Plasmonics has attracted tremendous interests for its ability to confine light into subwavelength dimensions, creating novel devices with unprecedented functionalities. New plasmonic materials are actively being searched, especially those with tunable plasmons and low loss in the visible-ultraviolet range. Such plasmons commonly occur in metals, but many metals have high plasmonic loss in the optical range, a main issue in current plasmonic research. Here, we discover an anomalous form of tunable correlated plasmons in a Mott-like insulating oxide from the Sr₃₋ₓNb₁₋ₓO₃₊δ family. These correlated plasmons have multiple plasmon frequencies and low loss in the visible-ultraviolet range. Supported by theoretical calculations, these plasmons arise from the nanometre-spaced confinement of extra oxygen planes that enhances the unscreened Coulomb interactions among charges. The correlated plasmons are tunable: they diminish as extra oxygen plane density or film thickness decreases. Our results open a path for plasmonics research in previously untapped insulating and strongly-correlated materials.
Plasmonics offers a crossroad between photonics and nanoelectronics by combining the former’s high-bandwidth capability with the latter’s nanoscale integrability. Plasmonics utilizes plasmon, a collective excitation of charges that arises from interactions between electromagnetic fields (such as photons) and free charges. Conventionally, the plasmon frequency depends on the free-charge density; thus, high-frequency plasmons are usually found in metals due to their abundance of free charges, but are rarely observed in conventional wide bandgap insulators.

In strongly-correlated materials, conventional forms of plasmons have been observed in the metallic or superconducting phases of these materials, and there have been studies to explore their potential for plasmonics in vanadium oxides and cuprates. In particular, localized conventional surface plasmons have been observed in the metallic phase of VO₂, and its temperature-dependent metal–insulator transition has been utilized for plasmonic switching and sensing. However, in strongly-correlated, insulating phases of these materials (such as in Mott insulators), correlated forms of plasmons under long-range Coulomb interactions have only been theoretically investigated but not experimentally observed.

Meanwhile, the Sr₁₋ₓNb₁₋ₓO₃₋₅ family of oxides are known to have rich structures and electronic properties that vary with oxygen content. For example, perovskite SrNbO₃ is conducting with an Nb-4d electronic structure, and Sr₁₋ₓNbO₃ (ref. 14) has been found to potentially be a good photocatalyst in water splitting applications. On the other hand, oxygen-rich SrNbO₃₄ and SrNbO₃₅, derived by interspersing the perovskite lattice of SrNbO₃ with extra oxygen planes along the [101] direction at certain periodic intervals, are a quasi-one-dimensional conductor and a ferroelectric insulator, respectively. Previously, there are no reported studies on plasmons in this family of oxides.

In this study, several Sr₁₋ₓNb₁₋ₓO₃₋₅ films with varying oxygen content, electrical conductivity (from metallic to insulator-like) and film thicknesses are studied using spectroscopic ellipsometry, transport measurements and supported by theoretical calculations based on coupled harmonic oscillators model and density functional theory. The results show a surprising observation of a new form of correlated plasmons in the insulator-like film, itself also revealed to be a strongly-correlated Mott-like insulator. The correlated plasmons usually have multiple plasmon frequencies (~1.7, ~3.0 and ~4.0 eV) and low loss (several times lower than gold) in the visible–ultraviolet range. Supported by theoretical calculations, these correlated plasmons arise from collective excitations of correlated electrons in the film, where the nanometer-spaced confinement of extra oxygen planes causes increased Coulomb repulsions among the electrons. The correlated plasmons are reproducible and tunable: they diminish and ultimately vanish as extra oxygen plane density or film thickness decreases. In particular, the decrease of extra oxygen plane density increases the electrical conductivity, and, as correlated plasmons are vanishing in the metallic films, the increased free-charge density causes conventional plasmon to arise at ~1.9 eV.

**Results**

**Transport measurements results.** The main batch of pressure-dependent Sr₁₋ₓNb₂O₃₋₅ films is deposited on (001)LaAlO₃ substrates using pulsed-laser deposition under three oxygen pressure conditions: 5 × 10⁻⁶, 3 × 10⁻⁵ and 1 × 10⁻⁴ Torr, labelled as lp-SNO, mp-SNO and hp-SNO, respectively. Transport measurements reveal that lp-SNO and mp-SNO are metallic with room-temperature resistivity of 1 × 10⁻⁴ and 6 × 10⁻³ Ω cm, respectively, while hp-SNO is insulator-like with room-temperature resistivity of 6Ω cm. The conducting lp-SNO have an unusually large room-temperature free-charge density of ~1 × 10²⁶ cm⁻³, while for mp-SNO it is ~4 × 10²⁵ cm⁻³. The room-temperature mobility of the conducting films is ~2.5 cm²V⁻¹s⁻¹ for lp-SNO and ~0.3 cm²V⁻¹s⁻¹ for mp-SNO. The thickness of the three main films is ~196, ~218 and ~168 nm for lp-SNO, mp-SNO and hp-SNO, respectively. For thickness-dependent study, thinner hp-SNO films with varying thicknesses of ~81, ~52 and ~20 nm are also deposited. For reproducibility, a second batch of pressure-dependent films is deposited as well under six oxygen pressure conditions: 5 × 10⁻⁶ Torr (lp-SNO-2), 1 × 10⁻³ Torr (mp-SNO-2), 3 × 10⁻⁴ Torr (mp-SNO-2), 7 × 10⁻⁵ Torr (mp-SNO-2), 1 × 10⁻⁴ Torr (hp-SNO-2) and 5 × 10⁻⁴ (hp-SNO-2). The lp-SNO-2, mp-SNO-2, mp-SNO-2 and mp-SNO-2 films are conducting, while the hp-SNO-2 and hp-SNO-2 films are insulating, and their thicknesses are kept to be within a narrow range of ~159–182 nm (see Supplementary Table 1 for details).

