Abstract We discuss a model-independent estimator of the likelihood of the compositeness of a shallow S-wave bound or virtual state. The approach is based on an extension of Weinberg’s relations in Weinberg (Phys Rev 137:B672, 1965) and it relies only on the proximity of the energy of the state to the two-hadron threshold to which it significantly couples. The scheme only makes use of the experimental scattering length and the effective range low energy parameters, and it is shown to be fully consistent for predominantly molecular hadrons. As explicit applications, we analyse the case of the deuteron, the $^1S_0$ nucleon-nucleon virtual state and the $\pi\rho\pi$ tetraquarks. The approach is based on an extension of Weinberg’s relations in Weinberg (Phys Rev 137:B672, 1965) and it relies only on the proximity of the energy of the state to the two-hadron threshold to which it significantly couples.

1 Introduction

Quantum chromodynamics (QCD), the theory of strong interactions, generates a rich spectrum of hadrons, most of which can be classified according to simple constituent quark models [2–6] as $qq$ (mesons) and $qqq$ (baryons) states. Despite this fact, the last two decades have witnessed the discovery of many states that defy this simple classification [7]. Different worldwide experiments (BaBar, Belle, BES, LHCb, ...) have reported the observation of a plethora of unstable states and peaks in mass-distributions located surprisingly close to different two bottomed/charmed-hadron thresholds, such as the XYZ mesons, the $P_c$ pentaquarks [8–16], or the doubly charmed $T^{+}_{cc}$ state [17,18]. There exist also clear examples of exotic candidates in the open charm and bottom sectors, e.g. $D^{*0}_{s0}(2317)$, $D^{*+}_{s0}(2300)$, $\Lambda_c(2595)$ [19–21], ..., $B_1(5721)$, $B_2^*(5747)$, $\Xi_b(6227)$ [22–26], etc. These states are often interpreted as hadron molecules [27–76], or compact tetraquarks/pentaquarks [77–79,79–100], and when allowed by their quantum numbers and flavour content, there are also attempts to describe these states as predominant $q\bar{q}$ or $qqq$ structures [101–103,103–113]. Other possibilities (hybrids, virtual poles, ...) for the nature of these exotics [114–120] or the role of kinematic (non-dynamical) effects (chiefly triangle singularities) in the interpretation of the observed peaks have also been stressed [55,120–130]. Further discussions and references can be found in Refs. [131–136]. In addition to knowing how many of these states exist and their masses and widths, it is clearly a fundamental task in hadron physics to study the dynamical details of their structure. Such analysis will be invaluable in improving our understanding of strong interactions.

It is a direct consequence of unitarity that the inverse single-channel two-particle scattering amplitude $f$ is given in terms of the phase shift $\delta$ by $f(E)^{-1} = k \cot \delta(k) - ik$, with $k = \sqrt{2\mu E}$, for non-relativistic kinematics, $\mu$ the reduced mass of the scattering particles, and $E$ the energy of the system relative to the threshold $(m_1 + m_2)$. The real part of the inverse scattering amplitude is a polynomial in even powers of $k$ and, in the case of S-wave, it leads to the effective range expansion (ERE):

$$k \cot \delta(k) = \frac{1}{a} + \frac{1}{2}rk^2 + O(k^4),$$  \hspace{1cm} \text{(1)}

where the parameters $a$ and $r$ are called the scattering length and effective range, respectively. Weinberg’s compositeness rules [1] connect these low energy observables with the probability $Z$ that an S-wave shallow bound state is found in a
where \( \gamma_b = \sqrt{2\mu|E_b|} \) (with \( E_b < 0 \), the binding energy), \( \beta \)

denotes the next momentum scale that is not treated explicitly

eventual computations, re-derivations, re-interpretation and

We discuss now two subtle points about the interpretation of \( Z \).\(^1\) In Eq. (18) of Ref. [1], \( Z \) is defined as a probability

1 Our discussion is similar to that of Ref. [73].
the exotic $D^+_0(2317)^\pm$ and $T^+_{cc}$ states in Sects. 4 and 6, respectively. We collect the most important conclusions of our work in Sect. 7.

