(Dated: April 30, 2019)

We determine the effective dipolar interaction between single domain two-dimensional ferromagnetic particles (islands or dots), taking into account their finite size. The first correction term decays as \(1/D^3\), where \(D\) is the distance between particles. If the particles are arranged in a regular two-dimensional array and are magnetized in plane, we show that the correction term reinforces the antiferromagnetic character of the ground state in a square lattice, and the ferromagnetic one in a triangular lattice. We also determine the dipolar spin-wave spectrum and evaluate how the Curie temperature of an ensemble of magnetic particles scales with the parameters defining the particle array: height and size of each particle, and interparticle distance. Our results show that dipolar coupling between particles might induce ferromagnetic long range order at experimentally relevant temperatures. However, depending on the size of the particles, such a collective phenomenon may be disguised by superparamagnetism.

I. INTRODUCTION

In this paper we are interested in two-dimensional magnetic particles interacting through the long range dipolar forces. These particles have a two-dimensional character in two respects: first, because they are platelet shaped, that is to say their thickness \(t\) is much smaller than their linear size \(L\); second, because they are arranged on a two dimensional substrate.

They can be obtained, \textit{e.g.}, growing by Molecular Beam Epitaxy (MBE) a magnetic element on a high symmetry substrate. In this case, growth is driven by surface diffusion, nucleation and aggregation:\textsuperscript{1} in the submonolayer regime, the magnetic overlayer is made up of an ensemble of atomically thick islands that generally are not uniform in size neither arranged in a regular array. The distribution of islands may be regular if nucleation (and therefore island formation) takes place on a reconstructed surface,\textsuperscript{2} or on a network of dislocations.\textsuperscript{3} Alternatively, particles can be produced via lithographic techniques:\textsuperscript{4} in this case, they are much bigger in size and their distribution is generally uniform.

In the following, small particles obtained by MBE growth in the submonolayer regime will also be called islands and large particles obtained by lithographic techniques will also be called dots. Particle is a generic term for both cases.

Each particle is made up of a large number \(N\) of spins which interact ferromagnetically through the strong intra-particle exchange interaction. In an island, \(N \approx 10^2 - 10^4\), while in a dot \(N\) may be several orders of magnitude greater.

Sufficiently small particles are expected to be in a single domain state, even if their actual magnetic state may depend on several factors: the shape of the particle, the strength of the anisotropies, the single crystal or polycrystalline character of the particle, and so on. In this paper we are assuming that particles are in a single domain state and have a crystalline structure. Within these hypotheses, the magnetic state of an isolated particle is fixed, first of all, by the balancing between dipolar interaction (which has an easy-plane effect) and possible anisotropies favouring the direction perpendicular to the plane (\(z\) direction, in the following). In the absence of quartic and higher order anisotropies a canted configuration is impossible and the resulting effect may be easy-axis or easy-plane only.

The effect of dipolar interaction between spins belonging to the same (ultrathin) particle has been studied in a previous paper.\textsuperscript{5} We showed that in-plane shape anisotropy is weak: this means that if the magnetization of the particle is within the film plane, its orientation is expected to be settled by the symmetry of the underlying lattice (through magnetocrysalline anisotropies) rather than by the shape of the particle (through the intra-particle dipolar coupling). Such a feature was indeed experimentally observed in MBE-grown Co on Cu(100) ultrathin particles.\textsuperscript{6}

In this paper we aim to study the interparticle dipolar interaction and to address the following questions:

i) Assuming the particle to be in a single domain state, how is the dipolar interaction between particles modified by their finite size?

ii) Assuming the particles to be arranged in a regular array, is the dipolar ferromagnetic (FM) state a stable configuration?

iii) If the ground state is ferromagnetic, is it stable at finite temperature and what is the value of the Curie temperature?

The previous questions are addressed in Sections II, III and IV, respectively; in Section V the conclusions are drawn.
between the two spins can be expressed as

\[ \vec{d} = 1/12 \] for a circular particle of radius \( \rho \), \( \mathcal{I} = \rho^2/2 \); for a triangular (equilateral) particle of side \( L \), \( \mathcal{I} = L^2/12 \).

Finally, we would like to remark that the isotropic coupling term, proportional to \( \langle \hat{S}_1 \cdot \hat{S}_2 \rangle \), has different correction terms according to the orientation of the spins: see Eq. (3). In other words, such a term is no more isotropic once the finite size of the particle is taken into account.

In Fig. 2 we compare the exact dipolar coupling \( E_{\text{dip}} \) (symbols) with the zero order approximation \( E_{\text{dip}}^{(0)} \) (dashed lines) and with the second order approximation \( (E_{\text{dip}}^{(0)} + E_{\text{dip}}^{(2)}) \) (full lines), in two cases: i) the particles are magnetized perpendicularly to the plane, along the \( \hat{x} \) axis (positive coupling energies), and ii) the particles are magnetized in plane along the \( \hat{z} \) axis (negative coupling energies). We can see that the second order approximation is fairly good except at very small distances: the smallest allowed distance between centers (without superposing the particles) is \( D_{\text{min}} = \sqrt{2}(L + a_0) = 29.7a_0 \), where \( L = 20a_0 \) is the side of the square particle. The smallest value of \( D \) plotted in Fig. 2 is \( D = 30a_0 \).