**Complex dielectric function and loss function.** Figure 1 shows the complex dielectric function, \( \varepsilon(\omega) = \varepsilon_1(\omega) + i \varepsilon_2(\omega) \), and loss function (LF), \( -\text{Im}[\varepsilon(\omega)] = \frac{\varepsilon_2(\omega)}{\varepsilon_1(\omega) + \varepsilon_2(\omega)} \), of the pressure-dependent Sr₁₋ₓNb₂O₃₋₅ films extracted from SE, where \( \omega \) is the photon angular frequency (see Supplementary Figs 2–5 for details). Each peak in the transverse \( \varepsilon(\omega) \) spectra indicates an optical excitation, while each peak in the longitudinal LF spectra indicates a plasmonic excitation. For sub-X-ray photons, the photon momentum transfer, \( q \), is finite but approaches zero because it is much less than the crystal momentum. In this limit, the distinction between longitudinal (l) and transverse (t) \( \varepsilon(\omega) \) vanishes, that is, \( \lim_{\omega \to 0} \varepsilon(l, \omega) = \varepsilon(t, \omega) \), which allows sub-X-ray optical spectroscopy to probe both optical and plasmonic properties of materials in the low-q limit. All of the optical and plasmonic peaks are listed in Table 1. It should be noted that longitudinal LF spectra is also the quantity probed by electron energy loss spectroscopy, which is another common technique used in the study of plasmonic properties of materials. However, as hp-SNO is insulator-like, such photoemission-based spectroscopy measurements might be challenging for hp-SNO due to significant charging effects.

The \( \varepsilon_2(\omega) \) of lp-SNO (Fig. 1b) shows an intraband Drude peak (\( A_1 \)) and the first interband transition peak (\( A_2 \) and \( A_3 \), > 4.6 eV), which has been attributed as O-2⁻ → Nb-4d transition. (Note that in the cited studies, the theoretical bandgap between O-2p and Nb-4d calculated using density functional theory was underestimated. Nevertheless, the \( A_2 \) peak from ~4.6 eV should still be regarded as originated from O-2p → Nb-4d transition because it is the lowest-energy interband transition in lp-SNO.) The LF of lp-SNO (Fig. 1b) shows a large peak (\( A'_1 \), ~1.9 eV), which coincides with the zero-crossing of \( \varepsilon_2(\omega) \) at ~1.84 eV (Fig. 1a) and is very close to the reflectivity minimum at ~2.1 eV (Supplementary Fig. 6), indicating that the peak comes from a conventional plasmon excitation. There is a slight blueshift between the \( A'_1 \) peak and the \( \varepsilon_2(\omega) \) zero-crossing due to the free-electron scattering. Consequently, from this blueshift along with the full-width half-maximum (FWHM) of the \( A'_1 \) peak (see equations 5 and 6), we can estimate the free-electron scattering, \( 1/\tau \), in lp-SNO to be ~0.47 eV and its conventional plasmon dephasing time, \( T_2 \), to be ~2.8 fs.
An important observation is shown in the $\varepsilon_2(\omega)$ and LF spectra of hp-SNO (Fig. 1d). The $\varepsilon_2(\omega)$ shows that hp-SNO has no apparent Drude peak, consistent with transport measurement, with a wide bandgap of $\sim 4.6$ eV ($C_5$ and $C_6$). Interestingly, below this bandgap there exist several mid-gap peaks at $\sim 1.7$ ($C_1$), $\sim 3.0$ ($C_2$), $\sim 4.0$ ($C_3$) and $\sim 4.5$ eV ($C_4$) with low overall $\varepsilon_2(\omega)$ (< 1 for $C_1$ and $C_2$). Particularly, $C_1$, $C_2$ and $C_3$ peaks share very similar shapes and energy positions with another group of three peaks in the LF spectrum: $C'_1$, $C'_2$ and $C'_3$, respectively (just like the similarities between $B_2$ and $B'_2$ peaks of mp-SNO). The energy positions of both group of peaks are also very close to the reflectivity minima of hp-SNO (Supplementary Fig. 6) at $\sim 1.9$, $\sim 3.2$ and $\sim 4.2$ eV. These indicate that the two groups of peaks come from a similar origin. The appearance of these mid-gap peaks in the LF spectrum indicates that they arise from plasmonic excitations and not from other effects such as spin–orbit coupling, phononic, excitonic or anisotropic effects (see Supplementary Note 2). Meanwhile, their concurrent existence in $\varepsilon_2(\omega)$ spectrum indicates that there is a coupling between optical and plasmonic excitations in hp-SNO (and to a lesser extent, in mp-SNO). As discussed later, these mid-gap plasmonic excitations are born from collective excitations of correlated electrons, and are thus called correlated plasmons.

As a first approximation, the dephasing time of these correlated plasmons may be estimated from FWHM of each peak. The FWHM of $C'_1$, $C'_2$, and $C'_3$ peaks is $\sim 0.7$, $\sim 0.68$ and $\sim 0.38$ eV, respectively. This leads to the dephasing time of $\sim 1.9$, $\sim 1.9$ and $\sim 3.5$ fs, respectively. We note that the scattering and dephasing mechanisms in correlated systems might be different from those in weakly correlated metals due to long-range correlation effects, as discussed later.

