cytoplasm respectively. In vitro studies showed increased expression of NMM II-B in HSCs activated by BDL compared to sham-operated animals. There were no apparent increases of NMM II-A and II-C protein expression in HSCs during hepatic BDL injury. To determine the contribution of NMM II-A and II-B to migration and contraction, NMM II-A and II-B expression were downregulated with siRNA. NMM II-A and/or II-B siRNA inhibited HSC migration by approximately 25% compared to scrambled siRNA-treated cells. Conversely, siRNA-mediated NMM II-A and II-B inhibition had no significant effect on HSC contraction; however, contraction was inhibited with the myosin II inhibitor, blebbistatin (38.7% ± 1.9%).

CONCLUSION: Increased expression of NMM II-A and II-B regulates HSC migration, while other myosin II classes likely modulate contraction, contributing to development and severity of liver fibrosis.

INTRODUCTION

The progressive pathology of hepatic fibrosis is characterized by continual deposition and accumulation of type I collagen heavily mediated by the hepatic stellate cell (HSC). HSCs are located in the perisinusoidal space of Disse between the hepatocytes and endothelial cells and comprise approximately 15% of the normal liver[1]. These lipid rich, vitamin A storing cells produce collagen and other extracellular matrix (ECM) components for maintenance of basement membrane and regulate hepatic microcirculation by modulating sinusoidal diameter[2-4]. In diseased liver, such as steatohepatitis, fibrosis, cirrhosis or hepatocellular carcinoma, damaged stimuli trigger transdifferentiation of quiescent HSCs to an activated, wound-healing process and influence both development and severity of hepatic fibrosis. Recent studies examined the expression and functionality of NMM II proteins in mouse HSCs[5,6]. Inhibition of myosin II ATPase by blebbistatin, a cell-permeable pharmacological agent, altered HSC morphology and reduced characteristic HSC contraction; however, NMM II isoform specificity of blebbistatin is not well understood[7]. While studies have shown the pharmacological inhibitor blocks skeletal muscle and NMM II activity with minimal effects on smooth muscle myosin II, others have shown that blebbistatin is specific to smooth muscle myosin II[8,9]. Lack of specificity associated with blebbistatin requires further investigation into the distinct roles of NMM II isoforms in the HSC. Furthermore, expression of NMM II isoforms in HSCs in vivo has not been investigated. In the present study we examined expression and functionality of NMM II isoforms in rat HSCs.

MATERIALS AND METHODS

Materials

Reagents were purchased from Sigma Aldrich (St. Louis, MO) unless otherwise indicated. ET-1 was purchased from American Peptide (Sunnyvale, CA). TRIzol, Lipofectamine and Superscript II kit were purchased from Invitrogen Corporation (Baltimore, MD). Blebbistatin was purchased from Calbiochem (San Diego, CA). Type I collagen was purchased from BD Biosciences (Franklin Lakes, NJ). Pronase and SYBR Green were purchased from Roche Molecular Biochemicals (Chicago, IL). Oligonucleotide primers were designed using Primer3 (v0.4.0) and synthesized by Integrated DNA Technologies (Coralville, IA). Monoclonal antibodies specific against NMM II-A and II-B isoforms, GAPDH, and anti-rabbit (or goat)-HRP secondary antibodies were obtained from Santa Cruz Biotechnology, Inc (Santa Cruz, CA). NMM II-C antibody was a gift, kindly provided by Dr. Robert Adelstein. Monoclonal antibodies specific against α smooth muscle actin (aSMA) were purchased from Dako (Glostrup, Germany). Chamber slides were purchased from Lab-Tek (Rochester, NY). Secondary fluorescent antibodies (AlexaFluro 488 anti-rabbit and 594 anti-mouse), rhodamine phalloidin and DAPI were purchased from Molecular Probes (Eugene, OR). ECL reagent was purchased from Amersham Biosciences (Piscataway, NJ). siRNAs for NMM II isoforms (II-A and II-B) were purchased from Ambion (Austin, TX). Optiprep was purchased from Axis-Shield (Oslo, Norway).

are associated with generation of contractile forces[11]. In nonmuscle cells, three isoforms of nonmuscle myosin II (NMM II-A, II-B and II-C) encoded by different genes have been identified and are expressed in multiple tissues[12-16]. Distinct enzymatic properties of each isoform confer specific functions and are important in modulating kinetic properties of the cell[17].

