This study aimed to address the dilemma of low peripheral blood-derived mesenchymal stromal cell (PBMSC) activity and reduced phenotype in bone or cartilage tissue engineering. Rat PBMSCs (rPBMSCs) were obtained by density gradient centrifugation, and stromal cell characteristics were confirmed by flow cytometry (FCM) and multi-differentiation potential induction experiments. Cell growth curve, viability experiments, and clone formation experiments were performed by [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium] (MTS) and cell counting, and the cell cycle was confirmed by cell FCM. The proliferation signal pathway and stemness-related proteins were detected by molecular methods including Western blot and real-time polymerase chain reaction. CD73, CD90, and CD105 were highly expressed, and CD14, CD19, CD34, CD45, and HLA-DR were barely expressed in rPBMSCs. rPBMSCs possessed the potential to differentiate into chondrocytes, adipocytes, and osteoblasts under their respective induction conditions. Cell growth curve and viability experiments were performed under hypoxic conditions: 19% O2, 5% O2, and 1% O2. Specifically, 5% O2 accelerated the proliferation and expression of the stemness of PBMSCs. Cycle experiments proved that hypoxia promoted the cell transition from the G1 phase to the S phase. Molecular experiments confirmed that 5% O2 hypoxia significantly elevated the expressions of hypoxia-inducible factor 1α and β-catenin and simultaneously the expressions of cycle-related genes including CyclinE/CDK2 and stemness-related genes including Nanog and SOX2. The appropriate concentration of hypoxia (i.e., 5% O2) enhanced the proliferation and stemness of rPBMSCs and increased the multidirectional differentiation potential of stromal cells. The proposed culture method could improve the viability and maintain the phenotype of rPBMSCs in cartilage or bone tissue engineering.

Keywords: peripheral blood-derived mesenchymal stromal cells (PBMSCs), hypoxia, HIF-1α, proliferation, stemness
INTRODUCTION

In recent years, mesenchymal stromal cells (MSCs) derived from adults have been widely used not only for bioregenerative tissue engineering but also for pathophysiological research and cell and gene therapy of bone diseases (1–4). Many studies have confirmed that bone marrow-derived MSCs are a relatively stable source, but the low yield and traumatic source of stromal cells had limited preclinical and clinical applications (5, 6). In recent literature, the applications of peripheral blood-derived MSCs (PBMSCs) in tissue engineering have attracted increasing attention because of their relatively easy collection, abundant sources, and multilineage differentiation potential (7, 8).

The committee of the International Society for Cellular Therapy standardized the criteria for defining human MSCs for basic and preclinical research. That is, cells can adhere and the MSC population must positively express CD105, CD73, and CD90 and negatively express CD45, CD34, CD14 or CD11b, CD79a or CD19, and HLA-DR. MSCs also have the potential to differentiate into chondrocytes, osteoblasts, and adipocytes (9). When many cells are needed for research or clinical applications, PBMSCs can take on this important task (10, 11). However, the reduced activity of PBMSCs cultured in vitro and phenotype loss easily limit this demand (11). Therefore, the key to cartilage tissue engineering is to provide phenotype-maintaining MSCs expanded in vitro. Some growth factors or physical factors, such as basic fibroblast growth factor (bFGF) (12), transforming growth factor-β (TGF-β) (13), and oxygen level (14), play a decisive role in stromal cell survival or proliferation. Thus, TGF-β, bFGF, and oxygen levels have affected stromal cell survival or proliferation (12–14). Hypoxia is a simple and easy-to-operate strategy with few side effects. The exposure of MSCs to a hypoxic environment for a moderate time could enhance cell survival characteristics and tissue repair capabilities, and this conclusion was confirmed by recent studies (15). To enhance the therapeutic effect, several studies have conducted hypoxic pretreatments in many disease-related organs and tissues, such as cardiomyocytes (16). In the literature, compared with normoxic conditions, a hypoxic condition significantly promotes MSCs to further express Oct4, cMyc, Nanog, and SOX2. Simultaneously, hypoxia-cultured MSCs exhibited a better growth trend and a higher proportion of S phase cells than normoxia-cultured MSCs (14–16).