Meanwhile, the $C_3$ peak may be excitonic in origin due to its relative sharpness, asymmetric shape and energy position that is just below the bandgap. This peak diminishes as free-charge density increases in conducting mp-SNO (see the similar $B_2$ peak in mp-SNO), and ultimately vanishes in lp-SNO. If this peak is indeed excitonic, its presence in hp-SNO indicates that electron–hole interactions are unscreened in the insulating hp-SNO film, while its diminishing behaviour in mp-SNO and lp-SNO indicates that electron–hole interactions are heavily screened in the conducting films.

**Figure 1 | Complex dielectric function and loss function spectra of pressure-dependent Sr$_2$NbO$_3$$_2$S$_2$ films.** (a) Real part of complex dielectric function, $\varepsilon_1(\omega)$, of lp-SNO (5 x 10$^{-6}$ Torr), mp-SNO (3 x 10$^{-5}$ Torr) and hp-SNO (1 x 10$^{-4}$ Torr) films. Vertical dashed lines indicate the zero-crossings of $\varepsilon_2(\omega)$ of lp-SNO (red) and mp-SNO (purple) films. (b) Imaginary part of complex dielectric function, $\varepsilon_2(\omega)$, and loss function, $\text{Im}[\varepsilon(\omega)]$, spectra of lp-SNO film. (c) The $\varepsilon_2(\omega)$ and $\text{Im}[\varepsilon(\omega)]$ spectra of mp-SNO film. (d) The $\varepsilon_2(\omega)$ and $\text{Im}[\varepsilon(\omega)]$ spectra of hp-SNO film. Insets show parts of the spectra zoomed in for clarity.

**Differences between correlated and conventional plasmons.** The correlated plasmons of hp-SNO are fundamentally different from conventional (bulk) plasmon in lp-SNO, conventional metals such as gold and the metallic phases of strongly correlated materials such as metallic VO$_2$ (refs 6–8) for the following reasons. First, since hp-SNO is insulator-like, the correlated plasmons do not originate from collective excitations of free charges. In fact, as free-charge density increases in mp-SNO, the correlated plasmons instead become weaker and ultimately vanish in lp-SNO. Second, in lp-SNO and gold the $\varepsilon_2(\omega)$ is negative below the conventional plasmon energy and conventional plasmons occur at the zero-crossing of $\varepsilon_2(\omega)$ (albeit with slight blue-shifts due to the free-electron scattering), while the $\varepsilon_2(\omega)$ of hp-SNO stays positive below the correlated plasmon energies. Third, conventional plasmons in lp-SNO and gold usually only have one (bulk) plasmon energy, while hp-SNO has at least three observable correlated plasmon energies with a seemingly ordered energy ratio. This is somewhat similar to a previous theoretical result where the presence of long-range Coulomb interaction in correlated systems could induce multiple correlated plasmon energies to appear. These theoretical plasmon energies also had an ordered ratio of $U^*$ and $U^*/2$, where $U^*$ was the effective local Coulomb interaction, although the energy ratio...
of the observed correlated plasmons of hp-SNO is not as straightforward to deduce (see Supplementary Note 3 for details). Fourth, the correlated plasmons appear in both $\varepsilon_2(\omega)$ and LF spectra of hp-SNO, which means that the correlated plasmons can readily be excited by, decay radiatively into and thus couple with free-space photons without any external mechanisms. This is unlike conventional surface plasmon resonance in metals, which needs external phase-matching mechanisms such as grating, Otto and Kretschmann configurations$^{3,27,28}$ to couple the plasmons with free-space photons. Intriguingly, the $\varepsilon_2(\omega)$ of hp-SNO below its bandgap is several times (for example, ~6 times at 3.0 eV) lower than that of gold$^{3,5,26}$, which means the correlated plasmons have low loss in the optical visible–ultraviolet range. To explain these differences, we further study the optical conductivity ($\sigma_1(\omega) = \varepsilon_1(\omega)\varepsilon_0$), spectral weight transfer and atomic structure of the films.

Optical conductivity and spectral weight analysis. The $\sigma_1(\omega)$ analysis (Fig. 2a) is important because it obeys the f-sum (charge conservation) rule$^{24,29,30}$: $\int_0^\infty \sigma_1(\omega)d\omega = \frac{nMe}{2\hbar}$. Where $n$, $e$ and $M_e$ is the total electron density, elementary charge and electron mass, respectively. From this rule, a partial spectral weight integral of an energy region (for example, from $E_i$ to $E_f$) can be defined as $W = \int_{E_i}^{E_f} \sigma_1(E)dE$. The W is proportional to the effective number of electrons participating in the optical excitations, which means by analysing the evolution of W we can identify the various charge transfers that occur in the films and gauge their electronic correlations$^{11,24,30–35}$. For this purpose, the $\sigma_1(\omega)$ are divided into three energy regions: $W_1$ for the Drude peak (0.6–2.0 eV), $W_2$ for the mid-gap plasmonic peaks (2.0–4.3 eV) and $W_3$ for the first interband transition of O-2p → Nb-4d (4.3–6.5 eV). The evolution of each W across the three films is shown in Fig. 2b (see also Supplementary Fig. 7 for more details).