HSC contraction and migration are necessary for the wound-healing process and influence both development and severity of hepatic fibrosis. Recent studies examined the expression and functionality of NMM II proteins in mouse HSCs[18-19]. Inhibition of myosin II ATPase by blebbistatin, a cell-permeable pharmacological agent, altered HSC morphology and reduced characteristic HSC contraction; however, NMM II isoform specificity of blebbistatin is not well understood[20]. While studies have shown the pharmacological inhibitor blocks skeletal muscle and NMM II activity with minimal effects on smooth muscle myosin II, others have shown that blebbistatin is specific to smooth muscle myosin II[21-23]. Lack of specificity associated with blebbistatin requires further investigation into the distinct roles of NMM II isoforms in the HSC. Furthermore, expression of NMM II isoforms in HSCs in vivo has not been investigated. In the present study we examined expression and functionality of NMM II isoforms in rat HSCs.
**Animals**
Male Sprague-Dawley rats [250 g (bile duct-ligation (BDL) model); 500-650 g (primary cultures)] purchased from Charles River Laboratories (Raleigh, NC) were used in these studies. All experiments were approved by The University of North Carolina at Charlotte Institutional Animal Care and Use Committee and performed in accordance with NIH guidelines.

**HSC Isolation and culture**
Primary HSCs were isolated from animals following in situ liver perfusion-pronase/type I collagenase digestion\[24\]. The liver was perfused with calcium free-buffered saline, pronase (0.035% w/v) and collagenase (1 mg/mL) for 10 min each. Digested liver suspension was centrifuged twice at 50 × r/min for 2 min. Nonparenchymal cells were recovered from the supernatant by centrifugation at 700 × r/min for 3 min. Density gradients were prepared in Opti-prep 40% (v/v) solution. The gradient was centrifuged at 700 × r/min for 17 min at 25°C. HSCs were recovered from the interface between the medium and density layer, washed and centrifuged at 700 × r/min for 5 min. Typical cell purity following isolation was ≥ 95% as determined by autofluorescence of stored retinoid esters in HSCs. Cell viability was determined by Trypan blue exclusion staining. Cells were either used immediately (quiescent) or cultured on plastic using DMEM supplemented with 10% fetal bovine serum, L-glutamine (2 mmol/L) and antibiotics (activated) as described previously\[24\]. Growth medium was changed on a daily basis for the first week in culture. Culturing HSCs on plastic is routinely used to mimic the in vivo activation process\[20\].

**Surgical procedures**
Animals were randomized into two groups; sham and BDL and allowed to recover for two weeks.

**Sham**:
Surgical anesthesia was induced by isoflurane inhalation and a midline laparotomy performed and closed in two layers.

**BDL**:
Surgical anesthesia was induced by isoflurane inhalation and a midline laparotomy performed. The hepatic bile duct was exposed, double ligated, transected and the abdominal incision closed in two layers.

**Post-operative care**:
In all experimental groups, animals received saline [0.9% (w/v)] resuscitation and buprenorphine (0.03 mg/kg, s.q.) immediately after each procedure. Buprenorphine was administered for the duration of the experiment as determined by the in-house veterinarian. The time points for data analysis were chosen as mild fibrosis ensued to identify specific changes in NMM II isoform expression in the liver.

**Tissue collection**:
Two weeks after BDL, animals were sacrificed by exsanguination and the liver resected. Tissue samples (100-200 mg) were fixed in formalin solution overnight and paraffin-embedded.

**mRNA analysis**
Total RNA from quiescent and culture-activated HSCs was isolated using TRIzol, DNase treated, reverse transcribed using Superscript II following manufacturer’s recommendations. RealTime PCR was run at 94°C 15 s; 58°C 25 s; 72°C 20 s, read 5 s using primers specific against NMM II -A, II -B and II -C (Table 1). Reaction mixture consisted of 1 μL each of cDNA, forward and reverse primers (5 μmol), 2 μL DEPC water, and 5 μL of SYBR Green Master Mix. cDNA concentration was used as a reference to normalize samples since the expression of housekeeping genes was modulated through days in culture\[20\]. Data were reported as cross-point, the point at which the detectable level of SYBR green fluorescence was detected above the background. All experiments were performed a minimum of three times.

