The redistribution of electrons in an ultrafast pump-probe experiment causes significant changes to the effective interaction between electrons and bosonic modes. We study the influence of these changes on pump-probe photoemission spectroscopy for a model electron-phonon coupled system using the nonequilibrium Keldysh formalism. We show that spectral rearrangement due to the driving field preserves an overall sum rule for the electronic self-energy, but modifies the effective electron-phonon scattering as a function of energy. Experimentally, this pump-modified scattering can be tracked by analyzing the fluence or excitation energy dependence of population decay rates and transient changes in dispersion kinks.

We find at short times that while the interactions are modified, the system possesses a sum rule for the energy integrated self-energy which characterizes the overall electron-phonon coupling in the system. Although the shift leads to a weakening of some features associated with the coupling in equilibrium (i.e. bosonic “kinks” and line widths), the electrons do not decouple from the phonons. Rather, the interaction is modified by redistributed spectral weight, and the apparent loss of interaction strength at low frequency is compensated for elsewhere. The weakening of spectral kinks has been observed experimentally in a cuprate material, where it was also attributed to light-induced changes in the interactions.

We solve the time-dependent equations of motion for the Holstein model (see SI for details), with a driving field included through the Peierls’ substitution. The bare interaction vertex is modified by redistributed spectral weight, and the apparent loss of interaction strength at low frequency is compensated for elsewhere. We work in the Hamiltonian gauge with no scalar potential, so the electric field is obtained via \( \mathbf{E}(t) = -\partial_t \mathbf{A}(t) \). We model the propagating pump pulse using a single central frequency and a Gaussian envelope. The equilibrium coupling strength is characterized by the dimensionless parameter \( \lambda \equiv -\partial \text{Re} \Sigma^R(\omega)/\partial \omega |_{\omega \to 0} \) which depends on the bare interaction vertex \( g \), electronic density of states, and temperature. The system parameters are chosen to represent a generic electron-phonon system, where the phonon frequency \( \Omega \) is near the Fermi level, and the coupling is sufficiently weak that the system can be described at the Migdal level. The pump and probe field profiles are taken to be relevant to current experiments, with achievable frequencies and durations. [see SI for a full discussion of model parameters]. Below, we will use two sets of parameters, chosen to emphasize certain aspects. In the first case, where we focus on the kink dynamics, we excite roughly 10% of the electrons in the band to above
the Fermi level. In the second case, where we study the fluence dependence of the decay rates, a maximum of 5% of the electrons in the band are excited (for the largest fluence).

We begin by studying a strongly coupled system at low temperatures, excited by a strong driving field. Figures 1(a) and (b) show the tr-ARPES spectra $I(k, \omega, t_0)$ at two time delays, prior to and during the pump pulse, respectively. Overlaid on the spectra are red dots indicating peaks in Lorentzian fits to various momentum distribution curves (MDCs) of the data taken at constant binding energy. The peak in the fit is an indication of the interacting dispersion. In equilibrium ($t_0 \rightarrow -\infty$), the tr-ARPES spectrum shows the characteristics of a strongly coupled Holstein phonon — well-defined spectral peaks at energies within the “phonon window” ($W = \omega \in [-\Omega, \Omega]$) where the linewidth is small, and a strong kink at $\Omega$. At zero time delay ($t_0 = 0$ fs), when there is maximum overlap between the pump and probe, the kink that occurs at the phonon frequency flattens out, indicating an apparent change in the effective electron-phonon interaction due to the pump.

With the decrease of the kink, it would appear that the underlying electron-phonon interactions have weakened. To investigate whether this is the case, we calculate the retarded self-energy $\Sigma^R(\omega, t')$ and perform a relative-time Fourier transform (or Wigner transform) to obtain the Wigner self-energy $\Sigma^W(\omega, t_{ave})$ (see SI for details). Figure 1(c) shows $\Sigma^W(\omega, t_{ave})$ in equilibrium and at $t_{ave} = 0$ (see $\Sigma^W(\omega, t_{ave})$ will be discussed later). In equilibrium, $\Sigma^W(\omega)$ has a region which is relatively small due to kinematic constraints, i.e. the phonon window. This phonon window was shown to be responsible for slow decay within some range of the Fermi level in tr-ARPES experiments.[5] During the pump, electronic spectral weight is redistributed leading to changes in $\Sigma^R(\omega, t_{ave})$, as illustrated in Fig. 1(d) which shows the difference between the result at $t_{ave} = 0$ and in equilibrium. These changes are positive inside $W$, as well as beyond the band edges, and negative elsewhere. However, the total interaction strength is unchanged, which can be seen from Fig. 1(e), where we plot the integrated changes both inside and outside $W$ versus time delay. The resulting curves show exactly canceling increases and