As free-charge density decreases from lp-SNO to mp-SNO, the decrease of $W_1$ (Drude region) is accompanied by an increase of $W_2$. This can be understood because the decreased number of electrons in the conduction band (Nb-4d) increases the available unoccupied states necessary for the first interband transition of O-2p → Nb-4d. Thus, as free-charge density further decreases and ultimately vanishes during a transition from metal to insulator, the diminishing of Drude peak is expected to be accompanied by a further increase of $W_1$. Surprisingly, Fig. 2 shows this is not the case for the metal–insulator transition (MIT) between mp-SNO and hp-SNO, because instead $W_1$ and $W_2$ both anomalously decrease as MIT occurs, leading to an overall decrease of W below 6.5 eV ($W_{tot}$). According to the f-sum rule$^{24,29,30}$ and because hp-SNO is insulator-like with no apparent Drude peak, this decrease has to be compensated by an equivalent increase of $W_{tot}$ above 6.5 eV, implying spectral weight transfers over wide energy ranges on the onset of the MIT. Such wide-range anomalous spectral weight transfers are a direct evidence of strong electronic correlations$^{11,24,30–35}$ and has also been observed in other strongly-correlated materials such as cuprates$^{11,30,33}$, vanadium oxides$^{34}$ and manganese$^{11,30,35}$. This anomalous spectral weight transfer behaviour signifies that hp-SNO is most likely a Mott-like insulator and the MIT occurs as the Coulomb repulsion between electrons becomes stronger (that is, unscreened) and electronic correlation increases. This also means that the plasmons in hp-SNO are a new type of correlated plasmons born from collective excitations of correlated electrons.

Transmission electron microscopy. The three films are also studied using TEM to determine their microstructures. Atomic resolution z-contrast scanning TEM images of lp-SNO, mp-SNO and hp-SNO are shown in Fig. 3a–c. The global arrangement of the atomic structure of lp-SNO (Fig. 3a) exhibits a long-range perovskite structure$^{13}$, whereas those of mp-SNO and lp-SNO

| Table 1 | Optical and plasmonic excitations in pressure-dependent Sr1−xNbO3−δ films. |
|---|---|
| Optical (ε(ω)) | Plasmonic (loss function) |
| Peak | Energy (eV) | Peak | Energy (eV) |
| lp-SNO | | | |
| $A_1$ | 0 | $A'_1$ | ~1.9 |
| $A_2$ | ~4.6–~5.3 |  |  |
| $A_3$ | ~5.3–~6.5 |  |  |
| mp-SNO | | | |
| $B_1$ | 0 | $B'_1$ | ~1.7 |
| $B_2$ | ~3.5 | $B'_2$ | ~3.5 |
| $B_3$ | ~4.5 | $B'_3$ | ~4.5 |
| $B_4$ | ~4.6–~5.2 |  |  |
| $B_5$ | ~5.2–~6.5 |  |  |
| hp-SNO | | | |
| $C_1$ | ~1.7 | $C'_1$ | ~1.7 |
| $C_2$ | ~3.0 | $C'_2$ | ~3.0 |
| $C_3$ | ~4.0 | $C'_3$ | ~4.0 |
| $C_4$ | ~4.5 | $C'_4$ | ~4.6 |
| $C_5$ | ~4.6–~5.5 | $C'_5$ | ~5.5 |
| $C_6$ | ~5.5–~6.5 |  |  |

The peaks in the imaginary part of complex dielectric function, ε2(ω), and loss function, −iε2(ω), spectra of lp-SNO (5 × 10−6 Torr) and hp-SNO (1 × 10−4 Torr) films are listed along with their photon energy positions. The peaks at 0 eV in lp-SNO and mp-SNO are Drude peaks associated with metallic free charges.
scanning TEM (STEM) images are shown for lp-SNO (5–101) and \{-101\} extra oxygen planes that occur every few unit cells (shown in high magnification in Fig. 3d). Their position-averaged atomic structure (Fig. 3e) matches with the known extra oxygen plane structure of bulk SrNbO$_3$$_4$ (ref. 17) shown overlaid onto the image (see Supplementary Note 1 for details). The density of these planes qualitatively appears to increase with oxygen deposition pressure (Fig. 3a–c), and quantitatively (see Supplementary Figs 8 and 9 for details), there is a fourfold increase from mp-SNO to hp-SNO. This is consistent with an increased incorporation of extra oxygen with higher oxygen deposition pressure.

Thickness-dependent study of correlated plasmons. To examine size-dependent effects on the properties of the correlated plasmons, hp-SNO films with thinner thicknesses of ~81–52 and ~20 nm are also deposited and studied using SE, and the results are shown in Fig. 4 (see also Supplementary Figs 10 and 11 for more details). Interestingly, both the energy and number of excited correlated plasmons in hp-SNO change when the film thickness changes. In particular, the number of correlated plasmon peaks decreases as the film thickness decreases. When the film thickness decreases further to ~20 nm, the correlated plasmon disappears (Fig. 4d). This means that besides using the oxygen deposition pressure, the correlated plasmons can also be tuned by varying the thickness of the hp-SNO film. This is again fundamentally different from conventional plasmons where only the plasmon energy is changing when the metallic nanoparticle size is changed.