2 Likelihood of the compositeness of a weakly bound state

The parameters of the ERE [cf. Eq. (1)] depend in turn on $\gamma_b$, which is determined by the binding energy of the state. The large values for both $a$ and $r$ when $Z$ is not zero appear because of the $1/\gamma_b$ contributions in Eq. (2). They may suggest that the next-to-leading order (NLO) approximation to the ERE, consisting in neglecting $O(k^4)$ terms, may itself break down when the particle is elementary. This, however, does not happen since only the first two terms in the expansion of $\cot \delta(k)$ in powers of $k^2$ become of order $\gamma_b$ for $Z \neq 0$ and $k \approx \gamma_b$. The third and higher terms are smaller by powers of $\gamma_b/\beta$ [1]. As a consequence, the approximate relation

$$\gamma_b \approx -\frac{1}{a} + \frac{1}{2} r \gamma_b^2$$

is expected to be fulfilled with great accuracy for weakly bound states. This is indeed the case for the deuteron. The above relation does not tell anything about the elementary nature of the particle, since it follows from the requirement $\cot(i \gamma_b) = +i$. In fact, it is exactly satisfied by $a_{\text{LO}}$ and $r_{\text{LO}}$ for all $Z$ [cf. Eq. (2)]. However, the deviations of the actual scattering length and effective range from their $\gamma_b-$expansion leading-order (LO) values $a_{\text{LO}}$ and $r_{\text{LO}}$ encode some valuable information on the compositeness of the state. Moreover, from the discussion above, the third and higher terms in the ERE of Eq. (1) could provide at most corrections\(^2\) of order $O(Z \gamma_b^2/\beta)$ to the difference $\gamma_b - (-1/a + r \gamma_b^2/2)$. With these ideas in mind, we introduce a phenomenological term $\delta r$ to estimate the NLO contribution to the effective range $r$, within its expansion in powers of the binding momentum $\gamma_b$.

$$r = -\frac{1}{\gamma_b} \left( \frac{Z}{1 - Z} \right) + \delta r + O\left( \frac{\gamma_b}{\beta^2} \right), \quad r_{\text{NLO}} = r_{\text{LO}} + \delta r.$$  

(5a)

This correction, $\delta r$, is expected to be of the order of the range of the interaction [$O(1/\beta)$]. The scattering length

will have a similar NLO contribution, $\delta a$, on top of the LO term in Eq. (2a). We fix this analogous NLO contribution to the scattering length such that the difference $\gamma_b - (-1/a_{\text{NLO}} + r_{\text{NLO}} \gamma_b^2/2)$ [cf. Eq. (4)] deviates from zero in terms of the order $O(\gamma_b^2/\beta^2)$. This is to say, we require that the $\gamma_b^2$ term in the Taylor expansion (in powers of $\gamma_b$) of the quantity $[\gamma_b - (-1/a_{\text{NLO}} + r_{\text{NLO}} \gamma_b^2/2)]$ vanishes. In this way, we obtain:

$$a = \frac{2}{\gamma_b} \left[ \frac{1 - Z}{2 - Z} \right] - \frac{\delta r}{2} \left( \frac{1 - Z}{1 - \frac{Z}{2}} \right)^2 + O\left( \frac{\gamma_b}{\beta^2} \right).$$

$$a_{\text{NLO}} = a_{\text{LO}} - \frac{\delta r}{2} \left( \frac{1 - Z}{1 - \frac{Z}{2}} \right)^2.$$  

(5b)