Oxygen gradients derived from the bone marrow niche create hypoxic conditions for stromal and stem cells (17). Hypoxia strongly affects several aspects of cell biology, such as angiogenesis, innate immunity, cell proliferation, and stemness (18). The effects of hypoxia on stem cells are usually mediated by HIF-1α and HIF2α (19). The literature reported that incubation of umbilical cord derived mesenchymal stem cells (UC-derived MSCs) with different concentrations of oxygen resulted in increased cell proliferation under hypoxia. In this case, significant levels of HIF-1α could be observed in hypoxic MSCs cultured in 2.5% or 5% O2 (20). Hypoxia-inducible factor 1α (HIF-1α), as a pivotal transcription factor regulating stress and adaptive responses to oxygen concentration (21), usually interacts directly with numerous proteins to regulate its function (22–24). Most classically, differentiation, proliferation, angiogenesis, and migration are directly correlated with HIF-1α and β-catenin (25–27). However, how HIF-1α is expressed in PBMSCs and how it regulates the maintenance of stemness and cell proliferation remain unclear.

This study hypothesized that hypoxia could promote the proliferation and differentiation of PBMCs by activating the expressions of HIF-1α, β-catenin, proliferative-related genes, and stemness-related genes. Thus, this study examined the ability of PBMCs to proliferate and maintain MSC phenotypes under different concentrations of oxygen in vitro culture to explore the effects and mechanisms of hypoxia on the maintenance of PBMC proliferation and stemness.

MATERIALS AND METHODS

Isolation and Culture of PBMCs

The animal ethics committee of Guangzhou Red Cross Hospital approved the research. Following previously published methods (28), a 3 cm × 3 cm wound was made on the back skin of the rats. The wound was disinfected every day, and the rats were provided with enough food and water to ensure their normal activities and survival. After 1 week, 0.8% pentobarbital was injected into the abdominal cavity of these animals for anesthesia. After anesthetization, approximately 5 mL of abdominal aortic blood was collected using a fine-needle approach, and the blood sample was diluted to 1:1 by PBS. Mononuclear cells (MNCs) were separated and collected with Ficoll separation solution (GBCBIO Technologies, Guangzhou, China) and centrifuged at 2000 rpm for 35 min. The middle layer was pipetted with a thin tube and washed twice with phosphate-buffered saline (PBS). MNCs (2×10^6/mL) were seeded onto the T-25 flask with 10 mL of complete Dulbecco’s Modified Eagle Medium (Gibco, MA). The complete medium contained 1% penicillin/streptomycin (Gibco), 20 ng/mL bFGF (R&D Systems, MN), and 20% fetal bovine serum (Gibco). With 21 days of culture, the cell convergence was 80%, and the third-generation cells digested by 0.25% trypsin were used for subsequent experiments. Representative bright-field images were captured by an inverted phase-contrast microscope (Nikon ECLIPSE TiS2, Nikon).

Immunophenotype Analysis of PBMCs

The cell immune phenotypes of third-generation PBMCs (P3 PBMSCs) were identified by flow cytometry (FCM). CD73, CD105, and CD90 (R&D Systems, US) were selected as positive markers of PBMSCs, whereas CD14, CD19, CD34, CD45, and HLA-DR (BD biosciences, US) were chosen as negative markers of PBMSCs. PBMSCs (2×10^6 cells/mL) were resuspended in PBS and mixed in CD14, CD19, CD34, CD45, CD73, CD90, CD105, and HLA-DR antibody solutions for 30 min, and the cell samples were then loaded on the machine for analysis.
Cell Cycle Distribution Assay
rPBMSCs treated under normoxic and hypoxic (5% O2) conditions for 24 h were collected, and rPBMSCs were then fixed with 70% (V/V) ethanol overnight. Moreover, 50 µg/mL propidium iodide (PI) (Beyotime Biotechnology, Shanghai, China) was diluted by PBS solution containing 1% Triton X-100. Cells were fully infiltrated in the freshly prepared PI solution for 30 min and were analyzed by a BD FACScan flow cytometer (BD Company, CA).