The disappearance of correlated plasmons in the ~20 nm hp-SNO film is particularly interesting. To investigate this further, we study the $\sigma_1(\omega)$ and $W$ of the thickness-dependent hp-SNO films shown in Fig. 5. It can be seen that as the film thickness decreases, the spectral weight of the first interband region ($>4.3$ eV), $W_1$, increases. This means that these thinner hp-SNO films have less wide-range spectral weight transfer that signifies their correlation strength$^{12,24,30–35}$. In particular, the $W_3$ of the ~20 nm hp-SNO film is almost as high as that of the metallic mp-SNO (Figs 2b and 5b), which means that the ~20 nm hp-SNO is most likely a weakly-correlated system. This further emphasizes the connection between the correlated plasmons, electronic correlation and the film dimensionality: as the film becomes thinner, the electronic correlation and thus the correlated plasmons also become weaker and ultimately vanish.

One possible reason for this thickness-dependent behaviour of the correlated plasmons might be due to the role of lattice mismatch. From Supplementary Fig. 1, it can be seen that the in-plane lattice constant of the Sr$_{1–x}$NbO$_3$$_4$ films is 4.04 Å, while the lattice constant of the LaAlO$_3$ substrate is 3.791 Å (ref. 36), which means that there is a relatively large lattice mismatch of ~6.6% between the films and the substrate. In thinner films, this large lattice mismatch should play a more significant role in influencing the electronic band structure of the whole film due to their relative thinness. The large lattice mismatch may reduce the unscreened Coulomb interactions between the electrons, resulting in less correlations and correlated plasmon excitations in thinner films. On the other hand, the role of lattice mismatch should be more minimized in thicker films, because their relative thickness should allow them to have more complete relaxations, leading to stronger correlations and more correlated plasmon excitations compared to thinner films.

Reproducibility of correlated plasmons. To test the reproducibility of the correlated plasmons, a second batch of pressure-dependent Sr$_{1–x}$NbO$_3$$_4$ films are deposited and measured using SE, and the analyses and results are shown in Supplementary Figs 12–17. The thickness of each film in this batch is kept within a narrow range of ~159–182 nm to minimize thickness-dependent effects (see Supplementary Table 1). From Supplementary Fig. 14, it can be seen that,
Figure 4 | Complex dielectric function and loss function spectra of hp-SNO films with varying thicknesses. (a) Real part of complex dielectric function, \(\varepsilon_r(\omega)\), of hp-SNO (1 × 10^{-4} \text{Torr}) films with varying thicknesses. (b) Imaginary part of complex dielectric function, \(\varepsilon_i(\omega)\), and loss function, \(-\text{Im}[\varepsilon_r(\omega)]\), of \(\sim 81\) nm hp-SNO film. Here, two correlated plasmon peaks are observed at \(\sim 3.2\) and \(\sim 4.4\) eV. (c) The \(\varepsilon_2(\omega)\) and \(-\text{Im}[\varepsilon_r(\omega)]\) of \(\sim 52\) nm hp-SNO film. Here, the only correlated plasmon peak is observed at \(\sim 4.0\) eV. (d) The \(\varepsilon_2(\omega)\) and \(-\text{Im}[\varepsilon_r(\omega)]\) of \(\sim 20\) nm hp-SNO film. No correlated plasmon peak is observed in this very thin film. For reference, the standard \(\sim 168\) nm thick hp-SNO film has three correlated plasmon peaks.

Figure 5 | Optical conductivity spectra and spectral weight of hp-SNO films with varying thicknesses. (a) The optical conductivity, \(\sigma(\omega)\), of hp-SNO (1 × 10^{-4} \text{Torr}) films with varying thicknesses. The \(\sigma(\omega)\) of the standard \(\sim 168\) nm hp-SNO is also shown for reference. (b) Evolution of spectral weight, \(W_i\) of three energy regions: \(W_1\) (0.6–2.0 eV), \(W_2\) (2.0–4.3 eV) and \(W_3\) (4.3–6.5 eV) across hp-SNO films with varying thicknesses. The \(W_{\text{tot}}\) is the total \(W\) from 0.6 to 6.5 eV. The \(W_3\) of mp-SNO (purple filled circle) is also shown for comparison. The abbreviation ‘CP’ stands for ‘correlated plasmon’.

in general, the behaviours of the correlated and conventional plasmons as well as excited peaks in this batch are very similar to what was observed in the main-batch films shown in Fig. 1 (see Supplementary Note 4 for details). Furthermore, Supplementary Fig. 16 also shows that the pressure-dependent MIT is reproducible as well, and that the films deposited under higher oxygen pressures consistently have the signature of strong electronic correlations. This indicates that the correlated plasmons are indeed reproducible, and its pressure-dependent behaviour can be reproduced consistently within similar thicknesses.

Discussion

The presence of extra oxygen planes in hp-SNO and their absence in lp-SNO accompanied by remarkable changes in \(\varepsilon(\omega)\) and \(\sigma(\omega)\) spectra indicate that the interplay between extra oxygen planes and electronic correlations plays important roles in the plasmonics excitations and MIT between the films. For lp-SNO, its negative \(\varepsilon(\omega)\) value below \(\sim 1.9\) eV, strong Drude response and no excitonic peak indicate that the Coulomb interactions between its Nb-4d electrons as well as between its electrons and holes are screened, making it a weakly-correlated metal similar to SrNbO3 (refs 14–16). Meanwhile, non-negative \(\varepsilon_2(\omega)\) value, wide-range spectral weight transfer and presence of excitonic signature in thick (~168 nm) hp-SNO indicate the Coulomb interactions among its Nb-4d electrons as well as between its electrons and holes are unscreened, which leads to strong electronic correlation. In this regard, the extra oxygen planes in the thick hp-SNO act as high-potential walls that prevent the Nb-4d electrons from hopping across the planes, confining them and making them feel stronger Coulomb repulsions. This changes their behaviour from itinerant to localized and transforms the system into a strongly-correlated Mott-like insulator11.

