ABSTRACT

This work proposes a new way of combining independently trained classifiers over space and time. Combination over space means that the outputs of spatially distributed classifiers are aggregated. Combination over time means that the classifiers respond to streaming data during testing and continue to improve their performance even during this phase. By doing so, the proposed architecture is able to improve prediction performance over time with unlabeled data. Inspired by social learning algorithms, which require prior knowledge of the observations distribution, we propose a Social Machine Learning (SML) paradigm that is able to exploit the imperfect models generated during the learning phase. We show that this strategy results in consistent learning with high probability, and it yields a robust structure against poorly trained classifiers. Simulations with an ensemble of feedforward neural networks are provided to illustrate the theoretical results.

Index Terms— Distributed classification, social learning, combination of classifiers, neural networks.

1. INTRODUCTION AND RELATED WORK

Social learning strategies allow the classification of unlabeled features by a heterogeneous network of agents [1][8]. The heterogeneity of the network is twofold: first, agents may be observing different (possibly non-overlapping) sets of attributes of the same underlying phenomenon; second, their statistical models need not be the same, e.g., two agents may be observing the same attribute from different perspectives. Neighboring agents then share statistics about the observed features and diffuse this information across the network to arrive at a conclusion on the nature of the observed phenomenon.

Many social learning approaches exist in the literature that have been shown to yield correct asymptotic learning of the true state of nature under mild identifiability assumptions [1][5][7][8]. These results, however, come at a cost: the strategies require prior knowledge of the true underlying distributions for the features. In practice we often have access to feature data only, or to some approximate models for the distributions. For example, uncertain likelihoods in social learning have been considered in [9], albeit only for a single random variable $x$. In this work, we will allow for a fairly broad class of distributions.

Another distinguishing aspect is that we will consider cooperation among spatially distributed classifiers, and aggregation over time of the inference produced from streaming data. An ensemble of classifiers is known to be a more robust structure than an isolated, perhaps poorly trained, classifier [10]. Examples of ensemble approaches are Bagging [11] and Boosting [12], in which classifiers combine weighted decisions across space. Boosting requires labeled samples to tune the combinations weights. Both bagging and boosting methods do not address the streaming data case.

We therefore propose the Social Machine Learning (SML) approach: a decentralized algorithm for combining the outputs of a heterogeneous network of classifiers over space and time, based on the adaptive diffusion algorithm proposed in [7][13][14]. The SML structure inherits the following qualities from social learning: the ability to combine classifiers with different dimensions and statistical models, while providing asymptotic performance guarantees in addition to continuous performance improvement even during the prediction phase. We show that i) with high probability, consistent learning occurs despite the imperfectly trained models; and ii) poorly trained classifiers can leverage the networked setup to improve their performance. We exploit these results particularly for the setup of a network of feedforward neural networks (FNN).

Notation: Random variables are written in bold font and deterministic variables in normal font. $E_x(\cdot)$ and $P_x(\cdot)$ respectively denote the expectation and probability measure computed with respect to the single random variable $x$.

2. THE DECISION-MAKING PROBLEM

A network of $K$ agents is engaged to accomplish the following decision-making task. There is a true underlying binary state of nature represented by an equiprobable binary random variable $\gamma \in \{-1, +1\} \equiv \Gamma$. As time progresses, each agent collects streaming data arising from the true state of nature. More specifically, agent $k = 1, 2, \ldots, K$ observes at times $t = 1, 2, \ldots$, the random feature vectors $h_{k,i} \in \mathcal{H}_k$. The feature vectors are independent and identically distributed (i.i.d.) over time (but not necessarily across the agents). According to this model, the features $h_{k,i}$ at agent $k$, given the underlying true hypothesis $\gamma$, form a sequence of i.i.d. random vectors distributed according to some conditional distribution (or likelihood):

$$h_{k,i} \sim L_k(\gamma), \quad h \in \mathcal{H}_k, \gamma \in \Gamma.$$ (1)

We allow the feature vectors to have different dimensions and attributes across the agents. The goal of the decision learning task is to let each agent learn, as $i \to \infty$, the right hypothesis $\gamma$.