In order to understand which configurations are energetically favoured, let us start by considering just a couple of spins \( \vec{S}_1, \vec{S}_2 \), located in plane along the \( \hat{x} \) axis. The dipolar coupling can be generally written as

\[ E_{12} \approx E_{12}^{(0)} + E_{12}^{(2)} \]

where \( E_{12}^{(0)} \) is the zero-order coupling and \( E_{12}^{(2)} \) takes into account the finite size of the particles:

\[
E_{\text{dip}}^{(0)} = \frac{1}{2} \Omega \left[ \vec{S}_1 \cdot \vec{S}_2 - \frac{3}{2} \left( \vec{S}_1 \cdot \vec{D} \right) \left( \vec{S}_2 \cdot \vec{D} \right) \right]
\]

\[
E_{\text{dip}}^{(2)} = \frac{9 \mathcal{I}_{12}}{4} \frac{\vec{S}^\parallel_1 \cdot \vec{S}^\parallel_2}{D^5} + \frac{3 \mathcal{I}_{12}}{4} \left[ \frac{\vec{S}_1^\perp \cdot \vec{S}_2^\perp}{D^5} - 5 \left( \vec{S}_1 \cdot \vec{D} \right) \left( \vec{S}_2 \cdot \vec{D} \right) \right]
\]
FIG. 2: Dipolar energy between two square particles, one monolayer thick, of side \( L = 20a_0 \) on a square lattice (21 spins per side). The centers of the two particles have the coordinates \((0,0)\) and \((D/\sqrt{2}, D/\sqrt{2})\). The sides of the squares are parallel to the axis \( x, y \). Positive and negative energies refer to spins parallel to \( z \) and \( x \), respectively. The exact calculation \( E_{\text{dip}} \) (symbols) is compared with \( E_{\text{dip}}^{(0)} \) (dashed lines) and \( (E_{\text{dip}}^{(0)} + E_{\text{dip}}^{(2)}) \) (full lines). Inset: the case of spins parallel to \( x \), in a log-log scale.

veritable spins \( s_1, s_2 \) or they may represent the effective spins of two particles \( S_1, S_2 \); in the former case one has \( \Omega_2 = 0 \), while in the latter \( \Omega_2 \) is the correction due to the finite sizes of the particles.

Both \( E_{12}^{(1)} \) and \( E_{12}^{(2)} \) are the sum of competitive interactions. For the sake of definiteness, let us consider \( E_{12}^{(2)} \). The sum \( 2S_1^z S_2^z + S_1^x S_2^x \) favours an antiferromagnetic (AFM) alignment of the spins in the \( z \) direction, perpendicular to their joining vector. The term \( -5S_1^z S_2^x \) favours a ferromagnetic (FM) alignment along the \( x \) axis. The energy of the former configuration is \(-3\Omega_2\) and the energy of the latter one is \(-4\Omega_2\). As proved in Appendix B, where a more detailed discussion is given, the latter configuration is the ground state indeed.

In conclusion, two spins interacting through the dipolar coupling minimize their energy by ordering ferromagnetically along the joining line.

We are now going to discuss the more complex case of a two dimensional lattice of spins. It is well known that in the presence of a direct exchange interaction, the system is ferromagnetic and magnetized in the plane, because of an easy-plane effect of \( E_{\text{dip}} \). If such an exchange interaction is absent, the easy-plane effect survives, but the actual configuration in the plane strongly depends on the lattice structure. It is useful to explain the origin of such a dependence on the spin arrangement.

We have seen that spins would like to point along the line joining them: in a two dimensional lattice it is impossible, of course, to fulfill this requirement for all couples of spins. It is possible, however, for a chain of spins: so, we can start by addressing the nature of the coupling between chains. Let us consider a ferromagnetic chain of spins along the \( y \) axis of the plane and evaluate the dipolar field \( \vec{H}_{\text{dip}} \) generated at a point at distance \( d \). Spins are oriented in the \(+y\) direction and \( \vec{H}_{\text{dip}} = H_{\text{dip}}\hat{y} \). In the continuum approximation,

\[
H_{\text{dip}} = -\frac{1}{2} \int_{-\infty}^{+\infty} dy \left( \frac{1}{r^3} - \frac{3}{5} \frac{y^2}{r^5} \right)
- \frac{3}{2} \Omega S L \int_{0}^{+\infty} dy \left( \frac{1}{r^3} - \frac{5}{3} \frac{y^2}{r^7} \right)
\]

where \( r = \sqrt{y^2 + d^2} \).

Both integrals have the form \( \int dy(\frac{1}{r^3} - (3 + n) \frac{y^2}{r^{3+n}}) \). It is sufficient to integrate by parts the term \( 1/r^{3+n} \) to prove that the integral vanishes for any \( n \) and for any \( d \). Therefore, in the continuum approximation \( H_{\text{dip}} = 0 \).

An exact calculation on a discrete lattice gives a finite value for \( H_{\text{dip}} \), but its sign depends on the actual lattice structure. Therefore, the reason for the sensitivity of the ground state on the spin arrangement is clear. Dipolar interaction favours the formation of spin chains magnetized ferromagnetically along the chain: these chains are very weakly coupled, in the continuum approximation being even uncoupled. The sign of the coupling and therefore the nature of the ground state do depend on the lattice structure.

In the next Section we are going to analyze the nature of the ground state and to study the spin-wave spectrum with respect to a ferromagnetic alignment.

III. GROUND STATES AND SPIN-WAVE SPECTRA IN TWO-DIMENSIONAL LATTICES

In the following we consider an orthorhombic lattice (see Fig. 3a) with primitive vectors

\[
\vec{u}_1 = \frac{1}{2}(a, -b), \quad \vec{u}_2 = \frac{1}{2}(a, b)
\]

where \( a = 2D_0 \sin(\phi/2) \), \( b = 2D_0 \cos(\phi/2) \), and \( D_0 \) is the rhombus side. For \( \phi = \frac{\pi}{7} \) and \( \phi = \frac{\pi}{5} \), the orthorhombic lattice reduces to a triangular and to a square lattice, respectively. The angle \( \phi \) can be supposed smaller than \( \frac{\pi}{7} \), because if \( \phi > \frac{\pi}{7} \) there is just an interchange between \( a \) and \( b \) (see Fig. 3a).