Furthermore, since the extra oxygen planes are embedded throughout the volume of the hp-SNO film, the correlated plasmons disappear in the very thin hp-SNO film, and as hp-SNO itself is a Mott-like insulator with little to no free electrons at its surface, the observed correlated plasmons are most likely bulk plasmons instead of surface plasmons. The occurrence of the extra oxygen planes every few unit cells (every 5 unit cells for SrNbO3,4) also means that the correlated plasmons have nanometre-spaced (~2 nm for SrNbO3,4) confinement in the film (see Supplementary Fig. 1 for the films lattice constants).

The electronic confinement is further supported by density functional theory (DFT) calculations shown in Fig. 6a,b. The calculations show that the presence of oxygen planes in SrNbO3,4, which shares similar extra oxygen plane structure with hp-SNO, can indeed induce the electronic confinement on Nb-4d electrons (Fig. 6b), consistent with previous report16 (see also Supplementary Fig. 18 for details). This confinement is not observed in SrNbO3 (Fig. 8a), which has no extra oxygen planes.
similar to lp-SNO. In the following discussion, we model and explain the conventional and correlated plasmons of the thick films based on this electronic confinement induced by the extra oxygen planes.

Conventional plasmon can be classically described using the Drude model\(^7\) as a collective oscillation of free charges against a positively charged ionic background (Fig. 6c). The theoretically calculated \(\varepsilon(\omega)\) and LF spectra of lp-SNO using Drude model (Fig. 6e,f) agree very well with the experimental data below the bandgap. The theoretical LF of SrNbO\(_3\) calculated using DFT with random phase approximation (RPA) method is also able to resemble qualitatively the experimental LF of lp-SNO (see Supplementary Fig. 19a and Supplementary Note 5 for details). This is not surprising because lp-SNO is a metal with little to no correlations and thus can be modelled using DFT-based calculations.

On the other hand, the theoretical LF of SrNbO\(_{3.4}\) calculated using DFT and RPA is not able to resemble the experimental LF of thick hp-SNO, particularly the three correlated plasmons peak that we observe in thick hp-SNO (Supplementary Fig. 19b). This is because hp-SNO is a correlated system, which cannot be properly treated using DFT. Thus, to model the correlated plasmons of thick hp-SNO, we instead use a phenomenological model in which the effective Coulomb interactions between neighbouring correlated electrons is modelled as that of an elastic spring, at least in the low wave vector (or momentum transfer, \([q \rightarrow 0]\)) limit. In this model (Fig. 6d and Supplementary Fig. 20), we qualitatively treat plasmonic oscillations of the correlated electrons as those of a chain of coupled harmonic oscillators bounded by two oxygen walls (where the walls are the extra oxygen planes that confine the Nb-4d electrons). Because the correlated electrons might have different effective masses and charges from bare electrons due to correlation effects\(^\text{12}\), in the calculations we vary these along with the number of oscillators in one chain to find the set of parameters that can best describe the experimental data (see Supplementary Fig. 21 and Supplementary Note 3 for details).

From the calculation results (Fig. 6e,g), we find that the coupled oscillator model is able to resemble qualitatively the experimental \(\varepsilon(\omega)\), LF and correlated plasmons of thick hp-SNO below the bandgap when the chain between the oxygen walls contains seven oscillators. To get the correct magnitude of \(\varepsilon(\omega)\), the effective masses of the quasi-electrons are set to \(\sim 25m_e\), suggesting that the masses are heavily renormalized due to electronic correlation. Interestingly, we also find that to match the intensity trend of the correlated plasmon peaks, the quasi-electrons need to have alternating charges, that is, the quasi-electrons nearest to the walls have \(-e\) charge, their immediate neighbours \(+e\) charge, and so on, suggesting that the originally itinerant electrons have transformed into quasi-electrons and holes distributed alternatingly along the chain due to correlation. This is consistent with previous report

---

**Figure 6 | Coupled harmonic oscillator model of correlated plasmons.** (a) Theoretical Nb-4d electron density iso-surface of SrNbO\(_3\) superimposed on SrNbO\(_3\) crystal structure (Sr = green, Nb = blue, O = red, iso-surface = yellow). (b) Theoretical Nb-4d electron density iso-surface of SrNbO\(_{3.4}\) superimposed on SrNbO\(_{3.4}\) crystal structure. Black dashed lines denote the oxygen walls. The Nb-4d electrons occupy only the middle three Nb planes, while those close to the oxygen walls are depleted of electrons. (c) Illustration of conventional plasmon. Red wave pattern represents the oscillation of free charges, while grey spheres denote the underlying positively charged Nb ionic background. (d) Illustration of coupled harmonic oscillator model of correlated plasmon, showing the case where there are seven oscillators in one chain bounded by two oxygen walls (the coupled seven-oscillator model). Red and green spheres represent the renormalized quasi-electrons coupled by spring-like interaction, while blue lines represent the oxygen walls. (e) Calculated real part of complex dielectric function, \(\varepsilon_r(\omega)\), of conventional plasmon using Drude model and that of correlated plasmon using coupled seven-oscillator model. Red dashed line indicates the zero-crossing of \(\varepsilon_r(\omega)\) calculated using Drude model. Inset shows parts of spectra zoomed in for clarity. (f) Calculated imaginary part of complex dielectric function, \(\varepsilon_i(\omega)\), and loss function, \(-\text{Im} \left[ \varepsilon^{-1}(\omega) \right]\), of conventional plasmon using Drude model. (g) Calculated \(\varepsilon_r(\omega)\) and \(-\text{Im} \left[ \varepsilon^{-1}(\omega) \right]\) of correlated plasmon using coupled seven-oscillator model.
of possible formation of charge density wave in SrNbO$_3$ (refs 18,19).

