ABSTRACT

Background: A raised pre-treatment carcinoembryonic antigen (CEA) level is frequently observed in colorectal cancer patients with metastatic disease and is thought to be a reflection of disease burden. Additionally, there is a growing body of evidence highlighting the influence of a pro-inflammatory host-response on colorectal cancer progression. Pro-inflammatory cytokines IL-1β, IL-6, IL-8 and TNF-α have been implicated in this relationship through experimental and clinical studies. We set out to evaluate whether combining circulating inflammatory markers, such as these, with CEA improves upon the stage-specificity of CEA alone.

Methods: Sixty patients were enrolled prospectively at a single centre over a sixteen month period into three groups: control (n=19), stage II (n=22) and stage IV (n=19) colorectal cancer. Baseline levels of carcinoembryonic antigen (CEA) as well as plasma IL-1β, IL-6, IL-8 and TNF-α were compared across the groups. The ability of each marker to distinguish patients by disease status was evaluated using Receiver Operator Characteristic (ROC) curve and Chi-squared analysis.

Results: CEA, IL-6 and IL-8 increased significantly between the three groups. CEA and IL-8 were most effective in discriminating between stage II and stage IV disease groups. We found IL8-CEA score was more effective in discriminating between stage II and stage IV CRC (OR 10.3, 95% CI 1.1-92.2, p=0.01) compared with CEA alone (OR 5.4, 95% CI 1.3-27.8, p=0.01).

Conclusion: Combining IL-8 with CEA improved upon the stage-specificity of CEA alone. This suggests a potential value for combining circulating inflammatory biomarkers with CEA to accurately stage CRC.

Key words: IL-8, CEA, colorectal cancer

INTRODUCTION

Colorectal cancer (CRC) is the third largest contributor to the global cancer burden and, despite advances in treatment, it remains a major source of cancer-related mortality (1). At presentation, approximately 20% of patients have distant metastasis (2) and experience significantly poorer outcomes as a result. Therefore, wherever possible, patients are routinely screened for distant metastases promptly after initial diagnosis. This is often pivotal in selecting the appropriate management strategy, which may involve assessment of resectability, or the decision of whether or not to pursue radical treatment.
Carcinoembryonic antigen (CEA) is a widely used tumour marker in colorectal cancer and raised circulating levels are frequently observed in patients with metastatic disease (3,4). This suggests a relationship between CEA and tumour burden, leading some to advocate its integration into the TNM staging system (5-7). Circulating biomarkers, such as CEA, have the advantage of being obtained at minimal discomfort or inconvenience to the patient. Furthermore, results may be available at the outset, in contrast to some elements of the TNM staging system, such as tumour depth, which in turn may require assessment of a surgical specimen.

As the influence of inflammation on colorectal cancer progression becomes better understood, so does the importance of the host’s immune and inflammatory response to cancer (8-10). Experimental evidence points to a bidirectional relationship between tumour and host cells, both within its microenvironment and at distant sites, that is integral to the development of metastatic disease (11,12). IL-1β, IL-6, IL-8 and TNFα are among the inflammatory mediators most consistently implicated in this process by promoting endothelial-mesenchymal transition, angiogenesis and chemo-attraction of neutrophils at metastatic sites (12-16). Like CEA, these inflammatory markers have been observed to increase with advancing disease stage (17,18). Additionally, indicators of systemic inflammation such as neutrophil lymphocyte ratio (NLR) have been combined with CEA to improve on its diagnostic ability (19,20). However, very little is known as to whether combining circulating inflammatory biomarkers with CEA adds value in evaluating colorectal cancer progression. Therefore, the aim of this study was to determine whether combining circulating inflammatory cytokines with CEA improves upon the disease stage-specificity of CEA alone.

METHODS

Patient selection

Patients were recruited prospectively at a single metropolitan centre over a sixteen-month period between October 2016 and February 2018. Healthy control patients were enrolled immediately prior to undergoing a colonoscopy requested on the suspicion of lower gastrointestinal malignancy. Patients were excluded if any evidence of inflammation or malignancy was subsequently detected. Patients were recruited into the stage II group on the basis of pre-treatment radiological staging. Rectal cancer patients underwent pre-operative staging MRI pelvis and CT chest abdomen and pelvis, and colon cancer patients underwent pre-operative CT chest, abdomen and pelvis. Imaging was reviewed by two Consultant Radiologists. Staging was confirmed postoperatively on pathology in the case of colon cancer patients. This was not applied to patients with rectal cancer due to a proportion undergoing neo-adjuvant therapy. Consecutive patients presenting with metastatic colorectal cancer at diagnosis were recruited into the stage IV group. Disease stages were assigned according to the 8th edition of American Joint Committee on Cancer guidance (21).

Exclusion criteria were: age below 18 years, emergency presentation, chronic inflammatory conditions including inflammatory bowel disease, other synchronous primary malignancy, colorectal cancer other than adenocarcinoma, and the use of immunosuppressive therapy including oral corticosteroids either at the time of, or within three months prior to, sample withdrawal.