The relations given in Eq. (5) constitute the main result of this work. The key point is that the same parameter $\delta r$ appears in both $a_{\text{NLO}}$ and $r_{\text{NLO}}$. Therefore, they provide a model-independent scheme to correlate the NLO corrections to $a$ and $r$, which turns out to be consistent as long as $Z \approx 0$, of the order of $O(\gamma_b/\beta \ll 1)$ or smaller. The fact that $Z$ is required to be at most of order $O(\gamma_b/\beta)$ is because the $O(k^4)$ terms in the ERE expansion could lead to corrections of order $O(Z \gamma_b^2/\beta)$ in Eq. (4), as mentioned before. These corrections should be, at most, comparable to those of $O(\gamma_b^2/\beta)$ neglected in the present scheme to correlate $r_{\text{NLO}}$ and $a_{\text{NLO}}$. When $Z$ takes these small values, it would mean that the model-independent contribution from the coupling $g^2$ in Eq. (3) should be large, giving a strong support to the molecular nature of the weakly bound state. In other words, a shallow bound state which couples to a two-hadron system, for which the scattering length and effective-range could be accurately described by $a_{\text{NLO}}$ and $r_{\text{NLO}}$ with values of $Z$ of the order of $(\gamma_b/\beta)$, small but not necessarily zero, can be reasonably seen as a hadron molecule. This is to say, its low energy properties, including the binding, can be naturally accommodated as result of the two-hadron interaction. To study systems for which $Z$ could take larger values,\(^3\) the $O(k^4)$ or higher terms in the ERE expansion will be required, which points to the need in these cases to include additional details of the short distance dynamics.

Given the experimental values for the mass, or equivalently the binding momentum $\gamma_b^{\text{exp}}$, the associated scattering length $(a^{\text{exp}})$, and the effective range $(r^{\text{exp}})$ parameters of a two-particle weakly bound state, we propose to study the

---

\(^2\) The point that Weinberg makes in Ref. [1] is that the coefficient of the $k^4$ term in the ERE does not diverge as $1/\gamma_b^2$ in the weak-binding limit, which will affect to the approximate relation of Eq. (4) at order $\gamma_b$. However, one cannot discard that this coefficient could scale like $Z/\gamma_b^3$. The factor of $Z$ in front is because this $1/\gamma_b^2$ behaviour will not appear in the absence of compact bare states ($Z = 0$). The reasoning runs in parallel for any other higher order term of the ERE. Hence, we simply discard any new contribution of order $O(\gamma_b^4)$ to Eq. (4) coming from the ERE terms beyond the scattering length and effective-range.

\(^3\) That is, larger than $O(\gamma_b/\beta)$ but not necessarily $Z \to 1$. For this latter case, corresponding to a purely compact state, the scattering amplitude that arises by considering a bare state propagator is exactly the ERE truncated at $O(k^2)$. Therefore, in the $Z \to 1$ case, no additional terms in the ERE beyond $a$ and $r$. 

---
following two dimensional (2D) distribution:

\[ \mathcal{L}(Z, \delta r) = \frac{1}{3} \left[ \left( \frac{a_{\exp} - a_{\mathrm{NLO}}}{\Delta a_{\exp}} \right)^2 + \left( \frac{r_{\exp} - r_{\mathrm{NLO}}}{\Delta r_{\exp}} \right)^2 
+ \left( \frac{\gamma_b^{\exp} - \gamma_b^{\mathrm{NLO}}}{\Delta \gamma_b^{\exp}} \right)^2 \right], \tag{6} \]

to estimate the likelihood of the compositeness of the state. Above, \( \gamma_b^{\mathrm{NLO}} \) is given by

\[ \gamma_b^{\mathrm{NLO}} = \frac{1 - \sqrt{1 + 2r_{\mathrm{NLO}}/a_{\mathrm{NLO}}}}{r_{\mathrm{NLO}}}, \tag{7} \]

which exactly satisfies \( [\gamma_b^{\mathrm{NLO}} - (-1/a_{\mathrm{NLO}} + r_{\mathrm{NLO}} (\gamma_b^{\mathrm{NLO}})^2/2)] = 0 \). Consistent with the order at which we are working, we evaluate \( a_{\mathrm{NLO}} \) and \( r_{\mathrm{NLO}} \) using \( \gamma_b^{\exp} \). It is important to notice that \( \Delta \gamma_b^{\exp}, \Delta a_{\exp}, \) and \( \Delta r_{\exp} \) should be fixed taking into account not only the uncertainties on the determinations of these observables, but also the expected accuracy of their NLO approximation, i.e., an \( O(\gamma_b^2/\beta^2) \) relative error. If the actual experimental errors are smaller than this expected accuracy, then a relative error \( (\gamma_b/\beta)^2 \) should be taken instead.