**Protein analysis**

**Western blot**:
Protein expression of NMM II isoforms during transdifferentiation of quiescent (freshly isolated), Day 1 (early activation) and Day 14 (late activation) HSCs was determined by an actin-selection assay\[20\]. Briefly, HSCs were homogenized in lysis buffer (50 mmol/L Tris-HCl, 0.1 mmol/L EDTA, 1 mmol/L phenylmethylsulfonyl fluoride, 2% (w/v) SDS, aprotinin and protease inhibitor cocktail). Sample lysates were equalized for protein concentration using the Bradford method and incubated with F-actin (10 mmol/L) for 30 min at 4°C. The protein complex was centrifuged at 320 000 × r/min for 30 min and the pellet suspended in Laemmli buffer. Immunoblot analysis was performed using 8% SDS-PAGE. Primary antibodies were diluted 1:500 (NMM II -A, II -B, or II -C) and incubated at 4°C overnight. Secondary antibody (anti-rabbit-HRP) was used at a dilution of 1:1000 and incubated for 1 h at room temperature. Rat-1 cell line was used as a positive control for NMM II isoform detection. Protein expression of NMM II -A and II -B siRNA inhibition was determined by standard Western blot analysis\[27\]. Briefly, HSCs were homogenized in lysis buffer, equalized for protein concentration using the Bradford method and immunoblot analysis performed using 8% SDS-PAGE.

### Table 1  Intron-spanning primers for the amplification of NMM II isoforms

Gene name: rMyh9: Rat nonmuscle myosin II -A; rMyh10: Rat nonmuscle myosin II -B, rMyh14: Rat nonmuscle myosin II -C.
Primary antibodies were diluted 1:500 (NMM II-A or II-B) or 1:1000 (GAPDH) and incubated at 4°C overnight. Secondary antibody (anti-rabbit-HRP or anti-goat-HRP) was used at a dilution of 1:1000-1:5000 and incubated for 1 h at room temperature. Signal intensity was analyzed using a digital camera and densitometric analysis program (Quantity One, Bio-Rad Laboratories, Inc).

Dual fluorescent immunostaining: The expression of NMM II isoforms was evaluated by: (1) immunocytochemistry (ICC) of culture-activated HSCs (Day 14) incubated on chamber slides and (2) immunohistochemistry (IHC) of paraffin-embedded liver sections from normal and injured liver. For immunocytochemistry, slides were washed with PBS, blocked with 5% (v/v) normal goat serum, incubated overnight at 4°C using rabbit polyclonal NMM II-A, II-B and II-C antibody (1:100). Samples were washed with PBS, incubated with secondary antibody (AlexaFluro 488: 1:500) for 1 h, followed by rhodamine phalloidin incubation for 15 min and finally with 4, 6-diamidino-2-phenylindole, dihydrochloride (DAPI) for 5 min. Immunohistochemistry, sections were de-paraffinized and hydrated in graded ethanol. Cross-linked proteins were exposed using heat-induced epitope retrieval and proteolytic enzyme digestion. Slides were washed, blocked [0.2% (v/v) NGS] and incubated overnight at 4°C using rabbit polyclonal NMM II-A, II-B and II-C antibody (1:500). In addition, mouse αSMA was used to detect activated HSCs. Slides were washed, incubated with fluorescent secondary antibodies (AlexaFluro 488 and AlexaFluro 594: 1:1000) and developed with DAPI. To demonstrate specificity immunoreactions, negative controls (normal serum from the same species replaced the primary antibody) were included for all immuno- reactions. Rat-1 cell line (ICC) and lung tissue (IHC) served as positive controls for NMM II isoform detection (data not shown). For microscopic images, cells were visualized using the Olympus IX71 microscope (Olympus America, Inc). Images of NMM II isoforms, αSMA, F-actin and DAPI were taken separately at identical exposures and color channels merged using IMAGEPRO software (Media Cybernetics Inc).

siRNA-mediated inhibition
Freshly isolated HSCs were seeded at 2 × 10⁶ cells on p60 tissue culture dishes and transfected on Day 3 of culture-activation with siRNAs for NMM II isoforms (II-A and II-B) using Lipofectamine reagent. In a 5 mL polystyrene tube, NMM II isoform or scramble siRNAs (final concentration was 100 nmol/L) was incubated with 600 μL OptiMEM and vortexed. In a separate 5 mL tube, 20 μL Lipofectamine reagent was incubated with 600 μL OptiMEM and vortexed. Solutions were combined, vortexed and incubated for 30 min at room temperature. Cells were washed and incubated with 1.5 mL OptiMEM. Cells were subsequently incubated with siRNA mixtures for 8 h. At the end of the transfection period, fresh media (2.5 mL) was added to wells and incubated for 48 h prior to analysis of mRNA and protein expression, contraction and migration analyses.

Preparation of collagen lattices
Contraction of HSCs was performed in a 24-well tissue culture dish coated with collagen as described with minor modifications[8,9]. Hydrated collagen lattices were prepared using an 8:1:1 of type I collagen: 0.2 mol/L HEPES: 10 × DMEM for final collagen concentration of 3.65 mg/mL. The mixture (300 μL) was aliquoted onto each well of a 24-well plate and allowed to congeal overnight at 37°C. Cells were serum-starved 24 h prior to seeding onto the congealed collagen lattice (3 × 10⁴ cells/well).