The estimated heavy effective mass and the alternating charge arrangement of the quasi-electrons should also affect the dephasing time of the correlated plasmons. The heavy effective mass of the quasi-electrons can make the confined electrons (and thus the correlated plasmons) much more inertial against scattering, which can significantly enhance the correlated plasmon dephasing time. Furthermore, the redistributed charge arrangement would also alter their scattering profile to be different from that of nearly free bare electrons in metals.

In conclusion, we have demonstrated that depending on the electronic correlation strength, different types of plasmons can be reproducibly excited in Sr$_2$-$_2$NbO$_3$ films. In weakly correlated metallic films, conventional plasmons dominate. Meanwhile, in strongly correlated Mott-like insulating films, low-loss correlated plasmons, which have fundamentally different properties and origins from conventional plasmons, are excitable instead. These correlated plasmons arise from the nanometre-spaced origins from conventional plasmons, are excitable instead. They are optically active instead.

**Methods**

**Materials preparations and characterizations.** The Sr$_2$-$_2$NbO$_3$ films are deposited at 750°C by pulsed-laser deposition in 10 Torr using a 1030 nm laser source. The laser used is a Lambda Physik Excimer KrF ultraviolet laser with a wavelength of 248 nm, energy density of 2 J cm$^{-2}$, and pulse frequency of 5 Hz. The three thick main-batch films are deposited at 750°C and oxygen partial pressures of 5 × 10$^{-6}$, 3 × 10$^{-3}$ and 1 × 10$^{-2}$ Torr, respectively. The pulsed-laser deposition target is prepared by solid solutions of Sr$_2$Nb$_2$O$_6$ powder, Nb (Alfa Aesar, 99.999%, 325 mesh), and Nb$_2$O$_5$ (Alfa Aesar, 99.998%, metals basis) powder mixtures with proper molar ratios. The precursor is prepared by calcining SrCO$_3$ (Alfa Aesar, 99.999%, metals basis) and Nb$_2$O$_5$ powder mixtures in a molar ratio of 4:1. The calcination and half an hour deposition.

The precursor is prepared by calcining SrCO$_3$ (Alfa Aesar, 99.999%, metals basis) and Nb$_2$O$_5$ powder mixtures in a molar ratio of 4:1. The calcination and half an hour deposition.

In the second method, the free electron scattering can be estimated from the blueshift between the plasmon energy, $G$, of the conventional plasmon peak taken from the LF spectra. The fitting analysis of the LaAlO$_3$ substrate is shown in Supplementary Table 1.

**Spectroscopic ellipsometry.** SE measurements are performed with specular reflection geometry at room temperature from 0.6 to 6.5 eV using Woollam V-VASE ellipsometry at 50°, 60° and 70° incident angles from the sample normal. The beam spot size is ~1.3 mm. The resulting ellipsometric parameters of each sample, tan$\phi$ exp(i$\Delta$) → $r_p$/$r_s$, where $r_p$ and $r_s$ are the p- and s-polarized component of the amplitude reflection coefficients, respectively, 19 are analysed to extract the complex dielectric function, $\varepsilon(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega)$, of the films using the Woollam VWAVESE32 and Woollam CompleteEase software. Since the samples are precious metals thin films on LaAlO$_3$ substrate, they are modelled as a two-layer system.25 The $\varepsilon(\omega)$ of the thin films is fitted using a combination of Drude37 and Herzinger–Johs Psmeni–Trivest oscillator functions, while the $\varepsilon(\omega)$ of the underlying LaAlO$_3$ substrate is modelled using Lorentz oscillator functions. 22 Oscillator functions are Kramers–Kronig transformable. 25 To account for the surface (~ 1 nm) and interface (~ 3 nm) roughnesses, a Bruggeman-mode effective medium approximation is used. 49 The fitting is performed until a least $\chi^2$ fit is achieved. Owing to the indications of possible anisotropy from XRD data (Supplementary Fig. 1), the SE data of the films is analysed using two modes: (1) isotropic mode, where the $\varepsilon(\omega)$ along all directions is assumed to be the same, and (2) uniaxial anisotropic mode, where the $\varepsilon(\omega)$ along the out-of-plane (extraordinary) direction is assumed to be different from the $\varepsilon(\omega)$ along the in-plane (ordinary) directions. The fitting analysis of the LaAlO$_3$ substrate is performed using isotropic mode and the resulting $\varepsilon(\omega)$ spectra are shown in Supplementary Fig. 2.