All patients recruited into this study gave their written informed consent and ethics approval was granted by the Health and Disability Ethics Committee (HDEC ref: 18/CEN/138).

Plasma sample collection and storage

A twenty millilitre venous blood specimen was withdrawn using a 23G BDTM vacutainer blood collection set into sodium citrate vacutainer tubes after discarding the first 5 mL. Wherever possible, venepuncture was performed from the antecubital fossa following a standard protocol and samples were centrifuged within 30 minutes of withdrawal at 2000 x g for ten minutes and plasma was stored at -80 degrees Celsius until time of analysis.

Cytokine assays

All assays were performed within twenty-four months of sample collection and in two or fewer freeze-thaw cycles. Levels of IL-1β, IL-6, IL-8 and TNFα were quantified from plasma using commercially available sandwich ELISA kits specific for each cytokine (Invitrogen, ThermoFisher Scientific) as per the manufacturers instructions. Absorbances were measured using the “Multiskan GO” (Thermo Scientific) specialised spectrophotometer. The detection limits were IL-6: 2-200 pg/mL, IL-1β: 2-150 pg/mL, IL-8: 2-250 pg/mL and TNFα: 4-500 pg/mL. Analytes with a detection rate below 75% were excluded. CEA (Roche Cobas e601, reference range <3.5 µg/L) was measured at the clinical diagnostics laboratory of the host institution.
Statistical analysis

Statistical packages SPSS® version 24.0 (IBM®) and GraphPad Prism 7 (San Diego, CA, USA) were used for analysis. The Shapiro-Wilk test of normality was used to distinguish parametric from non-parametric distributions. Continuous variables were presented as mean ± standard deviation (SD) for parametric data and median (interquartile range, IQR) for non-parametric. The groups were compared using ANOVA for parametric and the Kruskal-Wallis test for nonparametric variables. Receiver Operator Characteristic (ROC) curve analysis was performed to evaluate ability of markers to differentiate between patient groups and select the appropriate cut-off value based on optimal sensitivity and specificity. For categorical variables, proportions were compared between groups using Chi squared test. A p value of ≤0.05 was taken as the level of statistical significance.

RESULTS

A total of sixty patients were included in the study across three groups: control (n=19), stage II (n=22) and stage IV (n=19). The mean age was 65.9 years (range 29-85) with 33 (55.0%) males and 27 (45.0%) females. By ethnicity, 53 (88.3%) were European, 4 (6.7%) Maori and 3 (5.0%) other. The median body mass index (BMI) was 28.2 kg/m² (IQR, 25.0-31.7). There was a lower proportion of patients with ischaemic heart disease in the stage IV group compared with controls (p=0.05) and no other patient characteristics were found to vary significantly between the three groups (table 1).

IL-6 levels were detected in all and IL-8 in 59/60 (98.3%) patients. TNFα levels were detectable in 8/60 (13.3%) patients and IL-1β in 0/60 and were therefore excluded from further analysis. When biomarker levels were compared across the three groups, CEA (p<0.001), IL-6 (p=0.005) and IL-8 (p<0.001) all increased significantly with disease progression (table 2). The increases in CEA, IL-6 and IL-8 across groups were most pronounced between stage II and stage IV (fig. 1).

Control versus Stage II

Receiver operator characteristic analyses were performed to evaluate CEA, IL-6 and IL-8 as discriminators between patient groups. For the control versus stage II group, CEA (AUC 0.73, 95% CI 0.58-0.89, p=0.01) was

effective in differentiating between these groups in contrast to IL-6 (AUC 0.55, 95% CI 0.37-0.73, p=0.62) or IL-8 (AUC 0.68, 95% CI 0.51-0.85, p=0.06) (Table 3).

Stage II versus Stage IV

CEA, IL-6 and IL-8 accurately differentiated between stage II and stage IV. The most effective was CEA (AUC 0.81, 95% CI 0.67-0.95, p=0.001) followed by IL-8 (AUC 0.80, 95% CI 0.66-0.93, p=0.001) then IL-6 (AUC 0.75, 95% CI 0.58-0.91, p=0.007) (Figure 2). Interleukin-8 was therefore identified as the best cytokine to combine with CEA. The optimal cut off values were 4.4 µg/L for CEA (sensitivity 0.84, specificity 0.54) and 6.6 pg/mL for IL-8 (sensitivity 0.84, specificity 0.59). Patients with a low CEA and low IL-8 were assigned a combined CEA-IL8 score of ‘0’ and patients with a high CEA and/or IL-8 were assigned a score of ‘1’.

Of forty-one patients with colorectal cancer, 17 (41.4%) had a ‘low’ and 24 (58.5%) had a ‘high’ CEA. Stage IV disease was present in 4/17 (23.5%) with low CEA compared to 15/24 (62.5%) of those with a high CEA. Nine of the 41 patients with CRC (22.0%) had a

An IL8-CEA Combined Score is Stage-Specific in Colorectal Cancer
CEA-IL8 score of ‘0’ and 32 (78.0%) had a score of ‘1’. No significant associations were observed between the CEA-IL8 score and any of the demographic variables measured. Stage IV disease was present in 19/9 (11.1%) of patients with a CEA-IL8 of ‘0’ compared to 18/32 (56.3%) of those with a score of ‘1’.