Contraction assay
Collagen lattices were prepared and culture-activated HSCs (Day 4) trypsinized and seeded onto the congealed collagen lattice and allowed to recover overnight. Collagen lattices were dislodged from wells with a 10 μL pipette tip. Cells were treated with ET-1 (1 nmol/L) to induce contraction. Images were captured with UVP BioSpectrum AC Imaging System at indicated time points and PTI ImageMaster software was used to measure changes in collagen diameter immediately following ET-1 treatment and 24 h later. The differences in collagen diameters were reported as percentage change in collagen lattice circumference, which is reflective of ET-1-induced contraction. Assays were repeated using transfected HSCs to assess effects of siRNA knockdown on ET-1-mediated contraction.

Migration assay
A sterile pipette tip was dragged through the cell sheet, creating a cleared zone 48 h after transfection. Images were immediately taken of the scrape in four locations per dish using the Olympus IX71 microscope. Twenty-four hours later, images were taken in the exact same locations. To assess the number of migrating cells, the PTI ImageMaster software was used to measure changes in the distance traveled into the ‘damaged area’ (cleared zone).

Blebbistatin treatment
Collagen-seeded HSCs (Day 5) were pre-treated with increasing doses (0-25 μmol/L; 5 μmol/L increments) of the active enantiomer (-)-blebbistatin (Blebbistatin/ Bleb) or inactive enantiomer (+)-blebbistatin (Vehicle) for 30 min. The collagen lattices were dislodged from the wells and incubated with ET-1 (1 nmol/L) to induce contraction. To assess HSC contraction, the PTI ImageMaster software was used to measure changes in the collagen diameter over a 24 h incubation period.

Statistical analysis
Data are presented as mean ± SE. One-way ANOVA followed by Student-Newman-Keuls post hoc test was used to assess differences between groups at different stages of activation using Sigma Stat software. Results were considered significant for P < 0.05.
RESULTS

**NMM II isoform expression**

Throughout the HSC transdifferentiation process numerous qualitative and quantitative changes are associated with functional modifications that serve to accommodate normal or injured conditions. Our laboratory has recently demonstrated that HSC transdifferentiation from the quiescent to activated state results in significant morphological and gene expression changes\(^1\). Furthermore, significant alterations in the classic housekeeping genes are also present in culture activation. In the present study, we normalized gene expression in quiescent (freshly isolated), Day 1 (early activation) and Day 14 (late activation) HSCs to total cDNA concentration. RealTime PCR was performed to quantify mRNA expression of NMM II-A and II-B isoforms (Figure 1A). Our results demonstrate that expression was increased during transdifferentiation with significant increases seen in all pair-wise comparisons. Interestingly, mRNA expression of NMM II-B increased 2.8-fold over culture-activation, whereas II-A expression only increased 1.4-fold. NMM II-C mRNA expression was not significantly altered following culture-activation. To quantify NMM II protein we utilized an actin-selection assay and subsequent Western blot analysis. Sample lysates were equalized for protein concentration using the Bradford method and incubated with F-actin (10 mmol/L). (+ Ctrl; Rat-1 fibroblast cell line). Top panel: representative Western blots. Bottom panel: Western blot quantification using band intensity. \(^*P < 0.05\) as compared to quiescent.

**Cellular localization of NMM II isoforms**

Peak mRNA and protein expression levels were measured...
in fully activated HSCs that are present during wound-healing; therefore, Day 14 cells were utilized for immunocytochemistry (Figure 2). Culture-activated HSCs exhibited characteristic stress fiber formation as detected by F-actin (rhodamine phalloidin) staining. All three NMM II isoforms were detected in HSCs, which corresponded with mRNA and protein expression. Merged images revealed a stronger focus (yellow fluorescence) of NMM II-A and II-B with F-actin compared to II-C. Additionally, NMM II-A localization with F-actin showed a stronger intensity at the cell periphery, while II-B was predominantly located throughout the cytoplasm.

**NMM II isoform expression in normal vs fibrotic liver**

Increased isoform expression was seen in activated HSCs, the main effector cells in hepatic fibrosis. To confirm this observation in vitro, a BDL model of liver injury was utilized. BDL-induced fibrosis typically generates lesions surrounding bile duct epithelium and stimulates cholangiocyte proliferation, resulting in hepatic inflammation and injury. HSCs respond to BDL-induced injury and transdifferentiate into activated myofibroblast-like cells, characterized by αSMA expression. NMM II-A and II-B protein expression was minimally detected in normal liver tissue, while BDL liver tissue showed up-regulation of all three NMM II isoforms (green fluorescence), correlating with in vitro data. αSMA (red fluorescence) expression was observed in BDL-injured tissue (Figure 3) and, interestingly, NMM II-B was the only isoform found to merge (yellow fluorescence) with activated HSCs in BDL liver tissue.