If agent $k$ knows the true joint distribution of features and label, it can then apply the paradigm of Bayes classifiers [15]. The Bayes classifier is the solution to a maximum-a-posteriori (MAP) problem, where the label estimated by classifier $k$ is the label $\gamma$ that maximizes $p_k(\gamma | h_{k,1}, h_{k,2}, \ldots, h_{k,i})$, i.e., the posterior probability of $\gamma$ given the sequence of features $\{h_{k,i}\}_{i=1}^{\infty}$. However, agents might not have enough information to solve this classification problem alone, e.g., if the signals at agent $k$ are not informative enough (for example, it may be the case that $L_k(h) = 1$ for all $h \in \mathcal{H}_k$). If however the network as a whole possesses enough information, under the weaker assumption of global identifiability, then a social learning scheme can be used and allows agents to learn the truth [1][5][7][8].
In practice, the statistical characterization of the features and/or labels is often unknown. We will see next how the individual classifiers can be trained to approximate the unknown distributions.

3. LOCAL INSTANTANEOUS CLASSIFIERS

The fundamental assumption of this work is that the likelihoods \( L_k(h|\gamma) \) are unknown. To circumvent this lack of knowledge, we assume that each agent is able to train locally some standard binary classifier during a training phase. In order to avoid confusion, the random variables pertaining to the training set are topped with a sign \( \sim \). Whenever we are dealing with the training phase of the classifiers, feature vectors and labels are indexed with the time subscript \( n \). For the prediction (i.e., testing) phase, we use the time subscript \( i \).

Agent \( k \) is trained by collecting \( N_k \) examples constituted by pairs \((\mathbf{h}_{k,n}, \gamma_n)\)\(^{N_k}_{n=1}\). Labels \( \gamma_n \) are uniformly distributed over \( \Gamma = \{+1, -1\} \) so the pair \((\mathbf{h}_{k,n}, \gamma_n)\) is distributed according to the joint distribution:

\[
p_k(h, \gamma) = p_k(\gamma)L_k(h|\gamma), \quad h \in \mathcal{H}, \gamma \in \Gamma, \tag{2}
\]

with the uniform prior \( p_k(\gamma) = 1/2 \) for \( \gamma \in \Gamma \). We are interested in the following statistic:

\[
\log p_k(+1|h_{k,i}) \frac{p_k(+1|h_{k,i})}{p_k(-1|h_{k,i})} \triangleq f_k(h_{k,i}). \tag{3}
\]

where the equality in (a) follows from the Bayes rule and the uniform priors assumption. The log-likelihood ratio on the RHS of \(3\) is positive whenever the observation \( h_{k,i} \) is more likely to have come from class \(+1\) and negative when it is more likely to have originated from class \(-1\). This is the same sufficient statistic aggregated over space and time in social learning \(7\)[14] and in signal detection schemes \(13\)[6][7].

After training, the classifier will generate approximate posterior models \( p_k(\gamma|h) \). Thus, instead of \(3\), we rely on the following logit statistic:

\[
\log \frac{\hat{p}_k(+1|h_{k,i})}{\hat{p}_k(-1|h_{k,i})} = \log \frac{\hat{p}_k(+1|h_{k,i})}{1 - \hat{p}_k(+1|h_{k,i})} \triangleq f_k(h_{k,i}). \tag{4}
\]

The function \( f_k \) belongs to a specific class of functions \( \mathcal{F}_k : \mathcal{H}_k \rightarrow \mathbb{R} \) that depends on the choice of classifier. For example, in logistic regression with \( h \in \mathcal{R}^M \), \( \mathcal{F}_k \) is parameterized by a vector \( w \in \mathcal{R}^M \), and we have the linear logit function \( f_k(h; w) = w^\top h \).

Since the logit in \(4\) operates on the feature vector collected by an individual agent in a single time instant, we will refer to \(4\) as a local instantaneous logit.

The local instantaneous classifiers are trained by choosing the function \( f \) within \( \mathcal{F}_k \) that minimizes a suitable risk function \( R_k(f) \). We define this optimal function as the target model:

\[
f_k^u \triangleq \arg \min_{f \in \mathcal{F}_k} R_k(f). \tag{5}
\]