Multilineage Differentiation Potential Assay
P3 rPBMSCs were seeded into a 24-well plate at a density of 2 × 10^4/well and cultured at 37°C in an incubator with 5% CO2. When the cells grow to 70% confluence, chondrogenesis induction, osteoinduction, and adipogenesis tests were performed. For chondrogenesis, cells were induced for 21 days in a chondrogenesis induction medium kit (RAXMX-90041, Cyagen Biosciences, US). The differentiation was evaluated by alcin blue staining. For osteogenesis, the cultures were induced with an osteogenesis induction medium kit (RAXMX-90021, Cyagen Biosciences, CA). After culture for 21 days, alizarin red staining was performed to evaluate the osteogenic products. For adipogenesis, cells were induced for 21 days in an adipogenesis induction medium kit (RAXMX-90031, Cyagen Biosciences). The formation of lipid vacuoles was assessed by Oil Red O staining. All images were captured under an inverted phase-contrast microscope (Nikon ECLIPSE Ts2, Nikon).

Determination of the Growth Curve of rPBMSCs and the MTS Assay
P3, P5, and P6 rPBMSCs (2 × 10^3/well) were inoculated in microplates (24-well) in 5% CO2 incubators with a gradient concentration of oxygen at 37°C. The experiments were set up as the control group (21% O2 and 5% CO2), 19% O2 and 5% CO2 hypoxia group, 5% O2 and 5% CO2 hypoxia group, and 1% O2 and 5% CO2 hypoxia group, with three replicate wells in each group. Starting from the next day, each group of cells was digested and counted accurately with a cell counter at each time point (Days 1–8). The growth curves of each group were made according to the number of cells. For the MTS assay, the above-mentioned groups of cells were planted on the well plate after Day 8, and the absorbance was measured at 450 nm by a multifunctional microplate reader (BioTek, US).

Assessment of Population Doubling Levels
After the cells reached 80-90% confluence, cells were passaged and counted. Calculate the cumulative population doubling (CPD) value using the following formula (29):

\[
\log_{10}(\text{cells harvested}) - \log_{10}(\text{cells reseeded}) \over \log{10} (2)
\]

CPD was plotted against time in culture and performed in triplicate for each counting procedure.

Assay for Colony Formation
Moreover, 500 rPBMSCs were cultured in 6-well plates in an incubator capable of adjusting oxygen concentration for 14 days. After fixation with paraformaldehyde for 15 min, 1 mL of crystal violet staining solution was added to the culture plate for staining clones for 30 min. Under an inverted phase-contrast microscope (Nikon ECLIPSE Ts2, Nikon), the number of clones containing more than 50 cells was counted.

Multilineage Differentiation Potential of rPBMSCs Cultured Under Normoxic (21% O2 and 5% CO2) or Hypoxic (5% O2 and 5% CO2) Conditions
P3 rPBMSCs were seeded into a 24-well plate at a density of 2 × 10^4/well and cultured at 37°C in a 21% O2 and 5% CO2 incubator or a 5% O2 and 5% CO2 incubator. The induction medium and experimental procedures performed in the subsequent experiments were the same as the methods described in “Multilineage Differentiation Potential Assay.”

Immunofluorescence Microscopy
Furthermore, 10^5/well rPBMSCs were seeded in glass slides placed in plates treated under normoxia and hypoxia (5% O2) for 5 days. After sequential fixation, blocking, incubation of primary (β-catenin, 1:200, 8242, Cell Signaling Technology; HIF-1α, 1:200, #36169, Cell Signaling Technology; SOX2, 1:200, 8822, GAPDH, 1:3000, Cell Signaling Technology). The electrochemiluminescence detection mixture was used to detect the protein on the membranes. ChemiDoc XRS imaging system with Image Lab software (Bio-Rad) was used to analyze the graphs.

Real-Time Polymerase Chain Reaction (PCR)
The culture method of rPBMSCs was the same as with Western blot. Total RNA obtained by the TRIzol method was reversed into cDNA in the PrimeScript RT Master mix reaction system.
(Takara Bio, Japan). With reference to the instructions, SYBR-Green reagent (Takara Bio) was used to perform real-time PCR in triplicate in a fluorescence quantitative PCR instrument (Jena, Germany). GAPDH was used as a control to analyze relative gene expression in the $2^{ΔΔCt}$ formula (30). Primer sequences are presented in Table 1.