**Inhibition of NMM II isoforms**

siRNA-mediated inhibition was utilized to perform spe-
Specific knockdowns of NMM II-A and II-B in primary activated HSCs given that II-C mRNA and protein expression was not significantly altered during transdifferentiation (Figure 3). Cells were transfected with the appropriate siRNA (100 nmol/L). RealTime PCR confirmed successful inhibition of NMM II-A (60% reduction compared to scramble) (Figure 4A) and II-B (56% reduction compared to scramble) (Figure 4B). Similarly, transfections with NMM II-A or II-B resulted in reduced protein expression, 52% and 49% respectively (Figure 4C and 4D). Additionally, siRNA inhibition specificity was shown as indicated by no reduction in NMM II-A expression when transfected with II-B siRNA alone (Figure 4A). Parallel experiments also demonstrated specific knockdown of NMM II-B (Figure 4B).

Effect of NMM II isoform inhibition on HSC migration and contraction

To determine functional contributions of NMM II isoforms in the HSC, culture-activated cells (Day 5) were treated with scramble, II-A, II-B or II-A and II-B siRNAs. Using a plate scrape model of injury-induced migration, location-specific images were taken prior to and 24 h following damage and gap distance was marked and measured. As compared to the scramble siRNA, all isoform permutations displayed impaired migratory properties (Figure 5). Quantitative analysis of the change in gap distance revealed significant decreases with both siRNA treatments indicating importance of these molecular motors in HSC migration (bottom panel).

To further investigate additional known functions of NMM II-A and II-B, HSCs were transfected with specific siRNAs and subsequently treated with ET-1 for 24 h to induce contraction on collagen lattices. The effect of isoform inhibition was determined by changes in gel circumference after 24 h as compared to scramble control. Results indicated that siRNA-mediated knockdown did not result in inhibition of ET-1-induced contraction (Figure 6). Several adjustments to the contraction assay were made to validate results, siRNA concentration and incubation period were changed, in addition to altering matrix stiffness; however, these modifications also demonstrated

Figure 3 Immunohistochemical analysis of nonmuscle myosin II-A, II-B and II-C in normal and injured liver sections. Specific nonmuscle myosin (NMM) II immunoreactivity of representative fields is shown in green; α-actin smooth muscle, as a marker of hepatic stellate cell activation is shown in red and cell nuclei are stained blue (DAPI). Images of NMM II isoforms, F-actin, and DAPI were taken separately at identical exposures and color channels were merged using IMAGE-PRO software (200 ×).
induced hypercontraction and as expected, blebbistatin pretreatment abolished the aforementioned effect in a dose dependent manner (black bars), while vehicle pretreatment permitted ET-1-induced contraction (grey bars). Quantitative analysis revealed that 5 μmol/L blebbistatin treatment significantly reduced HSC contraction, as did higher doses of the pharmacological inhibitor. Consistent with previous findings, micrograph images of HSCs seeded onto collagen lattice exhibited a contractile star-like shape (Figure 7B). In response to ET-1 stimulus, myosin II activation resulted in HSC elongation along the cellular axis as previously described [18,30], while chemical inhibition of myosin II activation restored original cellular shape.

DISCUSSION
Chronic injury and unresolved fibrosis perpetuates HSC activation and further promotes the deleterious clinical effects of portal hypertension, which is associated with both increased portal blood flow and augmented intrahepatic vascular resistance [6,7]. In characterizing the expression profile of specific NMM II isoforms during differ-
Figure 5 Effect of nonmuscle myosin II inhibition on hepatic stellate cell migration. Culture-activated hepatic stellate cells (Day 3) were transiently transfected with siRNA targeted to all nonmuscle myosin (NMM) II permutations (NMM II-A, II-B, II-A & II-B) or scramble siRNA and incubated for 48 h. A plate scrape model of migration was used to simulate liver injury. After 24 h, migration was calculated as change in wound (gap) diameter over time. Top panel: representative micrographs. Bottom panel: Migration assay quantification. (*P < 0.05 as compared to scramble).
ent stages of HSC transdifferentiation, we were able to evaluate individual components that may be responsible for the fibrogenic response of activated HSC migration. In agreement with our findings, recent studies in mouse HSCs indicated that an increase in NMM II isoform expression regulates cellular motility[35,36]; however, in contrast to these studies, we report that NMM II isoforms in rat HSCs increases cellular migration.