In this work we focus on the logistic risk:

\[
R_k(f) = \mathbb{E}_{h_{k,i}, \gamma} \log \left( 1 + e^{-\gamma/h_{k,i}} \right), \tag{6}
\]

which is commonly used for binary classification tasks for traditional classifiers such as logistic regression or more complex structures such as neural networks with softmax output layers. Note that the expectation is computed under the (unknown) joint distribution of the pair \((h_{k,n}, \gamma)\). Since all agents rely on a finite set of training samples, they will solve instead an empirical optimization problem:

\[
\tilde{f}_k^N \triangleq \arg \min_{f \in \mathcal{F}_k} \tilde{R}_k^N(f), \tag{7}
\]

where the empirical risk is in the form of an empirical logistic risk:

\[
\tilde{R}_k^N(f) = \frac{1}{N_k} \sum_{n=1}^{N_k} \log \left( 1 + e^{-\gamma_n/h_{k,n}} \right), \tag{8}
\]

which is computed over the training set. Since agents solve \(7\) until convergence, we assume they reach an empirical minimizer \( \tilde{f}_k^N \) that is close enough to the target \( f_k^u \) for sufficiently large \( N_k \) under ergodicity assumptions. Next, we introduce the algorithm that allows these classifiers to be combined within a network.

4. SOCIAL MACHINE LEARNING

The network is modeled as a strongly connected graph (i.e., where there is always a path in both directions between any two agents and at least one self-loop) with a left-stochastic combination matrix \( A \), whose elements \( a_{\ell k} \) are nonnegative, and \( a_{\ell k} = 0 \) if agent \( \ell \notin \mathcal{N}_k \), where \( \mathcal{N}_k \) denotes the neighborhood of agent \( k \). Under this condition, we define the Perron eigenvector \( \pi \) as \[18\] :

\[
\pi = \pi, \quad \sum_{k=1}^K \pi_k = 1, \quad \pi_k > 0, \quad \text{for all } k = 1, 2, \ldots, K. \tag{9}
\]

During the prediction phase, agents are observing unlabeled streaming private features \( h_{k,i} \). In \[7\][14], an adaptive version of social learning was introduced, where agents update their beliefs (or opinions) \( \varphi_{k,i}(\cdot) \) as:

\[
\psi_{k,i}(\gamma) = \frac{2^{1-\delta}(\gamma)L_k^N(h_{k,i}|\gamma)}{\sum_{\gamma \in \Gamma} 2^{1-\delta}(\gamma)L_k^N(h_{k,i}|\gamma)} \tag{10}
\]

\[
\varphi_{k,i}(\gamma) = \frac{\exp \left\{ \sum_{\ell=1}^K a_{\ell k} \log \psi_{\ell,i}(\gamma) \right\}}{\sum_{\gamma \in \Gamma} \exp \left\{ \sum_{\ell=1}^K a_{\ell k} \log \psi_{\ell,i}(\gamma) \right\}} \tag{11}
\]

where \( 0 < \delta \ll 1 \) is a small step-size parameter. In \[19\], the agent uses its private observation \( h_{k,i} \) to update its belief into an intermediate belief \( \psi_{k,i}(\cdot) \). In \[11\], the agent combines the intermediate beliefs coming from neighbors into its updated belief \( \varphi_{k,i}(\cdot) \). Note that these relations rely on knowledge of the exact likelihood functions \( L_k(h|\gamma) \), whereas in this work these likelihoods will be estimated during the training phase. The objective is to show that with minimal pre-training, the estimated likelihoods will enable the social learning algorithm to classify unlabeled data correctly with high probability and, moreover, the confidence of the classifier in its decisions will continually grow over time in response to streaming data. This property is fundamentally different from existing static testing phases for traditional classifiers, where classification decisions are instantaneous and are not exploited to improve performance.

An equivalent way of representing \(10\) and \(11\) is in the form of an adaptive diffusion strategy:

\[
\lambda_{k,i} = (1 - \delta) \sum_{\ell=1}^K a_{\ell k} \lambda_{\ell,i-1} + \delta \sum_{\ell=1}^K a_{\ell k} c_{\ell,i}, \tag{12}
\]

where we defined \( \lambda_{k,i} \triangleq \log \varphi_{k,i}(+1)/\varphi_{k,i}(-1) \) and \( c_{k,i} \) is taken as the log-likelihood ratio seen in the RHS of \(4\). The algorithm in \(12\) constructs the aggregate classification variable \( \lambda_{k,i} \), from the past information, in the shape of \( \lambda_{k,i-1} \), and the present information \( c_{k,i} \) received from neighboring classifiers. The structure in \(12\) will enable cooperation over space and time.