Statistical Analysis
Data in three replicates are presented as mean ± standard deviation. Student’s t-test or one-way analysis of variance was used to analyze differences between the two groups and among multiple groups; P < 0.05 was used to mark significant differences.

RESULTS
In this study, rPBMSCs were successfully isolated and cultured. Stromal cell characteristics were proved by FCM and multidifferentiation potential induction experiments. The cell growth curves of P3, P5, and P6 rPBMSCs cultured under different oxygen concentrations were drawn based on the number counted at each time point. Then, the 5% hypoxia condition that significantly promoted cell growth was used for subsequent experiments. Hypoxia (5%) significantly increased the number of stromal cell clones and the proportion of S phase cells. Real-time RCR and Western blot results revealed that hypoxia (5%) significantly promoted the expression of HIF-1α, β-catenin, and proliferation-related and stemness-related genes.

Characterization and Identification of rPBMSCs
On the day after inoculation, round or polygonal adherent cells were observed in the primary culture. After 7 days, colonies gradually formed. After approximately 16 days, the culture area was 70%–80% of the bottom of the culture flask. At approximately 21 days later, the cell growth reached 100% (Figure 1A). Flow cytometry experiments revealed that rPBMSCs had high expression of CD73, CD90, and CD105, extremely low expressions of CD14, CD19, CD34, CD45, and HLA-DR (Figure 1B). Oil Red O staining indicated that rPBMSCs could differentiate into adipocytes embellished by red-stained lipid droplets. Alician blue staining demonstrated that after 21 days of induction, rPBMSCs could differentiate into chondrocytes embellished by blue-stained proteoglycans. Alizarin red staining presented that rPBMSCs could differentiate into osteoblasts embellished by red-stained bone nodules under osteogenic conditions (Figure 1C).

Hypoxia Promoted rPBMSC Growth and Proliferation
The results of the experiments are displayed in Figures 2A, B. In the first 2 days of culture, different concentrations of O2 had no noticeable effects on the proliferation of third-generation PBMCs (P3 rPBMSCs), fifth-generation PBMCs (P5 rPBMSCs), and sixth-generation PBMCs (P6 rPBMSCs). After 3 days, hypoxia (5% O2) significantly increased the number of cells and proliferation rate of P3, P5, and P6 rPBMSCs. After 8 days, the cells approached the plateau stage. At this time, the number of P3 rPBMSCs in the control group, 19% O2 hypoxia, 5% O2 hypoxia, and 1% O2 hypoxia groups were 55 × 10^3, 70 × 10^3, 96 × 10^3, and 71 × 10^3, respectively. Statistical analysis showed that compared with the number of P3 rPBMSCs in the control group, those in the 19% O2 hypoxia, 5% O2 hypoxia, and 1% O2 hypoxia groups were increased significantly (P < 0.05). Compared with 19% O2 hypoxia and 5% O2 hypoxia, 1% O2 hypoxia further increased the number of P3 rPBMSCs (P < 0.05). Similar to the growth curve, 5% O2 hypoxia significantly promoted the absorbance of P3 rPBMSCs seeded at Day 8. The CPD curve of P6 PBMCs proved that the CPD value of PBMCs in the 5% hypoxia group was significantly higher than that in the normoxia group. Compared with the normoxia group, the CPD values for P6 rPBMSCs in the 19% O2 hypoxia and 1% O2 hypoxia groups did not change significantly on Day 7. The shape of the growth curve and viability of P5 and P6 rPBMSCs were similar with those of P3 rPBMSCs, but the amounts of rPBMSCs and optical density values of P5 and P6 on Day 8 were lower than those of P3 rPBMSCs. Based on the cell growth curve and MTT assay results, 5% O2 hypoxia was selected for subsequent experiments. As presented in Figures 2C, D, 5% O2 hypoxia significantly promoted the formation of rPBMSC colonies. The number of rPBMSC colonies in the 5% O2 hypoxia group was increased by 53% compared with that in the control group (P < 0.05).