3 The deuteron

We first apply the compositeness distribution of Eq. (6) to the paradigmatic case of the deuteron, whose properties are known very precisely: \( E_b^{\exp} = -2.224575(9) \) MeV [or equivalently \( \gamma_b^{\exp} = 0.2316068(5) \) fm\(^{-1} \)] [163], and \( a_{\exp} = -5.42(1) \) fm and \( r_{\exp} = 1.75(1) \) fm from the Granada-group analysis of the \( pn \) isoscalar \( ^3S_1 \) wave [164] (see also Ref. [165]). The analysis of the latter work includes statistical errors, stemming from the data uncertainties for a fixed form of the potential, and systematic errors arising from the different most-likely forms of the potentials. Assuming they are independent, the total uncertainty corresponds to adding both errors in quadrature. Despite including systematic uncertainties, the errors of \( a \) and \( r \) turn out to be much smaller than the accuracy that can be expected from the NLO approximation, \( (\gamma_b^2/m_\pi^2) \sim 10\% \), taking \( \beta \simeq m_\pi \). Therefore, instead of taking the small errors quoted above, we fix \( \Delta \gamma_b^{\exp}, \Delta a_{\exp}, \) and \( \Delta r_{\exp} \) in Eq. (6) assuming a relative error of 10\%. With all these inputs, we show in Fig. 1 the 2D distribution \( \mathcal{L}(Z, \delta r) \) for the case of the deuteron. It strongly supports molecular probabilities (1 – \( Z \)) quite close to one, in conjunction with values of the NLO \( \delta r \) contribution of the order of 1/m_\pi \sim 1.4 \) fm, as expected. We also see in Fig. 1 (middle and right plots) that for a value \( \delta r = 1.75 \) fm, \( a_{\mathrm{NLO}} \) and \( r_{\mathrm{NLO}} \) are closer to the experimental values than the corresponding LO predictions [cf. Eq. (2)]. This model-independent analysis provides a consistent picture, where values of \( Z \) greater than \( \gamma_b^{\exp}/m_\pi \sim 0.3 \) are very implausible, which confirms the dominant molecular structure of the deuteron [1].

4 The \( D_{s0}^{*}(2317)^{\pm} \)

This scalar narrow resonance (\( \Gamma < 3.8 \) MeV), which lies 45 MeV below the \( DK \) threshold and has valence-quark content \( c\bar{s} \), was discovered in 2003 by the BaBar Collaboration [19]. Its abnormally light mass cannot be easily accommodated within constituent quark models [110, 111, 113, 166, 167], and as a consequence, it is common to describe this exotic resonance as the result of the S-wave \( DK \) interaction [35, 37, 50, 73, 168–173]. Unitarized heavy-meson chiral approaches predict that the \( D_{s0}^{*}(2317)^{\pm} \) would belong to a light-flavor SU(3) anti-triplet, completed by an isospin doublet associated to the scalar \( D_{s0}^{*}(2300) \) resonance [57, 59]. Here, we will discuss, within the scheme outlined above, the \( DK \) molecular probability of the \( D_{s0}^{*}(2317)^{\pm} \), neglecting the isospin-violating \( D_s \pi \) decay channel. Given the lack of \( DK \) scattering data, we take the values of the isoscalar S-wave \( DK \) scattering length and effective range obtained in Ref. [171] from the finite volume QCD levels reported in Refs. [169, 170]. Namely, we use \( a_{\exp} = -1.3(5) \) fm and \( r_{\exp} = -0.1(3) \) fm. In addition, we take \( E_{\exp} = -45(4) \) MeV, estimated from the experimental masses compiled in the PDG [7], which leads to \( \gamma_b^{\exp} = 0.95(4) \) fm\(^{-1} \) when isospin averaged masses are used for the kaon and \( D \) mesons. Due to the large uncertainties affecting both \( a_{\exp} \) and \( r_{\exp} \), it is not necessary to take into account the subtleties associated with the \( D^0 K^–D^+ K^0 \) isospin breaking effects. The scale \( \beta \) is in this case of the order of 300 MeV, estimated from the expected effects induced by the nearest \( D_s \eta \) threshold [137] and/or by the two-pion exchange interaction, none of which are explicitly treated in the ERE. Hence, we expect the accuracy of the NLO \( \gamma_b^{\exp} \) expansion to be of the order of \( (\gamma_b^2/\beta^2) \sim 40\% \), which we adopt for \( \Delta \gamma_b^{\exp} \), while for \( \Delta a_{\exp} \) and \( \Delta r_{\exp} \), we use the errors quoted above.