\(^1\)The belief \( \varphi_{k,i}(\cdot) \) quantifies the confidence of agent \( k \) at instant \( i \) that \( \gamma \) is the true state of nature.
In our approach, in the place of $c_k,i$, we will consider the local instantaneous logit statistic $f_k(h_{k,i})$. We also assume that each agent performs a debiasing operation before sharing the statistic $f_k(h_{k,i})$, by discounting its empirical mean over the training dataset. We define this empirical training mean as:

$$\tilde{\mu}_N^i(f_k) = \frac{1}{N^k} \sum_{n=1}^{N_k} f_k(\tilde{h}_{k,n}).$$

The diffusion strategy in (12) is then run with the choice:

$$c_{k,i} = f_k(h_{k,i}) - \tilde{\mu}_N^i(f_k)$$

Note that $c_{k,i}$ contains two independent sources of randomness. The first, introduced by $f_k(h_{k,i})$, contains the randomness from the prediction sample $h_{k,i}$. The second source of randomness comes from the training samples $\tilde{h}_{k,n}$, which are introduced in the term $\tilde{\mu}_N^i(f_k)$. The prediction and training feature vector samples are independent of each other.

The instantaneous decision of agent $k$, namely $\tilde{\gamma}_{k,i}$, is taken according to the rule:

$$\tilde{\gamma}_{k,i} = \text{sign}(\lambda_{k,i}),$$

where $\text{sign}(x) = +1$, if $x \geq 0$ and $\text{sign}(x) = -1$ otherwise. This choice is motivated by the fact that the logarithmic ratios in (4) are positive whenever the fiducial posterior probability $\hat{\pi}_k$ is able to learn consistently $\gamma = 0$. In view of (18), this gap (w.r.t. the class of functions) is:

$$\sup_{f \in F} \exp\left(-\frac{\Delta - R(f^N)}{2} - \rho^2 N_k\right),$$

with $\Delta = \log(1 + e^{-d})$, $R(f^N) = \sum_{k=1}^{K} \pi_k R_k(f_k)$ and $\rho^2 N_k = 2E_{h_k} R(F_{h_k}^{N_k})$.

**4.1. SML Consistency**

In Theorem 1, we will show that the SML strategy consistently learns the truth with high probability, as the number of training samples grows and for a moderately complex classifier structure. The complexity of the classifier structure is related to the complexity of the class of functions $\mathcal{F}_k$. The latter is quantified by using the concept of Rademacher average (initially introduced as Rademacher penalty in (19)). We follow the definition in (20) and introduce, for a class of functions $\mathcal{F}$ and $N$ samples $x_1, x_2, \ldots, x_N \in X$, the set of vectors $\mathcal{F}(x_1^N)$ as $(f(x_1), f(x_2), \ldots, f(x_N))$ with $f \in \mathcal{F}$. Then, the (empirical) Rademacher average associated with $\mathcal{F}(x_1^N)$ is:

$$\mathbb{R}(\mathcal{F}(x_1^N)) \triangleq \mathbb{E}_{\epsilon} \left[ \sup_{f \in \mathcal{F}} \frac{1}{N} \sum_{n=1}^{N} r_n f(x_n) \right],$$

where $r_n$ are independent and identically distributed Rademacher random variables, i.e., with $\mathbb{P}(r_n = 1) = \mathbb{P}(r_n = -1) = 1/2$.

**Theorem 1 (SML Consistency).** For the logistic loss, assume that $R(f^N) < \log 2$ and that $f_k(h_{k,i}) < B$ for every $h_k \in \mathcal{N}_k$ and $k = 1, 2, \ldots, K$, with $B > 0$. For any $d \in (0, - \log(e^{-R(f^N)} - 1))$, we have the following bound for the probability of consistent learning:

$$\mathbb{P} \left( \mu^+(f^N) > \mu^N(f^N), \mu^-(f^N) < \tilde{\mu}^N(f^N) \right) \geq 1 - 2 \sum_{k=1}^{K} \exp \left( - \frac{\Delta - R(f^N)}{2} - \rho^2 N_k \right),$$

where $\Delta = \log(1 + e^{-d})$, $R(f^N) = \sum_{k=1}^{K} \pi_k R_k(f_k)$ and $\rho^2 N_k = 2E_{h_k} R(F_{h_k}^{N_k})$.