Hypoxia Promoted Cell Cycle Transition and Maintained the Trilineage Differentiation Capacity of rPBMSCs
FCM was used to investigate the cell cycle transition of rPBMSCs treated under normoxia and hypoxia (5% O2). Hypoxia exerted a significant increase and decrease in the number of S phase and

**TABLE 1 | Sequences of primers used for gene amplification.**

| Genes | Forward | Reverse |

| HIF-1α | 5′-GGGTAAGTGGAGGAGCTGTTG-3′ | 5′-CGTCGTCAGTCCAGACAAA-3′ |
G1 phase cells, respectively (Figures 3A, B). Moreover, 5% O₂ hypoxia increased the percentage of rPBMSCs in the S phase from 27.26% to 46.32% (P < 0.05) and reduced the percentage of rPBMSCs in the G1 phase from 58.24% to 47.19% (P < 0.05). These data indicated that 5% O₂ hypoxia increased the DNA synthesis and cell cycle of rPBMSC progression at the S phase. After 21 days of culture with a differentiation agent under hypoxia or normoxia, the effect of hypoxia on the pluripotency of rPBMSCs was investigated. Figure 3C illustrates that hypoxia increased the ability of induced cells to differentiate into three lines, including osteoblasts, chondrocytes, and adipocytes.

**Hypoxia Activated the Expression of β-Catenin and HIF-1α in rPBMSCs**

As displayed in Figure 4A, 5% O₂ hypoxia significantly increased the HIF-1α (red) nuclei expression in rPBMSCs, compared with the control rPBMSCs. Simultaneously, the nuclei expression for
β-catenin (green) in rPBMSCs was also upregulated significantly with 5% O₂ hypoxia. Immunohistochemistry results (Figure 4B) that 5% O₂ hypoxia stimulated the upregulation of HIF-1α and β-catenin expressions are consistent with the promotion of HIF-1α and β-catenin stabilization and nuclear translocation in immunofluorescence experiments (Figures 4C, D).

**Figure 2** Effect of hypoxia on rPBMSC proliferation. (A) The cell growth curves of third-generation PBMSCs (P3 PBMSCs), fifth-generation PBMSCs (P5 PBMSCs), and sixth-generation PBMSCs (P6 PBMSCs) were drawn based on the number of cells counted at each time point, the cumulative population doubling curve of sixth-generation PBMSCs (P6 PBMSCs) was determined based on cell culture time. (B) Absorbance of P3, P5, and P6 rPBMSCs treated under normoxia and hypoxia (5% O₂) at Day 8. (C) Hypoxia increased the number of rPBMSC colonies. (D) Measurement of the number of colonies in each group. All data are presented as means ± SEM. P < 0.05; * vs control group. rPBMSCs, rat peripheral blood-derived mesenchymal stromal cells.

**Hypoxia Intensified the Expression of Cycle-Associated Genes and Stemness Genes in rPBMSCs**

For the objective investigation that hypoxia regulated the self-renewal and stemness of rPBMSCs, pluripotency factors and Cyclin E/CDK2 were primarily selected as indicators. Compared
with normoxia, hypoxia significantly triggered upregulation of mRNA and protein expression for β-catenin, CDK2, and Cyclin E in rPBMSCs (Figures 5A–C). Moreover, the mRNA and protein expressions of HIF-1α, Nanog, and SOX2 were significantly increased by hypoxia (Figures 5D–F).

**DISCUSSION**

As a typical representative of adult pluripotent stromal cells, PBMSCs provide various possibilities for clinical application and transformation in the field of regenerative medicine (31). PBMSCs are abundant in the body and have strong proliferation and self-renewal ability, as well as the potential to differentiate into multiple cell types (32). However, some problems and obstacles are still encountered in the application and transformation of MSCs in cartilage tissue engineering, including the reduced activity and phenotype of seed cells in vitro (33). Thus, this study aimed to determine a hypoxic culture method that allows PBMSCs to maintain their ability to proliferate and self-renew during expansion in vitro. For this reason, this study mainly focused on three aspects, namely, (1) successful isolation, culture, and identification of rPBMSCs; (2) proliferation, phenotype maintenance, and differentiation potential of hypoxia-treated rPBMSCs; and (3) proliferation- and phenotype-related gene expressions of hypoxia-treated PBMSCs. This study proposes a culture method that is conducive to maintaining self-renewal and proliferation capabilities to ensure cell yield and long-term expansion.