It is known that the ground state is ferromagnetic for \( \phi < \phi_c \approx 80^\circ \) and antiferromagnetic for larger values of the angle \( \phi \). It is noteworthy that we find \( \phi_c \) to be almost unaffected when \( E_{\text{dip}}^{(2)} \) is added to \( E_{\text{dip}}^{(0)} \): as a first approximation, the finite size of the particle has therefore negligible effects on the ground state. We can say as well that the finite size of the particles (\( i.e. \) the term \( E_{\text{dip}}^{(2)} \)) reinforces the FM character of the ground state for a triangular lattice, \( \phi = \frac{\pi}{7} \), and the AFM one for a square lattice, \( \phi = \frac{\pi}{5} \). This statement will be substantiated by the analysis of the spin-wave spectra at the end of this Section.
\begin{align*}
\vec{D} & \text{ obtained from Eqs. (3,4) summing over all sites } \vec{H} \vec{D} \text{ spins whose centers of mass are located on the sites } \vec{H} \vec{D} \text{ with respect to the } \hat{x} \text{ axis. We remind that,} \\
& \text{citations with respect to a ferromagnetic configuration } \theta \text{.}
\end{align*}

Next, exploiting the translational invariance in the film plane, we introduce the Fourier transform

\begin{align*}
a_j &= \sqrt{\frac{1}{N_\parallel}} \sum_k a_k^\dagger e^{-i\vec{k} \cdot \vec{D}_{ij}}, \\
& a_j^\dagger &= \sqrt{\frac{1}{N_\parallel}} \sum_k a_k^\dagger e^{i\vec{k} \cdot \vec{D}_{ij}},
\end{align*}

where \( \vec{k} = (k_x, k_y) \) is the two-dimensional in-plane wavevector ranging over the first Brillouin zone, generated by the primitive vectors (see Fig. 3b)

\begin{align*}
\vec{v}_1 &= 2\pi(\frac{1}{a}, -\frac{1}{b}), \\
\vec{v}_2 &= 2\pi(\frac{1}{a}, \frac{1}{b})
\end{align*}

and \( N_\parallel \) is the total number of spins in the two-dimensional lattice. The spin-wave Hamiltonian takes the form

\begin{align*}
\mathcal{H}_{\text{ap}} &= \sum_k \left[ A_k a_k^\dagger a_k + \frac{1}{2} B_k (a_k a_{-k}^\dagger + a_k^\dagger a_{-k}^\dagger) \right] \\
& = \mathcal{H}^{(0)}_{\text{ap}} + \mathcal{H}^{(2)}_{\text{ap}}; \text{ it is obtained from Eqs. (3,4) summing over all sites}
\end{align*}

\begin{align*}
\mathcal{H}^{(0)}_{\text{ap}} &= \frac{1}{2} \Omega \sum_{\vec{D}_i, \vec{D}_j} \left[ \mathcal{S}_i \cdot \mathcal{S}_j \right] \\
& - 3 \left( \mathcal{S}_i \cdot \vec{D}_{ij} \right) \left( \mathcal{S}_j \cdot \vec{D}_{ij} \right) D_{ij}^2 \\
\mathcal{H}^{(2)}_{\text{ap}} &= \frac{1}{2} \Omega \sum_{\vec{D}_i, \vec{D}_j} \left\{ 3 \mathcal{I}_{ij} \left[ \frac{\mathcal{S}_i \cdot \mathcal{S}_j}{D_{ij}^2} \right] \\
& + 3 \mathcal{I}_{ij} \left[ \frac{\mathcal{S}_i \cdot \mathcal{S}_j}{D_{ij}^2} - \frac{3}{5} \left( \mathcal{S}_i \cdot \vec{D}_{ij} \right) \left( \mathcal{S}_j \cdot \vec{D}_{ij} \right) \right] \right\}
\end{align*}

where \( \vec{D}_{ij} = \vec{D}_j - \vec{D}_i \) and \( \mathcal{I}_{ij} = \frac{1}{2}(\mathcal{I}_i + \mathcal{I}_j) \) is the semism of the “moments of inertia” of two particles whose centers of mass are located in \( \vec{D}_i \) and \( \vec{D}_j \), respectively. In the following we are assuming to have an array of identical particles, so that \( \mathcal{I}_i = \mathcal{I} \).

Taking the \( \hat{y} \) direction as quantization axis, we perform the Holstein-Primakoff transformation from spin to boson operators

\begin{align*}
\mathcal{S}_j^x &= i \sqrt{\frac{S}{2}} (a_j^\dagger - a_j) , \\
\mathcal{S}_j^y &= \mathcal{S} - a_j a_j^\dagger, \\
\mathcal{S}_j^z &= \sqrt{\frac{S}{2}} (a_j + a_j^\dagger)
\end{align*}

Let us now calculate the frequency of spin-wave excitations with respect to a ferromagnetic configuration with magnetization directed in plane. We remind that, depending on the value of the rhombic angle \( \phi \), the ferromagnetic ground state is different: for \( \phi \leq \pi/3 \), the dipoles are oriented along the short diagonal of the rhombus (i.e. along the \( \hat{x} \) axis in Fig. 3a) while for \( \pi/3 \leq \phi \leq \phi_c \), along the long diagonal (\( \hat{y} \) axis).

The effective dipolar interaction between particles of spins whose centers of mass are located on the sites \( \vec{D}_i \) of an orthorhombic lattice is \( \mathcal{H}_{\text{ap}} = \mathcal{H}^{(0)}_{\text{ap}} + \mathcal{H}^{(2)}_{\text{ap}} \); it is obtained from Eqs. (3,4) summing over all sites

\begin{align*}
\mathcal{D}_{\alpha\beta}(\vec{k}) &= \sum_{\vec{D}_j} \left[ \frac{1}{D_{ij}^{3+n}} \left[ 1 - 3(3+n) \frac{D_{ij}^2 D_{ij}^2}{D_{ij}^2} \right] e^{i\vec{k} \cdot \vec{D}_{ij}} \right]
\end{align*}

where for \( n = 0 \) and \( n = 2 \) one has respectively the zero and second order expressions in the ratio \( L/D_0 \) between the linear dimension of the particle and the interparticle distance. The spin-wave energy is

\begin{align*}
\epsilon_k &= \left[ (A_k - B_k)(A_k + B_k) \right]^{1/2}.
\end{align*}

In the continuum limit \( \vec{k} \to 0 \), one finds the approximate analytic expression

\begin{align*}
\epsilon_k &\approx \Omega S \left[ \left( \Delta_1(\phi) - \frac{4\pi k}{ab} + O(k^2) \right) \\
& \times \left( \Delta_0(\phi) + \frac{4\pi k}{ab} \cos^2 \theta_k + O(k^2) \right) \right]^{1/2}
\end{align*}

where \( \Delta_0 \) and \( \Delta_1 \), defined in Appendix C, depend on the angle \( \phi \). In particular, \( \Delta_0 \) vanishes for the highly symmetric cases \( \phi = \pi/3 \) (triangular lattice) and \( \phi = \pi/2 \) (square lattice). The angle \( \theta_k \) defines the orientation of the in-plane wavevector \( \vec{k} \) with respect to the \( \hat{x} \) axis.
It is worth stressing that $\epsilon_{\vec{k}}$ has the same structure both at zero and second order, because $H_{\text{dip}}^{(2)}$ does not contribute to the linear term in $k$. In particular, we have that the linear term in the quantity $(A_{\vec{k}} + B_{\vec{k}})$ vanishes when $\vec{k}$ is oriented along the magnetization ($\theta_{\vec{k}} = \pi/2$). Its sign is therefore decided by the quadratic term, which is different for different lattices. It is positive for the triangular lattice (see Fig. 4) and it may be either positive (Fig. 5b) or negative (Fig. 5a) for the square lattice, depending on the orientation of the magnetization.