FIG. 1. tr-ARPES spectra along the $k_x = k_y$ direction (a) in equilibrium and (b) at 0 time delay. Red points indicate peaks in the MDC curves as determined from Lorentzian fits, and the black dashed line indicates the phonon window $W$. (c) Imaginary part of the Wigner self-energy $\Sigma^W(\omega, t_{ave})$ corresponding to panels (a) and (b). (d) Spectral weight change in $\Sigma^W(\omega, t_{ave})$ at $t_{ave} = 0$. (e) Time evolution of the shift in spectral weight of $\Sigma^W(\omega, t_{ave})$ within (green) and outside (blue) $W$. The red line indicates the total change in spectral weight, which is zero due to the sum rule. The grey area shows the region where pump effects are present (see text).
decreases inside and outside the phonon window, indicating that the total interaction strength remains constant during (and after) the pump. The oscillations are due to the field profile and the region shown in gray indicates times where the Wigner transform \( t_{ave} \) is within one standard deviation of the peak field, i.e. the field is “on”.

The constant integrated interaction strength is due to a sum rule for the self-energy, which can be obtained analytically. We evaluate the zeroth moment of the self-energy, which is the equal-time self-energy \( \Sigma^R(t,t') \); as shown in the SI, this becomes

\[
\Sigma^R(t,t' = t) = -i g^2 \left[ 2 n_B(\Omega/T) + 1 \right],
\]

where \( n_B(x) \) is the Bose function. Hence the self-energy, and by extension the total transient effective interaction, obeys a sum rule. This can be viewed as an alternative measure of the electron-phonon coupling strength, which is relevant for non-equilibrium physics.

It is important to note that the changes in the ARPES spectra are not caused by changing the electron-phonon coupling itself, known as a quantum “quench” where one of the parameters of the system is changed ad hoc. Instead, our self-consistent evaluation of the equations of motion captures the redistribution of spectral weight by the pump and its effects on the transient effective electron-phonon interactions. As the spectral weight rearrangement is controlled to a large degree by the pump strength, the signatures of the interaction in the time domain—the kink and decay rates—depend strongly on the pump fluence or excitation density. As the pump fluence increases, spectral weight redistribution increases concomitantly and a time- and fluence-dependent effective electron-phonon interaction emerges.

We can understand changes in the effective electron-phonon interactions by considering the scattering processes in equilibrium and after excitation. The self-energy in equilibrium is related to the scattering rate via \( \text{Im} \Sigma^R(\omega) = [2\tau(\omega)]^{-1} \); out of equilibrium both sides of the equation acquire a non-trivial time dependence and the equation becomes a proportionality due to complications of the Wigner transform.

Fig. 2 illustrates the scattering processes that occur in phonon emission for both cases. In equilibrium, the scattering rate of a single excited particle is principally determined by the amount of phase space available for scattering. A particle that is excited within \( W \) of the Fermi level cannot emit a phonon to scatter because the final states are fully occupied; similarly, a particle that is excited above \( W \) scatters more easily. It was shown previously that these scattering rates can be quantitatively connected to the equilibrium self-energy in the limit of weak fluence or excitation density. However, when the fluence is increased a particle within \( W \) has available phase space to scatter into, leading to an increased scattering rate compared to equilibrium based solely on this redistribution of electronic spectral weight.

On the other hand, particles outside \( W \) now have a decreased scattering rate due to the accessible final states being partially occupied. These changes in the scattering phase space and rates are reflected in Fig. 1(c) and (d), where \( \text{Im} \Sigma^R(\omega, t_{ave}) \) increases inside the phonon window, and decreases outside. In addition to scattering via phonon emission, there will be processes that scatter particles into states at higher energy, i.e. phonon absorption. However, for low excitation densities these processes will not qualitatively affect the simple picture discussed here.