In this study, rPBMSCs were successfully isolated and cultured, and third-generation rPBMSCs were selected for FCM for phenotypic identification. rPBMSCs did not express...
CD45, CD34, CD14, CD19, and HLA II, but highly expressed CD73, CD90, and CD105, indicating that the rPBMSCs had stromal cell performance, without other surface antigen markers (34, 35). Successfully isolated rPBMSCs positively expressed CD90, CD73, and CD105. Cell growth curve determination and cell cloning experiments revealed that 5% O2 hypoxia can significantly promote the formation of clones and the rapid proliferation of PBMCs. Many recent studies have...
reported that an appropriate hypoxic condition can significantly stimulate the proliferation of MSCs and PBMCs, which is consistent with the results of the present study. The recent studies confirmed hypoxia accelerated proliferation of PBMCs, increased migration of PBMCs, and reduced PBMC differentiation into osteoblasts by increasing Notch1 expression (36). In our study, four oxygen concentration gradients were set up to more rigorously explore the effects of various oxygen concentrations on the proliferation and stemness of PBMCs, as well as the role of HIF-1α pathway in the proliferation and stemness maintenance of PBMCs.

Other studies have also reported that hypoxia promotes the proliferation of cord blood derived MSCs without changing the cellular immune phenotype (37). In this study, hypoxia significantly promoted the transition of PBMCs from the G1 phase to the S phase. Since the S phase is an important stage of cell DNA synthesis (38, 39), under hypoxic conditions, PBMCs pass the G1/S phase checkpoint and enter the DNA synthesis phase. Moreover, a study revealed that hypoxia can drive cells into the cell cycle and promote the expression of cyclins and related kinases to drive umbilical cord derived MSCs through cell cycle checkpoints, thereby promoting DNA synthesis (40).

HIF-1α is an extremely critical transcription factor, which is strongly induced during hypoxia and adapts to hypoxic tension (41). Studies have reported that HIF-1α causes cell cycle arrest in the G0/G1 phase through p27 expression (42); however, under different cell environments, HIF-1α activation can demonstrate varying results by affecting various aspects of cell biology (39). The present study presents that upregulating the expression of HIF-1α under 5% hypoxia can increase the proportion of rPBMCs in the S phase. β-catenin is a typical cytoplasmic protein, as part of the classic Wnt signaling, which plays a role in cell adhesion (43). β-catenin coactivated LRH-1 on the cyclin E1 promoter and induced G1 cyclin-mediated cell proliferation, Cyclin E interacts with CDK2 to control the G1/S phase transition (44). In this experiment, after hypoxic treatment of rPBMCs, the transition of cells from the G1 phase to the S phase and the activation of Cyclin E/CDK2 indicated that hypoxia may regulate the cell cycle position to control the self-renewal of rPBMCs. Similar reports have suggested that HIF-1α promotes cell vitality and proliferation of MSCs (45, 46).

The expression of stemness markers was observed under hypoxic conditions. The significant role of low oxygen in altering the characteristics of various types of stromal cells was previously investigated (47). A study suggested the upregulation of stemness genes such as OCT4 and Nanog of BMSCs cultured in 1% oxygen (48). Similar results were observed in the present study, where the expressions of Nanog and SOX2 of rPBMCs under 5% oxygen conditions were promoted, indicating that the stemness of rPBMCs was enhanced by a hypoxic environment. The inhibition of senescence of MSCs suggests the increased expression of pluripotency markers (49). In this study, hypoxia-treated rPBMCs demonstrated a higher differentiation potential, including cartilage, osteogenic, and adipogenic potentials compared with normoxia-treated cells. However, the control of hypoxia on stromal cells involves transcription factors such as HIF-1α and β-catenin. However, further research is needed to understand how HIF-1α and β-catenin regulate and interact with each other.

CONCLUSION

In summary, the stemness, proliferation, and self-renewal potential of hypoxia-treated rPBMSCs were enhanced. Therefore, conditional hypoxia (5%) culture can be used as a convenient strategy to maintain the function of rPBMSCs. The
general process and conclusions of this study are clearly illustrated in Figure 6.