In Figs. 4, 5 we show the dispersion relation of the spin waves, as obtained from Eq. (12), in the case of a triangular lattice ($\phi = \pi/3$) and of a square one ($\phi = \pi/2$), for different orientations $\theta_{\vec{k}}$.

In the remaining part of this Section we are making general comments on these results.

Dipolar interaction, since it couples the spins to the underlying lattice, is not rotationally invariant, contrary to, e.g., the Heisenberg interaction ($\mathcal{H} = -J \vec{s}_1 \cdot \vec{s}_2$). Therefore, the energy of a generic spin configuration depends on how the spins are oriented with respect to the lattice. However, lattices with four-fold ($\phi = \pi/2$) or six-fold ($\phi = \pi/3$) symmetries are special, in the sense that the energy of certain configurations (the ferromagnetic one, for example) is rotationally invariant. This means that the dipolar ferromagnetic ground state of a triangular lattice has a continuous degeneracy.

The coupling between spins and crystal lattice manifests itself in two ways (we are considering the highly symmetric cases, $\Delta_0(\phi) = 0$). First, the spin-wave energy $\epsilon_{\vec{k}}$ depends on the orientation of the wavevector in the continuum limit $\vec{k} \to 0$ as well. According to Eq. (13), $\epsilon_{\vec{k}} \sim |\cos \theta_{\vec{k}}| k^{1/2}$, showing that the $\theta_{\vec{k}}$-dependence of $\epsilon_{\vec{k}}$ is maintained in the limit $\vec{k} \to 0$.

Second, even if the energy of the FM state is degenerate with respect to its orientation in the plane, the spin-wave energy is not (see Fig. 5). This is true for the triangular lattice as well (not shown), but it has most striking consequences for the square lattice. In this case, the FM configuration is known to have a higher energy than the structure where spins are ferromagnetically coupled along lines and antiferromagnetically coupled between neighbouring lines. The FM state, if oriented along an axis of the square lattice (the typical configuration considered in the literature) is not even locally stable. This is clearly shown in Fig. 5a where the square of the spin-wave energy is plotted, in the case of $\vec{k}$ and $\vec{M}$ parallel to the $y$-axis and three different propagation directions are reported: (a) $\theta_{\vec{k}} = 0$; (b) $\theta_{\vec{k}} = \pi/6$; (c) $\theta_{\vec{k}} = \pi/2$. Note the different periodicities of the spin-wave energy.

![Fig. 4: Spin-wave dispersion curves calculated for the triangular lattice (rhombic angle $\phi = \pi/3$) both numerically (Eq. (12), symbols) and in the continuum limit (Eq. (13), lines). Solid circles and full lines refer to $H_{\text{dip}}^{(0)}$; open circles and dashed lines refer to $(H_{\text{dip}}^{(0)} + H_{\text{dip}}^{(2)})$, with $\mathcal{I} = 0.1$ (units with $D_0 = 1$ are used). The magnetization is assumed to lie along the $y$ axis and three different propagation directions are reported: (a) $\theta_{\vec{k}} = 0$; (b) $\theta_{\vec{k}} = \pi/6$; (c) $\theta_{\vec{k}} = \pi/2$. Note the different periodicities of the spin-wave energy.](image)
IV. THE CURIE TEMPERATURE

The Curie transition temperature of an orthorhombic lattice of particles with magnetization directed in plane along the \( \hat{\mathbf{y}} \) axis can be estimated in the framework of spin-wave theory. The relative deviation of the magnetization from the saturation value takes the formalism of the spin-wave theory. The relative deviation of the magnetization directed in plane along a side of the square lattice, the square of the spin-wave energy is found to be negative, signaling the instability of the ferromagnetic configuration. (b) When magnetization and wavevector \( \mathbf{k} \) are directed along the diagonal of the square, the ferromagnetic state is found to be metastable.

\[
\frac{\delta S}{S} \approx \frac{T}{W_{\text{eff}}} \int_0^{2\pi} d\theta \int_0^{q_M} \frac{dq}{c_1 q \cos^2 \theta + c_2 q^2} \]  (15)

where \( q = kD_0 \), \( \theta = \theta_0 \), and \( c_1 \) and \( c_2 \) are positive constants, and \( q_M \approx 1 \). The double integral can be easily evaluated, giving

\[
T_C \approx W_{\text{eff}} \cdot \frac{c_2}{2\pi} \left[ \ln \left( \frac{q_M + \sqrt{q_M^2 + (c_1/c_2)^2}}{c_1/c_2} \right) \right]^{-1} \]  (16)

In the limit \( c_1 = 0 \), \( \epsilon_k \approx c_2 q^2 \) reproduces the dispersion curve of the Heisenberg ferromagnet and the Curie temperature \( T_C \) vanishes, in agreement with the Mermin-Wagner theorem.

Finally, it is interesting to discuss the case where a uniaxial single-ion anisotropy \( \lambda \), favouring the in-plane \( \hat{\mathbf{y}} \) axis, is present in the system. The effect of the finite size of the particle is straightforward, in this case:

\[
E_{\text{ani}} = -\lambda N \sum_{\overline{D_i}} (s^y_i)^2 = -\tilde{\lambda} \sum_{\overline{D_i}} (S^y_i)^2 \]  (17)

where \( \tilde{\lambda} = \lambda / N \) and, as usual, \( \tilde{S} = N \hat{\mathbf{s}} \).