The compositeness 2D distribution of Eq. (6) for the \( D_{s0}^{*}(2317)^{\pm} \) is shown in Fig. 2. The results favor \( DK \) molecular probabilities of at least 50\%, which is in agreement with previous calculations [50, 73, 137, 140, 171, 173, 174]. We cannot be as predictive in this case as for the deuteron, not only because of the bigger uncertainties of the input, but also because of the larger size of the power-counting parameter \( \gamma_b/\beta \sim 0.6 \). Nevertheless, the approach is still consistent since values of \( Z \) of order \( O(\gamma_b/\beta) \), or smaller, are favored by the compositeness distribution for this state. We however should note that the binding energy of the \( D_{s0}^{*}(2317)^{\pm} \) is significantly higher than that of deuteron, and the NLO approach employed here is at the limit of its applicability. To be quan-
interaction in the isoscalar $^3S_1$ wave. Middle and right: $Z$ dependence of $a$ (middle) and $r$ (right) at LO (red, dashed-dotted lines) and NLO (blue, solid lines), compared with the experimental values (green bands).

Neglecting $O(\gamma_v^4)$ corrections and using the experimental $a_{\text{exp}}$ and $r_{\text{exp}}$ values, the above equation leads to

$$\gamma_v^{\text{exp}} \approx \frac{-1 + \sqrt{1 + 2r_{\text{exp}}/a_{\text{exp}}}}{r_{\text{exp}}} = 0.03999(5) \text{fm}^{-1},$$  

(9)

where the error comes from the uncertainties of the experimental ERE parameters. This error turns out to be around a factor of ten greater than the corrections induced by the $O(\gamma_v^4)$ term in Eq. (8). This virtual binding momentum corresponds to $E_v = -0.0663(4) \text{MeV}$.

It is not trivial to extend the notion of compositeness to states other than bound states, since wave functions derived from poles on the unphysical sheet are not normalizable and the probabilistic interpretation is lost. They are not QCD asymptotic states, and thus it seems difficult to argue about wave-function components. However, one could think of some variation of QCD parameters, e.g. quark masses, such that these virtual states could become physical, bound states. From this perspective, it would make sense to generalize the notion of compositeness. On the other hand, formally relying on the definition of the field renormalization $Z$ in the non-relativistic theory [137], relations between $a$, $r$ and $Z$ can be derived also for a virtual state with a pole at $k = -i\gamma_v$, and they are similar to those of a bound state. One should simply replace $\gamma_b$ with $-\gamma_v$ in $a_{\text{NLO}}$ and $r_{\text{NLO}}$ given in Eqs. (2) and (5). In addition, $\gamma_v^{\text{NLO}}$ should be evaluated using Eq. (9), but with the NLO ERE parameters. Thus, we can use the definition of Eq. (6) for the compositeness distribution of a virtual state. The accuracy of the NLO $\gamma-\text{expansion}$ $(\gamma_v^2/m_\pi^2) \sim 0.3\%$ is larger than the experimental errors on $a_{\text{exp}}$ and $r_{\text{exp}}$, and we take it to set $\Delta a_{\text{exp}}$ and $\Delta r_{\text{exp}}$, while we use the experimental error to fix $\Delta r_{\text{exp}}$. Due to the high precision of the input parameters, very small variations of $Z$ and $\delta r$ produce quite large changes of $\mathcal{L}(Z, \delta r)$. In Fig. 3, we show the neperian logarithm of the compositeness distribu-