Isoform-specific localization of NMM II along actin stress fibers has previously been ascribed to cellular functions in multiple cell types[33]. Specifically, in bovine aortic endothelial cells, NMM II-A merges with actin filaments at the leading edge of cells, while NMM II-B merges within the cytoplasm, which facilitates endothelial cell expansion under diseases states[33]. In contrast to these findings, studies in mouse HSCs demonstrated that NMM II-A is distributed along qSMA-containing stress fibers following culture-activation, while NMM II-B is located at the leading edge of lamellipodia[18]. In our studies, upregulation of NMM II-A and II-B expression was associated with F-actin stress fibers in the cellular periphery and throughout the cytoplasm of rat HSCs respectively. These results are consistent with previous studies in fibroblast cells suggesting that NMM II-A activation facilitates rearrangement of actin bundles into cellular protrusions and NMM II-B incorporates into cytoplasmic stress-fibers[30].

While the expression of the NMM II isoforms is relatively ubiquitous in most nonmuscle cells it has yet to be determined whether these proteins play redundant, overlapping or distinct roles in performing various mechanical functions in rat HSCs. Therefore, we performed migration and contraction studies using siRNA-mediated knockdown of NMM II-A and II-B, which were upregulated during culture-activation of HSCs in vitro. While Liu et al reports that siRNA-mediated NMM II-A inhibition increased cellular migration in mouse HSCs[18,31], our studies demonstrated that NMM II-A and II-B knockdown significantly reduced the migratory capacity of rat HSCs. While previously studies have suggested that isoform-specific rearrangement of actin stress fibers may be responsible, in part, for differences in migration rates among different cell types[32], further analysis is needed to validate these conflicting species-specific findings.

Based on the kinetic properties of NMM II-B, it has been proposed that this isoform may be involved in maintaining tonic force needed for particular cellular functions such as hypercontraction[35]. Furthermore, it has been demonstrated that the loss of NMM II-B decreases 3D collagen gel contraction[35]. While Liu et al reported that NMM II-A is the essential isoform necessary for contraction in mouse HSCs, our results indicated that NMM II-A and/or II-B knockdown in rat HSCs does not significantly alter basal or ET-1-induced contraction. In order to confirm these results, we optimized our contraction assay by increasing siRNA concentration and incubation times, altering collagen lattice concentration and cell number; however, changing these parameters had no effect on HSC contraction (data not shown). In the studies performed by Meshel et al, NMM II-B isoform demonstrated significant differences in cell movement and contraction depending on experimental substrate[26,34]; therefore, it is possible that technical differences in experimental design may explain our conflicting results. Future studies will more closely examine the contribution of NMM II isoforms using a Cre-lox recombination system to completely inhibit these isoforms and assess HSC hypercontraction.

While cellular localization suggests possible mechanisms by which NMM II may function in the diseased state, further investigation in vivo was explored using a bile-duct ligation (BDL) model of hepatic injury. Obstruction of the common bile duct initiates rapid proliferation of biliary cholangiocytes and inflammation[35]. Following epithelial expansion, sustained blockage of bile flow causes continual activation of HSCs in the periportal region, which promotes biliary fibrosis. In our studies, NMM II-B expression was evident in activated HSCs during BDL-induced hepatic fibrosis, while NMM II-A and II-C were only associated with biliary cholangiocytes. These results may suggest that NMM II-A and II-C may not be detectable in HSC in the in vivo setting.

Previous studies have identified an important role for NMM II in cellular adhesion and collagen remodeling during wound repair[26,35]. While NMM II-B may be the important isoform contributing to the development and progression of hepatic fibrosis, NMM II-A and II-C may be contributing to the initiation of the inflammatory response by stabilizing integrins and other cellular adhesion molecules. Together, the in vitro and in vivo data suggest that each NMM II isoform may be responsible for specific molecular functions during liver injury.