The effect of \( E_{\text{ani}} \) on the spin-wave energy is simply to add the quantity \( 2\lambda \) to \( A_k \); for large particles, this constant factor dominates the dipolar terms in Eq. (13). Because of that, spin-wave approximation is no more suitable and Eq. (14) can not be used to evaluate \( T_C \): in fact, it would give a Curie temperature \( T_C \approx 2N\lambda \), which diverges when \( \lambda \to \infty \).

On physical grounds, we expect that \( T_C \) is an increasing function of \( \lambda \), but in the limit of strong anisotropy, \( T_C \) is always of order \( W_{\text{eff}} \). An analogy can be done with the three-dimensional Heisenberg model in the presence of an easy-axis anisotropy \( \lambda \). \( T_C \) increases with \( \lambda \), but \( T_C(0) \) and \( T_C(\infty) \) are of the same order of magnitude and are both of order \( J \), the exchange coupling constant. In our case, \( W_{\text{eff}} \) replaces \( J \) and the dimension of the system is two instead of three (the two-dimensional Heisenberg model is not ordered at finite temperature in the absence of anisotropy).

In order to corroborate our argument, \( T_C \) will be calculated in the mean field approximation, starting from
the Hamiltonian
\[
\mathcal{H}^{MF} = \sum_{\vec{D}_i} \left[ \xi S_i^y - \tilde{\lambda}(S_i^y)^2 \right]
\]  
(18)
where \( \xi = \frac{1}{2}\Omega \langle S^y \rangle D_{yy}^{(0)}(0) \). The magnetization is given by
\[
\langle S^y \rangle = \frac{\sum_{M=-S}^{S} M e^{-\xi M - \tilde{\lambda} M^2 / T}}{\sum_{M=-S}^{S} e^{-\xi M - \tilde{\lambda} M^2 / T}}
\]
(19)
where \( M, M^2 \) denote the eigenstates of \( S^y \), \( (S^y)^2 \) respectively. As \( T \rightarrow T_C \) one has \( \langle S^y \rangle \rightarrow 0 \) so that \( \xi \rightarrow 0 \) and the exponential can be expanded. Thus \( \langle S^y \rangle \approx -\frac{\tilde{\lambda}}{T_C} R \)
where \( R \) is defined as
\[
R = \frac{\sum_{M=-S}^{S} M^2 e^{-\xi M^2 / T}}{\sum_{M=-S}^{S} e^{-\xi M^2 / T}} = \langle (S^y)^2 \rangle_{T_C}.
\]
(20)
For \( \tilde{\lambda} = 0 \) one has \( R = \frac{1}{2}S(S+1) \), so that \( T_C(\tilde{\lambda} = 0) = \frac{1}{2}\Omega[-D_{yy}^{(0)}(0)]S(S+1) \approx W_{\text{eff}} \).

For \( \tilde{\lambda} \neq 0 \) the mean field critical temperature is
\[
\frac{T_C(\tilde{\lambda})}{T_C(\lambda = 0)} = \frac{3}{2S(S+1)} \langle (S^y)^2 \rangle_{T_C},
\]
(21)
where the mean on the r.h.s. must be calculated numerically. Now we observe that in the limit \( \tilde{\lambda} \rightarrow \infty \), one has \( \langle (S^y)^2 \rangle_{T_C} \rightarrow S^2 \), so that the ratio \( T_C(\infty)/T_C(0) \) tends to the finite value \( 3S/(S+1) \). We conclude that for any value of \( \tilde{\lambda} \), the Curie transition temperature remains of the order of the effective dipolar interaction \( W_{\text{eff}} \), with a prefactor changing by a factor three as \( \tilde{\lambda} \) increases from 0 to \( \infty \).

V. DISCUSSION

Let us get back to the three questions formulated at the end of the Introduction.

i) What is the effective dipolar interaction between single domain particles?

In the hypothesis that spins are strongly coupled ferromagnetically inside each particle, it is straightforward to define an effective dipolar coupling between (microscopic) spins \( \vec{s} \) of two particles at distance \( D \): \( W_{\text{eff}} = \Omega(sN)^2/D^3 \), where \( \Omega = (g\mu_B)^2 \) and \( N \) is the number of spins in each particle. If \( L \) and \( t \) are respectively its linear size and thickness, \( W_{\text{eff}} \approx (g\mu_B s)^2(L/a_0)^4(t/c_0)^2/D^3 \). If a single-ion anisotropy \( \lambda \) is present, its effective value is just \( 3(3/2)\lambda_{\text{eff}} = \lambda N \approx \lambda(L/a_0)^2(t/c_0) \).

The full dipolar interaction between particles can be expanded in (even) powers of \( (L/D)^m \). The first correction term (\( m = 2 \)) gives an interaction decaying as \( 1/D^5 \) with the distance between particles. A couple of remarks are in order here. First, the ‘purely’ spin term in the dipolar interaction (i.e., the term not coupled to the lattice) is no more rotationally invariant: the z-components are more strongly coupled than in-plane components. Second, \( E^{(2)}_{\text{dip}} \) preserves two important features: it is minimized when spins are aligned ferromagnetically along the joining line, and the dipolar field generated by a ‘continuum’ line of spins aligned along the line in a point outside the line, vanishes.

ii) What is the dipolar ground state of an ordered array of magnetic particles?

We have considered the class of orthorhombic lattices, which comprises the triangular and the square lattices. It is known that in the case of a lattice of spins, the ground state for the six-fold symmetry is ferromagnetic and for the four-fold symmetry has zero net magnetization. These results are not modified when single-domain particles replace single spins and \( E^{(2)}_{\text{dip}} \) is considered in addition to \( E^{(0)}_{\text{dip}} \). The effect of \( E^{(2)}_{\text{dip}} \) is to reinforce, in some sense, the effect of \( E^{(0)}_{\text{dip}} \). In particular, therefore, a triangular lattice of two dimensional particles interacting through the dipolar interaction has a ferromagnetic ground state.

iii) What is the finite temperature behaviour of a in-plane ferromagnetically ordered array of particles?