**Sketch of proof:** The proof cannot be included for space limitations, but we present some insights for it. First, define the average network risk as $R(f) \triangleq \sum_{k=1}^{K} \pi_k R_k(f_k)$. We have that:

$$R(f^N) \geq \sum_{k=1}^{K} \pi_k \log \left( 1 + \exp \left( -E_{h_{k,i}} \gamma f_k^{N_k}(h_{k,i}) \right) \right),$$

where in (a) and (b) we used Jensen’s inequality with the convexity of $\log(1 + e^x)$. The inequality in (22) translates into:

$$R(f^N) \leq \log \left( 1 + e^{-d} \right) \Rightarrow \mu^+(f^N) - \mu^-(f^N) \geq d.$$
In what concerns the expression in (20), the term $\phi_N^{(k)}$ contains the complexity of the chosen classifier structure, which depends itself on the training set size $N_k$. We will see in the next section that it evolves as $O(1/\sqrt{N_k})$ for feedforward neural networks. Therefore as $N_k$ grows, we can neglect $\phi_N^{(k)}$. Now, since by assumption $d \in (0, -\log(e^{\max|f|}-1))$, both terms $d$ and $\Delta = R(f^*)$ are strictly positive. This implies that both exponential terms in (20) vanish, which in turn implies that the probability of consistent learning for the proposed strategy approaches 1, as the training sets grow.

4.2. Neural Network Complexity

In this section, we complement the result from Theorem 1 by showing that the term $\phi_N^{(k)}$ in (21), which depends on the Rademacher complexity of the classifier, vanishes with an increasing number of training samples in the case of feedforward neural networks (FNN). Assume that one classifier has the structure of a FNN with $L$ layers (excluding the input layer) and activation function $\sigma$. We drop index $k$ as we are referring to a single FNN. Each layer $\ell$ consists of $n_\ell$ nodes, equivalently the size of layer $\ell$ is given by $n_\ell$.

At each node $m = 1, ..., n_\ell$ of layers $\ell = 1, 2, ..., L$, the following function $g_m^{(\ell)}$ is implemented:

$$g_m^{(\ell)}(h) = \sum_{j=1}^{n_{\ell-1}} w_{mj}^{(\ell)} \sigma(g_j^{(\ell-1)}(h)) - \theta_m^{(\ell)}.$$  \hspace{1cm}  (24)

The parameters $w_{mj}^{(\ell)}$ correspond to the elements of the weight matrix $W_\ell$ of dimension $n_\ell \times n_{\ell-1}$. The offset parameters $\theta_m^{(\ell)}$ are the elements of a vector $\theta^{(\ell)}$ of dimension $n_\ell$. For the first layer, the function implemented at node $m$ is of the form:

$$g_{m_0}^{(1)}(h) = \sum_{j=1}^{n_0} w_{mj_0}^{(1)} h_j - \theta_m^{(1)}.$$  \hspace{1cm}  (25)

where the input vector $h$ has dimension $n_0$.

For a FNN whose purpose is to solve a binary classification problem, we denote the output at layer $L$ by $z \in \mathbb{R}^2$, where $z = g_0^{(L)}(h)$ for $m = 1, 2$. The final output is given by applying the softmax function to $z$. In this case the logit function is given by:

$$f^{\text{NN}}(h) = \log \frac{\hat{p}(+1|h)}{\hat{p}(-1|h)} = z_1 - z_2$$ \hspace{1cm}  (26)

where we say that $f^{\text{NN}}$ belongs to a class of functions $\mathcal{F}^{\text{NN}}$, which is parameterized by matrices $W_\ell$ and bias vectors $\theta^{(\ell)}$, for $\ell = 1, 2, ..., L$, according to (24), (25) and (25).

We are interested in finding an expression for the Rademacher complexity of class $\mathcal{F}^{\text{NN}}$ described above. An upper bound for this complexity can be found in Lemma A inspired by results from [22] (proof is omitted due to space limitations).

**Lemma 1 (Rademacher Complexity of FNNs).** Consider an $L$-layered feedforward neural network, satisfying $\|w_\ell^{(\ell)}\|_1 \leq b$, $|\theta^{(\ell)}(m)| \leq a$, for every node $m = 1, 2, ..., n_\ell$ and every layer $\ell = 1, 2, ..., L$. Assume that the input vector $h \in \mathbb{R}^{n_0}$ satisfies $\|h\|_\infty \leq \frac{1}{2}$ that the activation function $\sigma(x)$ is Lipschitz with constant $L_\sigma$ and that $\sigma(0) = 0$. Then the Rademacher average for the set of vectors $\mathcal{F}^{\text{NN}}(h^L)$ is bounded by:

$$R(\mathcal{F}^{\text{NN}}(h^L)) \leq \frac{2}{\sqrt{N}} \left( 2bL_\sigma \right)^{L-1} \left[ \log(2n_0) + 2bL_\sigma a \right].$$ \hspace{1cm}  (27)