Although siRNA data confirmed that successful knockdown of one isoform does not influence expression of another NMM II isoform (Figure 4A and 4B), it is plau-
Moore CC et al. NMM II regulates HSC migration

Figure 7  Blebbistatin-inhibited endothelin-1-induced hepatic stellate cell contraction. Culture-activated hepatic stellate cells (HSCs) (Day 4) were serum-starved 24 h prior to seeding onto collagen lattices (3 × 10⁵ cells/well). Cells were pretreated with inactive (Vehicle) or active (Blebbistatin) myosin II inhibitor in increasing doses (0-25 μmol/L; 5) and subsequently treated with blebbistatin-inhibited endothelin-1 (ET-1) (1 nmol/L) after 30 min. (P < 0.05 as compared to scramble). A: Representative light micrographs of collagen lattices: with or without seeded HSCs; with or without chemical treatments (top panel). Twenty-four hours following chemical treatment, hepatic stellate cell contraction was quantified using PTI ImageMaster software and reported as percentage change in gel circumference (bottom panel). B: Representative light micrographs of collagen-seeded HSCs with or without chemical treatments.

Possible that these findings resulted from a species-specific replacement to compensate for the deficiency of one isoform by producing a functionally equivalent signaling mechanism to activate migration and contraction using other myosin II classes. Since HSCs are nonmuscle cells, the focus of the current study was to evaluate NMM II isoforms; however, HSCs express a large number of early and late smooth muscle cell markers including α smooth muscle (SM) actin, SM22a, desmin, SM myosin heavy chain, h1-calponin, h-caldesmon and myocardin, which also may contribute to HSC migration and hypercontraction during hepatic injury[37]. Alternatively,
HSC migration and hypercontraction may be controlled by independent signaling mechanisms that are mutually exclusive, partly explaining the observed species-specific differences. While upregulation of the Rho signaling pathway in activated HSCs confers an increase in contractile potential, Rac phosphorylation of the MHC induces filament instability, promotes disassembly of actomyosin complexes and decreases migration.

In the current studies, siRNA knockdown of NMM II isoforms does not eliminate the possibility that actin stabilization and/or other myosin II sub-classes may be contributing to the hypercontractile phenotype of activated HSCs. Consistent with previous reports, micrograph images from our studies suggest that ET-1-induced contraction is associated with HSC cytoskeletal remodeling and cellular hypercontraction (Figure 7B). In order to facilitate contraction, NMM II may mediate cellular stretching and elongation, while other myosin II classes may be responsible for coordinated force generation. Therefore, we used the chemical inhibitor blebbistatin, which has previously been shown to block protrusion-mediated lamella formation and cellular contraction. By using this selective inhibitor, in combination with our siRNA data, we demonstrate that in rat HSCs myosin II is the protein responsible for ET-1-induced cytoskeletal remodeling and hypercontraction; however, we concede that this controversial chemical inhibitor is not specific to NMM II. Differences between each experimental approach suggest that other myosin II sub-classes may also contribute to the contractile phenotype of rat HSCs.

In addition to sinusoidal constriction being associated with portal hypertension, hepatic microcirculatory failure contributes to end-organ failure in septic patients. Prolonged oxygen deprivation of abdominal organs results in ischemia, tissue damage and necrosis culminating in increased mucosal permeability. Endotoxin and microbial debris can subsequently penetrate the gut wall and permeate into the portal and hepatic artery where sinusoidal endothelial cells (SECs) and Kupffer cells (KCs) establish the first line of inflammatory defense. KCs release a host of inflammatory cytokines, while activated SECs lose their normal anticoagulant state, promote leukocyte infiltration and increase secretion of ET-1. Neighboring HSCs are responsive to these inflammatory and vasoconstrictor signals, which promotes sustained HSC activation and contractility. Compelling evidence has demonstrated the efficacy of targeting SEC/leukocyte interactions, which improved sinusoidal congestion and portal hypertension. Effective experimental treatments have also targeted KC activation, which results in preservation of hepatic function and improved survival after sepsis. In addition to current treatment modalities, manipulation of migrating, hypercontractile HSCs may also reduce hepatic microcirculation and patient survival during sepsis. While modulating HSC contraction may improve the microcirculation, controlling migration may prove to be beneficial in ameliorating the severity of fibrosis by decreasing the rate of collagen formation. Portal hypertension remains the main cause of morbidity and mortality in patients with cirrhosis. Although progress has been made in understanding the pathophysiology of portal hypertension, current pharmacological therapies have been limited to non-selective beta-blockers and statins; however, these treatments result in vasomodulation of the splanchic circulation. Given that increased hepatic microvascular resistance to portal circulation is the leading factor in cirrhotic portal hypertension, a direct molecular therapy may be more effective. Modulating intrahepatic vascular tone may provide additive benefit in patients suffering with unresolved fibrosis and cirrhosis, thus targeting all complications associated with portal hypertension. Therefore, delineating the role of NMM II isoforms in HSC-associated portal hypertension could lead to new therapeutic targets.