Fig. 1 Left: distribution of Eq. (6) for different values of the probability $Z$ of ending the deuteron in a bare elementary particle, as a function of the NLO contribution $\delta r$ [Eq. (5a)] to the effective range of the $pn$ interaction in the isoscalar $^3S_1$ wave. 5 The $^1S_0$ nucleon-nucleon virtual state

The $pn$ scattering length and effective range determined in Ref. [165] for this isovector partial wave are $a_{\text{exp}} = 23.735(16) \text{fm}$ and $r_{\text{exp}} = 2.68(3) \text{fm}$, respectively, with the total uncertainties obtained by adding statistical and systematic errors in quadrature. This partial wave has a shallow virtual state (pole on the real energy-axis below the threshold on the unphysical sheet), the position of which is determined by the condition $\cot \delta(-i\gamma_v) = +i$, with $\gamma_v = \sqrt{2|E_v|}$ and $E_v < 0$, the binding energy of the virtual state. From the ERE, it follows

$$\gamma_v \approx \frac{1}{a} - \frac{1}{2}r_v^2 + O(\gamma_v^4).$$  

(8)
An estimation of $T_{cc}^+$ compositeness

The $T_{cc}^+$ state has been recently discovered by the LHCb collaboration [17,18] as a prominent peak in the $D^0 D^0 \pi^+$ spectrum. It is very close to the $D^{*0} D^0$ threshold, since the experimental analysis throw $\Delta M_{T_{cc}^+} = M_{T_{cc}^+} - m_{D^{*0}} - m_{D^0} = -273(61)$ keV [17] or $\Delta M_{T_{cc}^+} = -360(40)$ keV [18]. However, the $D^{*0} D^0$ threshold is only 1.4 MeV above, and therefore must consider coupled channels in order to have a fully accurate description of the state. In this situation one cannot straightforwardly apply Weinberg’s compositeness criteria, which requires the coupling of the bound state to a single channel.

The approach should be modified in the presence of close coupled channels that play an important role on the long-distance dynamics of the state, and as a consequence, they significantly modify the effective range parameter [137]. In Ref. [180], it is shown for the $X_{c1}(3872)$ and $T_{cc}^+$ exotic states that the appearance of a large and negative effective range, which in the one-channel case would indicate the dominance of a compact component [1], can be naturally generated by the coupled-channel dynamics. Hence, in presence of coupled channels, and before analyzing the estimator of the compositeness proposed in this work, it would be necessary to correct the effective range by a term [137,180] that stems from coupled-channel effects, and which clearly needs to be attributed to the molecular component of the state. Other efforts beyond the one just mentioned have been devoted to extend the compositeness condition to coupled channels (see references in Sect. 1).