In two dimensional systems, long range order at finite temperature is not certain: however, the long range dipolar forces are known to grant it. In this respect, \( E^{(2)}_{\text{dip}} \) is of minor importance, because it decays as \( 1/D^5 \) and consequently the dipolar sums in the \( \vec{k} \)-space do not contribute to the terms linear in \( \vec{k} \), but to the quadratic terms only.

In the absence of anisotropies, it is elementary that the Curie temperature \( T_C \) is of order of the effective dipolar coupling, \( T_C \approx W_{\text{eff}} \), because it is the only energy scale in the problem. If in-plane easy-axis anisotropies are present, we have shown that \( T_C \) is expected to increase, but not to change in order of magnitude: according to mean field theory, \( T_C \) increases by a factor three passing from the ‘weak’ anisotropy regime into the ‘strong’ anisotropy regime.

Denoting by \( w = (g\mu_B s)^2/a_0^3 \) the dipolar coupling between microscopic spins on a two-dimensional lattice with atomic distance \( a_0 \), the effective dipolar interaction between particles of linear dimension \( L \) and thickness \( t \) at distance \( D_0 \) can be rewritten as \( W_{\text{eff}} = w(L/a_0)^4(t/c_0)^2/(D_0/a_0)^3 \). Thus, the Curie temperature \( T_C \approx W_{\text{eff}} \) of an ensemble of magnetic particles may be significantly larger than the Curie temperature of a two-dimensional lattice of microscopic spins, which is of order \( w \). However, \( L \) cannot be made larger than \( D_0 \), because \( D_0 \) scales with \( L \); at the best, therefore, \( T_C \approx w(L/a_0)^4(t/c_0)^2 \).

Even if we have no definite evaluation of the numerical prefactor appearing in the previous estimate for \( T_C \), we suggest that regular arrays of two-dimensional particles magnetized in plane might sustain long range order at experimentally relevant temperatures (see also Ref. [4]). However, this collective phenomenon may be masked by
the superparamagnetic behaviour of the single particle, appearing below the blocking temperature $T_B \approx \lambda a = \lambda (L/a_0)^2 (t/a_0)$.

The condition $T_B > T_C$ is equivalent to $\lambda/w > \eta L^2 t/D_0^3$, where $\eta$ is an unknown numerical factor. If such a condition is satisfied, the Curie phase transition at $T = T_C$ is not visible because thermodynamic equilibrium cannot be attained below $T_B$. So, if we decrease temperature from the high-$T$ region each particle becomes superparamagnetic when dipolar forces are still unable to induce a long range order in the system. When $T = T_C$ dipolar interaction comes into play, but the magnetization of each particle is frozen and the system is unable to attain equilibrium. In the opposite case, $T_C > T_B$, a phase transition at $T_C$ should be visible.

Recently, the system Co/Cu(001) has drawn the attention because it has been suggested that for $t < 1.8$ ML (ML=monolayer) this system displays a dipolar induced ferromagnetic order. $T_C(t)$ is seen to be finite and increase from $T_C(1$ML$)=25$K to $T_C(1.8$ML$)=200$K, where it has a sudden jump, attributed to the percolation in the second layer.

The growth morphology of the system Co/Cu(001) is complicated by the alloying of the two elements, which mainly takes place in the first layer (75% in Co, 25% in Cu). However, with such a high percentage of Cobalt, it is hard to suppose that the first layer of deposition and diffusion gives rise to a non-uniform distribution of sizes and positions. This fact, along with frustration due to dipolar interaction, makes difficult even the determination of the ground state, because the system has a glassy behaviour with a lot of metastable states.

**APPENDIX A: MULTIPOLAR EXPANSION OF INTERPARTICLE INTERACTION**

We start from Eq. (4), assuming single monolayers. Summations on $\vec{R}_{12}$ are replaced by sums on $\vec{r}_{12}$ (see Fig. 1 for notations):

$$E_{\text{dip}} = \frac{1}{2} D^5 \sum_{1}^{2} \sum_{1}^{2} \left[ \frac{\hat{s}_1 \cdot \hat{s}_2}{R_{12}^3} - 3 \frac{(\hat{s}_1 \cdot \vec{R}_{12})(\hat{s}_2 \cdot \vec{R}_{12})}{R_{12}^7} \right]$$

We make the expansions:

$$\frac{1}{R_{12}^7} \approx \frac{1}{D^7} \left[ 1 - 3 \frac{r \cdot \vec{D}}{D^2} - 3 \frac{r^2}{2 D^2} + \frac{15 (r \cdot \vec{D})^2}{2 D^4} \right]$$

(A1)

(A2)

The following expressions are easily calculated:

$$\sum_{\vec{r}_1} 1 = N_1, \sum_{\vec{r}_2} 1 = N_2$$

$$\sum_{\vec{r}_1} \sum_{\vec{r}_2} r = N_1 N_2 (\langle \vec{r}_2 \rangle - \langle \vec{r}_1 \rangle)$$

$$\sum_{\vec{r}_1} \sum_{\vec{r}_2} r^2 = N_1 N_2 (\langle \vec{r}_2^2 \rangle + \langle \vec{r}_1^2 \rangle - 2 \langle \vec{r}_1 \rangle \cdot \langle \vec{r}_2 \rangle)$$

$$\sum_{\vec{r}_1} \sum_{\vec{r}_2} (\vec{V}_1 \cdot \vec{r})(\vec{V}_2 \cdot \vec{r}) = N_1 N_2 (\langle (\vec{V}_1 \cdot \vec{r}_1)(\vec{V}_2 \cdot \vec{r}_1) \rangle$$

$$+ (\langle \vec{V}_1 \cdot \vec{r}_2)(\vec{V}_2 \cdot \vec{r}_2 \rangle - \langle \vec{V}_1 \cdot \vec{r}_1 \rangle = \langle \vec{V}_2 \cdot \vec{r}_1 \rangle$$

$$- (\vec{V}_1 \cdot \langle \vec{r}_1 \rangle)(\vec{V}_2 \cdot \langle \vec{r}_2 \rangle)$$