ACKNOWLEDGMENTS

We would like to thank Dr. Kyle J Thompson and Whitney Ellefson for critical reading of the manuscript and Dr. Didier Dreau for his guidance with HSC migration assays (UNC-Charlotte). We appreciate the NMM II-C antibody from Dr. Robert Adelstein (National Lung, Heart and Blood Institute). Additionally, we acknowledge guidance from Dr. Alyssa A Gulledge for assistance with primer design and RealTime PCR analysis (UNC-Charlotte).

COMMENTS

Background

Hepatic fibrosis results from normal wound-healing processes going awry and is the main cause of increased intrahepatic vascular resistance during liver injury. When the injury is chronic, type I collagen deposition by hepatic stellate cells (HSCs) exceeds collagen resolution as a result of imbalance between fibrogenesis and fibrolysis. Altered extracellular matrix (ECM) architecture and mechanical distortion culminates in increased blood pressure in the portal venous system, as blood must be diverted away from the liver. In addition to occlusion and compression of the microvasculature by excess collagen deposition, HSC hypercontractility contributes to increased resistance of the sinuosids leading to the clinical manifestation of portal hypertension. HSCs regulate intrahepatic vascular resistance and blood flow at the sinusoidal level through upregulation and activation of motor proteins. Specifically, HSC cytoskeletal remodeling, migration and hypercontraction has been previously associated with nonmuscle myosin (NMM) II upregulation and activation. Function of NMM II isoforms (II-A, II-B and II-C) have been previously characterized in migrating fibroblasts and mouse HSCs, suggesting an essential role in perpetuation of chronic liver injury.

Research frontiers

Through its effects on cytoskeletal remodeling, targeting NMM II may provide a novel mechanism to modulate multiple interrelated pathways such as cellular migration, adhesion and ECM remodeling.

Innovations and breakthroughs

Recently, Liu et al reported that siRNA-mediated NMM II-A inhibition increased cellular migration in mouse HSCs; however, our results suggest both NMM II-A and II-B mediate HSC migration. Consistent with findings by Vicente-Manzanares et al, our results demonstrate that NMM II inhibition decreases cellular components associated with migration such as cytoskeletal remodeling and elongation. In addition, our studies are the first to report the expression profile of NMM II isoforms in a fibrotic injury model in vivo. Finally, studies have shown the pharmacological inhibitor, blebbistatin blocks skeletal muscle and NMM II activity with minimal effects on smooth muscle myosin II, while others have shown that blebbistatin is specific to smooth muscle myosin II. Conversely, we demonstrate that in rat HSCs this controversial chemical inhibitor is not specific to NMM II.
Applications
Although progress has been made in understanding the pathophysiology of fibrosis and portal hypertension, current pharmacological therapies have been limited to treatments, which result in vasomodulation of the splanchic circulation. Given that increased hepatic microvascular resistance to portal circulation is the leading factor in cirrhotic portal hypertension, a direct molecular therapy may be more effective. Modulating intravascular hepatic vascular tone may provide additive benefit in patients suffering with unresolved fibrosis and cirrhosis, thus targeting all complications associated with portal hypertension. Therefore, delineating the role of NMM II isoforms in HSC-associated portal hypertension could lead to new therapeutic targets.

Terminology
Quiescent HSCs: Under physiological conditions, the inactivated cell projects extensive cytoplasmic processes through the space of Disse and reach between hepatocytes and endothelial cells wrapping around neighboring sinusoids similar to tissue pericytes suggesting a functional role in maintenance of vascular tone similar to smooth muscle cells. Quiescent HSCs also play a vital role in normal matrix maintenance and remodeling, similar to a fibroblast. Activated HSCs: HSCs proliferate, lose retinol droplets, increase expression of alpha smooth muscle actin and secrete excess type I collagen for matrix repair. Increased microprojections from the myofibroblast allow for increased chemotactic signaling, which induces cellular migration to the site of injury. Because of the anatomical location and increased contractile apparatus expression, it has been suggested that HSCs are capable of disrupting liver blood flow by hypercontracting, impeding microcirculation and contributing to portal hypertension. Culture-activated HSCs: Transdifferentiation of quiescent HSCs into the activated state in vitro is routinely accomplished by culturing cells on plastic tissue culture dishes, which mimics the in vivo environment of hepatic fibrosis. Blebbistatin: A small pharmacological inhibitor with high binding affinity for myosin II, which blocks the motor protein in an actin-detached state. Actomyosin complex: Produced when bipolar myosin filaments interact with polymerized actin filaments to exert tension or produce movement. Lamella: A network of actin fibers which forms the outer edge of cellular protrusions.

Peer review
It’s an interesting study and excellent.