However, in this work we adopt a different perspective and for illustrative purposes, we have qualitatively applied our generalization of Weinberg compositeness condition to the $T_{cc}^+$ state within a simplified scenario. We have reduced the coupled-channel problem to a single-channel one by considering the model of Ref. [76] in the exact isospin limit, which we briefly outline below. The latter work performs an $S$-wave $D^{*0} D^0$, $D^{*0} D^+$ coupled-channel analysis in terms of two coupling constants $C_{0,1}$ and an ultraviolet cutoff $\Lambda$. If one takes common masses for the $D^{(*)}$ mesons, $m_{D^{(*)}} = (m_{D^{(*)}} + m_{D^{(*)}})/2$, then the two-channel problem diagonalizes and one ends up with two independent amplitudes for each of the definite-isospin ($I = 0$ and $I = 1$) sectors. Taking this limit, and using the values for the constant $C_0$ fitted in Ref. [76], we obtain $a_{ph} = -5.38(30)$ fm and $r_{ph} = 0.95(32)$ fm for the isoscalar$^5$ scattering length and effective range, respectively. The central values account for the averages of Eqs. (3.9a) and (3.9b) in Ref. [76], computed for two different values of the cutoff $\Lambda = 0.5$ GeV and 1.0 GeV. The quoted errors represent the addition in quadrature of the statistical error and half of the dispersion between both determinations. In this isospin limit, the $T_{cc}^+$ binding energy (respect to the average threshold) increases, and we find $\Delta M_{T_{cc}^+}^\text{ph} = -833(67)$ keV and $-856(53)$ keV for $\Lambda = 0.5$ GeV and $\Lambda = 1.0$ GeV, respectively, which lead to a binding momentum $\gamma_{ph}^\text{III} = 40.2(1.7)$ MeV. Taking the scale $\beta \simeq m_\pi$, one obtains $(\gamma_{ph}^\text{III} / \beta)^2 \simeq 8\%$, which is of the order of the uncertainty in the scattering length and smaller than that of the effective range.

For the $T_{cc}^+$ and contrary to the case of the deuteron, we are not determining the binding momentum, the scattering length and the effective range from an experimental analysis, but instead from a phenomenological model [76]. For this reason, we have denoted these quantities as $r_{ph}^\text{III}$, $a_{ph}$ and $r_{ph}$, respectively. It is worth pointing out that two recent LQCD simulations [181,182] have also computed the scattering length and effective range for $S$-wave $I = 0$ $D D^*$ scattering, and have found a value $r_0 \simeq 1$ fm, similar to the one obtained in Ref. [76], to be used in our work. We also note that, while here $r_{ph}$ is small and positive, the experimental value for the effective range obtained in Ref. [18] is large and negative. However, in the latter work, the negative value is a built-in property of the model used in the analysis. More importantly, it is obtained in a coupled channel scheme, whereas $r_{ph}$ obtained here refers to the single channel case in

$^5$ We assume that the $T_{cc}^+$ state is mostly an isoscalar state, as suggested by additional experimental information besides the $D^0 D^0 \pi^+$ spectrum, see Refs. [17,18,76].
the exact isospin limit. Therefore, the comparison between the two values is not meaningful. Further discussions on this subject can be found in Refs. [71,137,180].

Nevertheless, we should mention that the results of Ref. [76] are consistent with those found in the state of the art work of Ref. [71], where (i) the $D^+ D^0$, $D^{*0} D^+$ coupled-channel dynamics, (ii) long-range interactions provided by the one pion exchange mechanism and (iii) effects from the three-body $D D \pi$ thresholds, which lie very close to and below the two-body $D^* D$ ones, are accurately taken into account. Indeed, the parameters of the effective range expansion from the low-energy scattering amplitude are also reliably extracted in Ref. [71], and it turns out that both scattering length and effective range are compatible, within uncertainties, with $a_{ph}$ and $r_{ph}$ used here, and obtained from the analysis of Ref. [76]. This is so since the largest contribution to the effective range, originated from isospin breaking related to the $D^{(*)}$ meson mass differences, that is, from the coupling of $D^+ D^0$ to the slightly higher $D^{*0} D^+$ channel is discounted\(^6\) (see Table IV and Eq. (40) of Ref. [71]), as mentioned in the beginning of the section. Therefore, though the results shown below for the compositeness of the $T_{cc}^+$, obtained within the model of Ref. [76] in the isospin limit, should be considered as only qualitative ones, they might be sufficiently realistic to illustrate the performance of the estimator of the compositeness proposed in this work.