The following expression for the effective dipolar interac-
tion between two particles at distance $\vec{D}$:

$$E_{\text{dup}} = \frac{1}{2} \Omega \frac{\vec{S}_1^2 \cdot \vec{S}_2^2}{D^3} \left( 1 + \frac{9 T_{12}}{2 D^2} \right) \quad (A6)$$

$$+ \frac{1}{2} \Omega \frac{\vec{S}_1^2 \cdot \vec{S}_3^2}{D^3} \left( 1 + \frac{3 T_{12}}{2 D^2} \right) \quad (A7)$$

$$- \frac{3}{2} \Omega \left( \frac{\vec{S}_1^2 \cdot \vec{D}}{D^5} \right) \left( 1 + \frac{5 T_{12}}{2 D^2} \right) \quad (A8)$$

**APPENDIX B: MINIMIZATION OF THE DIPOLAR COUPLING BETWEEN TWO SPINS**

Let us consider two unitary spins $\vec{S}_1, \vec{S}_2$ located at a distance $R_{12}$ along the in-plane $\hat{x}$ axis, taken as the polar axis, while the $\hat{z}$ axis is perpendicular to the plane. Their orientations are defined by the polar and azimuthal angles $\theta_1, \phi_1$.

The dipolar coupling can be generally written as

$$E_{12} \approx E_{12}^{(0)} + E_{12}^{(2)}$$

$$\approx \tilde{\Omega}_0 (\vec{S}_1 \cdot \vec{S}_2 - 3 \vec{S}_1^2 \vec{S}_2^2)$$

$$+ \tilde{\Omega}_2 (2 \vec{S}_1^2 \vec{S}_2^2 + \vec{S}_1 \cdot \vec{S}_2 - 5 \vec{S}_1^2 \vec{S}_2^2)$$

where $\tilde{\Omega}_0 = \frac{1}{2} \Omega S^2 / R_{12}^3$ and $\tilde{\Omega}_2 = \frac{4}{3} \Omega_{12} S^2 / R_{12}^5$ (see Eqs. [3]).

Both terms $E_{12}^{(0)}$ and $E_{12}^{(2)}$ are minimized by the same configuration. First, let us treat the zero-order term. We have to minimize the function

$$E_{12}^{(0)} / \tilde{\Omega}_0 = \sin \theta_1 \sin \theta_2 \cos (\phi_1 - \phi_2) - 2 \cos \theta_1 \cos \theta_2 \quad (B1)$$

By taking the derivatives with respect to $\phi_{1,2}$ we find that $(\phi_1 - \phi_2) = 0, \pi$ or that one $\theta_i$ at least must vanish. If, e.g., $\theta_1 = 0$, it is straightforward to derive that $\theta_2 = 0$ as well. If both $\theta_1, \theta_2$ are not vanishing, taking the derivatives with respect to them implies cos $\theta_1 = \cos \theta_2 = 0$, i.e. $\theta_1, \theta_2 = \frac{\pi}{2}$. In simple words, it is sufficient to consider two kinds of configurations: i) the configuration where both spins are perpendicular to the joining vector and they are parallel or antiparallel; ii) the configuration where both spins are aligned along the joining vector. The former configuration, with antiparallel spins, corresponds to the minimization of $(\vec{S}_1 \cdot \vec{S}_2)$ and its energy is $-\tilde{\Omega}_0$. The latter configuration, with parallel spins, corresponds to the minimization of $(-3 \vec{S}_1^2 \vec{S}_2^2)$ and its energy is $\tilde{\Omega}_0 - 3\tilde{\Omega}_0 = -2\tilde{\Omega}_0$. We conclude that $E_{12}^{(0)}$ is minimized by the ferromagnetic configuration with spins aligned along their joining vector.

The minimization of $E_{12}^{(2)}$ proceeds along the same lines, with the minor difference that configurations with both spins perpendicular to the joining line are no more degenerate with respect to a global rotation around the $\hat{x}$ axis: the lowest energy one corresponds to antiparallel spins along the $\hat{x}$ direction and its energy is $-3\tilde{\Omega}_2$. On the other hand, the ferromagnetic configuration with both spins parallel to the $\hat{x}$ axis has the energy $-4\tilde{\Omega}_2$, so the conclusion is unchanged.

**APPENDIX C: DIPOLAR SUMS FOR THE ORTHOROMBIC LATTICE**

For spins ferromagnetically oriented along the $y$ axis, the coefficients of the spin-wave Hamiltonian in Eq. [10] take the form

$$A_k^{(0)} / \Omega S = \frac{1}{2} D_{zz}^{(0)} (\vec{k}) + \frac{1}{4} (\tilde{D}_{yy}^{(0)} (\vec{k}) - \tilde{D}_{yy}^{(0)} (0))$$

$$B_k^{(0)} / \Omega S = \frac{1}{2} D_{zz}^{(0)} (\vec{k}) - \frac{1}{2} D_{xx}^{(0)} (\vec{k}) + i D_{xx}^{(0)} (\vec{k})$$

$$+ \frac{1}{2} \Omega (\vec{k}) + \frac{1}{2} \Omega (\vec{k}) + i \Omega (\vec{k})$$

where $N$ is the number of spins in each particle and the dipolar sums are defined as $(\alpha, \beta = x, y, z)$

$$D_{\alpha\beta}^{(n)} (\vec{k}) = \sum_{\vec{D}_i} \frac{1}{D_{ij}^{n+1}} \left[ 1 - (3 + n) \frac{D_{ij}^{2} D_{ij}^{2}}{D_{ij}^{2}} \right] e^{i \vec{k} \cdot \vec{D}_i} \quad (C1)$$

$$X^{(n)} (\vec{k}) = \sum_{\vec{D}_i} \frac{e^{i \vec{k} \cdot \vec{D}_i}}{D_{ij}^{n+1}} \quad (C2)$$