The IL8-CEA score was more effective in discriminating between stage IV and stage II CRC (OR 10.3, 95% CI 1.1-92.2, p=0.01) compared with CEA alone (OR 5.4, 95% CI 1.3-27.8, p=0.01).

**DISCUSSION**

In this study of sixty prospectively-enrolled participants, we found CEA to discriminate between healthy controls and those with stage II disease, whereas inflammatory markers IL-6 and IL-8 did not. We found all three markers to vary significantly between those with stage II and stage IV disease. IL-8 was the more effective inflammatory marker, and when combined with CEA, the resulting score outperformed CEA alone in discriminating between stage II and stage IV disease.

An association between raised serum CEA and the presence of early-stage CRC has been observed in other studies (22). However, as demonstrated in a meta-analysis by Liu et al, poor sensitivity limits its application as a screening or diagnostic test (23). Although the existing data is much sparser for interleukins, a pooled analysis of five case-control studies including 668 CRC patients and 374 controls showed IL-8 to have moderate diagnostic accuracy (23). This was not corroborated by the findings of this study and while this may have been partly due to the small sample size, we were not led to evaluate a score combining CEA with an inflammatory cytokine in the discrimination between healthy controls and stage II disease.

Our finding that CEA, IL-6 and IL-8 effectively discriminated between stages II and IV disease supports the findings of others. In their study of 75 patients, Mahboob et al utilised Proseek and bioplex immunoassays and identified CEA, IL-6 and IL-8 as amongst the most stage-specific cytokines from a panel of 92 protein biomarkers (24). Paczel et al’s recent study of 59 CRC patients found a raised CEA (p<0.005) and IL-8 (p=0.004) to be significantly associated with the presence of distant metastases (15). Liu et al’s study of 30 patients did not find IL-6 or IL-8 to differ significantly by TNM stage although they did not analyse stage IV disease separately but compared stages 0 and I with stages II, III and IV (25).

To our knowledge, a combined IL8-CEA score, such as that utilised in the present study, has not been previously evaluated as a marker of metastatic CRC. However, the approach of combining CEA with circulating inflammatory biomarkers has shown some promise in diagnostic studies. Li et al found that combining platelet-lymphocyte ratio (PLR) or lymphocyte-monocyte ratio (LMR) with CEA improved diagnostic efficacy for CRC (19), whereas Tang et al’s study of 138 patients with non small cell lung carcinoma (NSCLC) found that the sensitivity of tumour markers including CEA in the diagnosis of NSCLC was improved by combining it with IL-6 (26).

Experience in the clinical setting suggests the CEA value to be an indicator of disease burden. This is apparent through its more established roles in post-operative surveillance for CRC recurrence and in monitoring metastatic disease progression in those undergoing chemotherapy (27). In contrast to this, circulating pro-inflammatory cytokines, such as IL-8, levels are likely to reflect a functional, host-response to cancer (11,12,14). IL-8 is a chemokine produced primarily by macrophages resulting in neutrophil chemo-attraction into the tumour microenvironment (11). Furthermore, animal studies have shown that exposure to IL-8 may increase the metastatic potential of colon cancer cells (28). In their experiments on mice using a circulating tumour cell (CTC) model, Kim et al found that tumour-derived IL-8 acted as a chemo-attractant of tumour cells to the primary tumour and metastatic sites (29,30). Our observation that combining IL-8 with CEA improves upon the stage-specificity of CEA alone may reflect a more global assessment of both disease burden and host-response.

This study was limited by a small sample size which may, in turn, have been partly a result of strict eligibility criteria. Patients presenting as an emergency and with chronic inflammatory conditions and a recent history of taking anti-inflammatory or immunomodulatory medications were excluded to avoid confounding. The results of this study may therefore not be generalizable to these patient sub-groups. While the findings of this study strengthen the approach of combining tumour markers with inflammatory biomarkers as a proof-of-principle, further validation studies are necessary in larger samples. Additionally, we were unable to control for histopathological features such as T stage, N stage and lympho-vascular invasion. This was not possible as most patients in the stage IV group did not undergo surgical resection of their primary tumour, but were instead treated with palliative chemotherapy. Limiting patients in the stage IV group to those undergoing resection of their primary tumour would exclude a majority of patients with...
disseminated disease and introduce an unacceptable likelihood of bias.

CONCLUSION

Circulating inflammatory cytokines IL-6 and IL-8 were not found to be effective discriminators between healthy controls and early-stage CRC. However, both biomarkers were effective in discriminating stage IV from stage II disease; IL-8 more so than IL-6. Combining CEA with IL-8 resulted in a score that outperformed CEA alone in discriminating between stage II and stage IV disease. Although these findings support the principle of combining CEA with IL-8 to accurately stage patients, larger validation studies are required. A combined IL8-CEA score may add value to radiological pre-operative staging.