The changes in the scattering phase space due to the
rearrangement of spectral weight by the pump (as shown in Fig. 2) imply that the measured decay rates depend on the pump fluence. Thus, we now explicitly consider the dependence of the effective electron-phonon interactions on the pump fluence or excitation density. In particular, the analysis of Ref. 5 is repeated, and the decay rates are extracted from tr-ARPES spectra integrated over a cut along the (11) momentum direction [as in Figs. 1(a) and (b)] for various pump fluences. To be able to extract the decay rates from the spectra, sufficient signal is needed for an exponential fit. At the strong coupling considered above, the signal decays too rapidly, which is remedied by decreasing the coupling strength, and increasing both the driving frequency and temperature (see SI). Fig. 3 shows the decay rates obtained just after the pump pulse, together with the equilibrium result. The decay rates directly reflect the changes discussed in Fig. 2 compared to equilibrium, the scattering rates increase inside \( W \) and decrease outside \( W \). As the fluence increases, the rates deviate further from their values in equilibrium.

Finally, we return to the weakening of the kink in the tr-ARPES spectra. The dispersion is determined from Fig. 1 by fitting the MDCs with a Lorentzian (as discussed above) and extracting the peak position. Figure 4(a) shows the dispersion in equilibrium (\( t_0 \to -\infty \)) and at \( t_0 = 0 \). Clearly, the kink is much more pronounced in equilibrium then during the pump. To get a measure of the kink as a function of time, the Fermi velocity is extracted by fitting the dispersion near the Fermi level to a line. The inset of Fig. 4(a) shows the inverse of the velocity at the Fermi level (1/\( v_F(t_0) \)), normalized to the equilibrium value (1/\( v_{F,eq} \)). The kink is suppressed strongly at zero time delay, when the field amplitude is largest. To explain the changes in the kink, we calculate the real part of the Wigner self-energy (defined above), which is plotted in Fig. 4(b). The strength of the kink is related to the peaks in \( \Sigma^R(\omega, t_{ave}) \), which clearly decrease due to the pump.

Our previous studies5,9 have linked the decay rates and oscillation frequencies to the equilibrium self-energy in the limit of weak excitation, which is achieved either by going to long times or low pump fluences. At larger fluences, it is tempting to continue to discuss the pump-induced changes in the effective electron-phonon interaction in terms of equilibrium physics. In particular, the changes in the kink are strikingly similar to a situation where either the electron-phonon coupling strength is decreased, or the temperature is elevated. One could speak in the first case about the decoupling of electrons from the phonons, in the second case about an elevated electron temperature. As we have shown, neither situation is correct in discussing the pump-induced changes.

A similar decrease in the kink strength can be expected from an increase in the sample temperature; however, there are key differences in such a scenario. An increase in temperature would lead to a change in the sum rule, which depends on temperature through the Bose function. As shown in Ref. 5, the photoemission spectra on the unoccupied side of the Fermi level do not reflect a heated Fermi-Dirac distribution. Nevertheless, we can extract time-varying temperature by performing the Fermi function fits close to 0 energy, which leads to a maximum temperature of 1500 K. A spectrum at this temperature has broad features, and does not exhibit the features of the kink still visible in the pumped spectra (see SI for details).

We can further eliminate the quantum quench scenario because there is a frequency-dependent reorganization of the effective interactions. Instead of an overall decrease of the scattering rate, as one would expect if the electrons...
were decoupled from the phonons, we observe an increase within the phonon window \( W \). If none of the physical parameters were changed, the sum rule would display a time dependence, which is absent in our calculations.

In equilibrium, the decrease of interactions at low energies would lead to a weakening or disappearance of the emergent phenomena which depend on the interactions at those scales. In non-equilibrium, this is not yet known. We have shown that the pump can cause a non-trivial redistribution of the effective interactions to different energies. This behavior cannot be captured by an elevated temperature or quantum quench picture. Instead, the spectral weight redistribution is critical to understanding the non-equilibrium response, and will have similar relevance in pumping systems with emergent states. It is again tempting to describe the effective interactions within an equilibrium picture with modified parameters; however, to capture the full physical description, the non-equilibrium process should be considered within the framework presented here.

We would like to thank P. Kirchmann, J. Sobota and S. Yang for helpful discussions. This work was supported by the Department of Energy, Office of Basic Energy Sciences, Division of Materials Sciences and Engineering (DMSE) under Contract Nos. DE-AC02-05CH11231. J.K.F. was supported by the McDevitt bequest at Georgetown.