We observe that in the ultraflat particle limit, one has $X^{(n)} (\vec{k}) \approx D_{zz}^{(n)} (\vec{k})$ and $D_{zz}^{(n)} (\vec{k}) \approx 0$ and $D_{\alpha\alpha}$’s can be approximately expressed

$$D_{xx}^{(n)} (\vec{k}) \approx Y^{(n)} (\vec{k}) - (2 + n) X^{(n)} (\vec{k})$$

$$D_{yy}^{(n)} (\vec{k}) \approx X^{(n)} (\vec{k}) - (2 + n) Y^{(n)} (\vec{k})$$

$$D_{zz}^{(n)} (\vec{k}) \approx X^{(n)} (\vec{k}) + Y^{(n)} (\vec{k})$$

in terms of the dipolar sums

$$X^{(n)} (\vec{k}) = \sum_{\vec{D}_i} \frac{(D_{ij}^{2})^2}{D_{ij}^{2n+1}} e^{i \vec{k} \cdot \vec{D}_i} \quad (C3)$$

$$Y^{(n)} (\vec{k}) = \sum_{\vec{D}_i} \frac{(D_{ij}^{2})^2}{D_{ij}^{2n+1}} e^{i \vec{k} \cdot \vec{D}_i} \quad (C4)$$

The latter sums can be numerically calculated in a very efficient way following a method, developed some years ago by Benson and Mills, similar to Ewald’s one for the evaluation of lattice sums. For $n = 0$ one has

$$X^{(0)} (k_x, k_y; a, b) = U^{(0)} (k_x, k_y) + V^{(0)} (k_x, k_y)$$

(C6)
where \(U\) is a summation over the sites of the orthorombic lattice which are located at integer multiples of \(a\) and \(b\)

\[
U^{(0)}(k_x, k_y) = \frac{16}{3} \sum_{l=1}^{+\infty} \cos(k_x a l) \frac{\pi m}{b} + \frac{k_y}{2} y^2 K_2 \left[ 2a(l + \frac{1}{2}) \frac{\pi m}{b} + \frac{k_y}{2} \right]
\]

while \(V\) refers to semi-integer multiples

\[
V^{(0)}(k_x, k_y) = \frac{16}{3} \sum_{l=0}^{+\infty} \cos \left[ k_x a(l + \frac{1}{2}) \right] \left( \frac{\pi m}{b} + \frac{k_y}{2} \right)
\]

For \(n = 2\) one has

\[
X^{(2)}(k_x, k_y; a, b) = U^{(2)}(k_x, k_y) + V^{(2)}(k_x, k_y) \quad (C7)
\]

where

\[
U^{(2)}(k_x, k_y) = \frac{32}{15} ab \sum_{l=1}^{+\infty} \cos(k_x a l) \frac{\pi m}{b} + \frac{k_y}{2} y^3 K_3 \left[ 2a(l + \frac{1}{2}) \frac{\pi m}{b} + \frac{k_y}{2} \right]
\]

and

\[
V^{(2)}(k_x, k_y) = \frac{32}{15} ab \sum_{l=0}^{+\infty} \cos \left[ k_x a(l + \frac{1}{2}) \right] \left( \frac{\pi m}{b} + \frac{k_y}{2} \right)
\]

Here above, \(K_2(z)\) and \(K_3(z)\) are the modified Bessel functions of second and third order, respectively. By symmetry reasons, one has

\[
Y^{(n)}(k_x, k_y; a, b) = X^{(n)}(k_y, k_x; b, a) \quad (C8)
\]

Finally, in the continuum limit \(\hat{k} \to 0\), one can obtain analytical expressions for the dipolar sums. Denoting by \(\hat{k}\) the modulus of the two-dimensional wavevector \(\hat{k} = (k_x, k_y)\) and by \(\theta_k\) the angle that \(\hat{k}\) forms with the \(x\) axis, we obtain

\[
X^{(0)}(k) \approx X^{(0)}(0) - \frac{2\pi}{ab} k \left[ 1 + \frac{1}{3} \cos(2\theta_k) \right]
\]

\[
Y^{(0)}(k) \approx Y^{(0)}(0) - \frac{2\pi}{ab} k \left[ 1 - \frac{1}{3} \cos(2\theta_k) \right] \quad (C9)
\]

and

\[
X^{(2)}(k) \approx X^{(2)}(0) + O(k^2)
\]

\[
Y^{(2)}(k) \approx Y^{(2)}(0) + O(k^2) \quad (C10)
\]

where for the triangular lattice one has \(X^{(0)}(0) = 5.5170879/D_0^3\), \(X^{(2)}(0) = 3.3809493/D_0^3\) and for the square lattice \(X^{(0)}(0) = 4.5168109/D_0^3\), \(X^{(2)}(0) = 2.5451291/D_0^3\). From the previous expressions one obtains approximate expansions for the quantities in Eqs. (12,14):

\[
\frac{A_E - B_E}{\Omega S} \approx \frac{\Delta_0}{\pi k} \cos^2 \theta_k + O(k^2)
\]

\[
\frac{A_E + B_E}{\Omega S} \approx \frac{\Delta_1}{\pi k} + O(k^2)
\]

\[
\frac{A_E}{\Omega S} \approx \frac{\Delta_2}{\pi k} \sin^2 \theta_k + O(k^2) \quad (C11)
\]

where

\[
\Delta_0 = 3 \left[ Y^{(0)}(0) - X^{(0)}(0) \right] + \frac{15}{2} \left[ Y^{(2)}(0) - X^{(2)}(0) \right]
\]

\[
\Delta_1 = 3 \left[ Y^{(0)}(0) + \frac{3}{2} \left[ 4 Y^{(2)}(0) - 2 X^{(2)}(0) \right] \right]
\]

\[
\Delta_2 = \frac{3}{2} \left[ 2 Y^{(0)}(0) - X^{(0)}(0) \right] + \frac{9}{4} \left[ 4 Y^{(2)}(0) - X^{(2)}(0) \right] \quad (C12)
\]

Hence we observe that for a generic orthorombic lattice one has \(X^{(n)}(0) \neq Y^{(n)}(0)\), so that the dispersion curve \(\epsilon_k = \left[ (A_E - B_E)(A_E + B_E) \right]^{1/2}\) presents a gap for \(\hat{k} \to 0\). For the special cases of the triangular and the square lattice one has \(X^{(n)}(0) = Y^{(n)}(0)\) by symmetry reasons; this implies that \(\Delta_0 = 0\), so that a Goldstone mode is present in the dispersion curve: \(\epsilon_k \to 0\) for \(\hat{k} \to 0\).