Bearing all these caveats in mind, we have computed the distribution of Eq. (6), using the numerical values discussed above for $a_{ph}$, $r_{ph}$ and $\gamma_{ph}$. The results are shown in Fig. 4, similarly as done for the deuteron in Fig. 1. As can be seen in the leftmost panel, $\mathcal{L}(Z, \delta r) < 0.5$ for $Z < 0.2$ with $\gamma_{ph}/\beta \approx 0.3$, and the minimum of $\mathcal{L}(Z, \delta r)$ is quite compatible with $Z = 0$. Indeed in the middle panel, for $\delta r = 0.95 \text{ fm}(=r_{ph})$ such that $\gamma_{NLO}(Z = 0, \delta r = 0.95 \text{ fm}) = r_{ph}$, it can be seen that the scattering length $a_{NLO}$ coincides with $a_{ph}$ at $Z = 0$. This analysis supports a molecular picture for the $T_{cc}^+$ state, as previous works have also concluded [71,75], and in particular the model of Ref. [76], whose predictions for the binding momentum, scattering length and effective range have been used here.

\( ^6 \) Such correction is so large that it leads to a positive residual finite range ($\approx r_{ph} \sim 1 \text{ fm}$), which is the quantity entering in the Weinberg’s relations.

### 7 Summary and discussion

We have discussed a model-independent estimator of the likelihood of the compositeness of a shallow S-wave bound or virtual state. It relies only on the proximity of the energy of the state to the two-hadron threshold to which it significantly couples and on the experimental scattering length and effective range low energy parameters. The approach is based on NLO Weinberg’s relations and it is self-consistent as long as the obtained $Z$ is small of the order of $\mathcal{O}(\gamma_{b}/\beta)$. To systematically study systems where $Z$ could take larger values, the order $\mathcal{O}(k^4)$ or higher terms in the ERE would be required. This is because in those cases, it would be necessary to include additional details to further constrain the short-range structure of the wave-function. We have analysed the case of the deuteron (Sec. 3), the exotic $D_{s0}^*(2317)^\pm$ resonance (Sec. 4), and the $1S_0$ nucleon-nucleon virtual state (Sec. 5), and found strong support to the molecular interpretation in all cases. Nevertheless, results are less conclusive for the $D_{s0}^*(2317)^\pm$ due to the large size of the power-counting parameter $\gamma_{b}/\beta \sim 0.6$ and therefore the NLO approach employed here is at the limit of its applicability.

As discussed in Sect. 6, the Weinberg compositeness criteria as well as the extension presented here are only valid

---

**Fig. 4** Left: distribution of Eq. (6) for different values of the probability $Z$ of the $T_{cc}^+$ state ending in a bare elementary particle (compact tetraquark), as a function of the NLO contribution $\delta r$ [Eq. (5a)] to the effective range of the isoscalar $DD^*$ interaction. Middle and right: $Z$ dependence of $a$ (middle) and $r$ (right) at LO (red, dashed-dotted lines) and NLO (blue, solid lines), compared with the phenomenological values (green bands) discussed in Sect. 6.
for the case of a single channel, and the approach needs to be modified when coupled channels are present [137, 180]. To avoid this problem, in Sect. 6 we have discussed the case of the $T_{c}^{+}$ by reducing the coupled-channel ($D^{++} D^{0} D^{0} D^{+}$) problem to a single-channel one in the isospin limit using the phenomenological model of Ref. [76]. Applying the generalization of Weinberg’s compositeness condition proposed in the present work, we have shown that the parameters are compatible with a molecular interpretation of the $T_{cc}^{+}$ state. These results are, however, only qualitative and for illustrative purposes, since we have not considered the complexity of the very close thresholds $D^{0} D^{++}$ and $D^{+} D^{0}$, which could make more difficult to appreciate the main ingredients of the approach (expansion) derived in this paper.

Acknowledgements We warmly thank E. Ruiz-Arriola for useful discussions.