The SE data of lp-SNO and mp-SNO, as well as lp-SNO-2, mp-SNO-2, mp-SNO-2 and mp-SNO-2, cannot be fitted properly using isotropic mode and can only be fitted well at all incident angles using uniaxial anisotropic mode (Supplementary Figs 3 and 12). This indicates that these conducting films have a slight uniaxial anisotropy along the out-of-plane direction, consistent with XRD data (Supplementary Fig. 1). The resulting ordinary (along in-plane directions) $\varepsilon(\omega)$ and LF, $\Delta$ Im [$\varepsilon^{-1}(\omega)$], of lp-SNO and mp-SNO films are shown in Fig. 1, their extraordinary (along out-of-plane direction) $\varepsilon(\omega)$ and LF spectra are shown in Supplementary Fig. 4. Meanwhile, the resulting ordinary $\varepsilon(\omega)$ and LF of the second-batch conducting films are shown in Supplementary Fig. 14, while their extraordinary components are shown in Supplementary Fig. 15. Since the features of extraordinary $\varepsilon(\omega)$ of lp-SNO and mp-SNO are similar to their ordinary $\varepsilon(\omega)$, only the ordinary $\varepsilon(\omega)$ of lp-SNO and mp-SNO are shown in Fig. 1 for clarity. The SE analyses also show that the thicknesses of lp-SNO and mp-SNO films are ~196 nm (with thickness non-uniformity of ~11%) and ~218 nm (with thickness non-uniformity of <5%), respectively. The thicknesses of the second-batch films are shown in Supplementary Table 1.

Meanwhile, the SE data of hp-SNO, as well as hp-SNO-2 and hpr-SNO-2, can be fitted well at all incident angles using the isotropic mode (Supplementary Figs 5 and 13) and analysis using anisotropic mode yields the same ordinary and extraordinary $\varepsilon(\omega)$ and LF spectra of the film, indicating that hp-SNO is optically isotropic and it has little to no anisotropy (see Supplementary Note 7 for more details). This is consistent with XRD data (Supplementary Fig. 1), which shows that the in-plane and out-of-plane lattice constants of hp-SNO are much closer to its in-plane lattice constants as compared to those of lp-SNO and mp-SNO. The resulting $\varepsilon(\omega)$ and LF spectra of hp-SNO are shown in Fig. 1, while those of hp-SNO-2 and hpr-SNO-2 are shown in Supplementary Fig. 14. The SE analysis also shows that the thickness of the thicker hp-SNO film is ~186 nm (with thickness non-uniformity of ~34%). The SE data of the thinner hp-SNO films (~81, ~52 and ~20 nm) is similarly analysed using isotropic mode (Supplementary Fig. 10).

From the obtained $\varepsilon(\omega)$, the refractive index ($n(\omega)$), extinction coefficient ($k(\omega)$), normal-incidence reflectivity ($R(\omega)$), and absorption coefficient ($\sigma(\omega)$) of the films can be extracted using the Fresnel equations and the following relations:

$$\varepsilon(\omega) = \frac{2n(\omega) - 1}{k(\omega)^2 + \sigma(\omega)^2} \left(1 + \frac{4\pi k(\omega)}{\lambda} \right)^2$$

$$\sigma(\omega) = \frac{4\pi k(\omega)}{\lambda}$$

$$R(\omega) = \frac{\left[n(\omega) - 1\right]^2 + k(\omega)^2}{\left[n(\omega) + 1\right]^2 + k(\omega)^2}$$

$$\Delta = \frac{\left[n(\omega) - 1\right]^2 - k(\omega)^2}{\left[n(\omega) + 1\right]^2 - k(\omega)^2}$$

Conventional plasmon dephasing time. Based on $\varepsilon(\omega)$ and LF, the free electron scattering, $1/\tau_p$, can be estimated by at least two methods. In the first method, by using the Drude model (Supplementary equation 6b), $1/\tau_p$ can be extracted from the blueshift between the plasmon energy, $\omega_p$, and the zero-crossing of the $\varepsilon(\omega)$ around $\omega_p$: $\omega_p = \omega + i\tau_p$. Hence, $\tau_p = 1/\omega_p$. In the second method, the free electron scattering can be estimated from the FWHM, $2\Delta$, of the conventional plasmon peak taken from the LF spectra. The free electron scattering contributes to the dephasing of the conventional plasmon, meaning that the conventional plasmon dephasing time, $\tau_p$, can be obtained using $\tau_p = 1/2\Delta$. 28

Optical conductivity and spectral weight. Since the $\varepsilon(\omega)$ of lp-SNO and mp-SNO, as well as lp-SNO-2, mp-SNO-2, mp-SNO-2 and mp-SNO-2, are slightly anisotropic, their optical conductivity, $\sigma(\omega)$, and spectral weight, $W$, are...
Transmission electron microscopy. The main-batch Sr$_x$Nb$_{2}$O$_{3+y}$ thin films are prepared for TEM measurements via the lift-out method using an FEI Strata 235 dual beam focused ion beam. The samples are then locally ion milled using a Fischione 1040 Nanomill at 900 eV and then 500 eV to remove the focused ion beam damaged surfaces. The TEM and selected-area electron diffraction (SAED) are performed on a FEOL 3010 operating at 300 kV. Zone axis SAED patterns are collected for all three films (Supplementary Fig. 8) back-to-back using identical SAED apertures, magnification and beam illumination (beam fully spread).

Distinct Bragg peaks are visible for the Sr$_x$Nb$_{2}$O$_{3+y}$ films and LaAlO$_3$ substrates in both the out-of-plane (00l) and in-plane (h00) directions indicating at least partial strain relaxation for all three cases. Superlattice reflections along the (101) and (100) axis around the main SrNbO$_3$ Bragg peaks in the mp-SNO and hp-SNO films are also observed, which are due to the difference in lattice parameter of the extra oxygen planar defects. A magnified region around the (100) Bragg peaks for each sample is shown at the bottom of Supplementary Fig. 8 plotted on identical, colorized, intensity scales. To isolate the superlattice reflections the main SrNbO$_3$ and LaAlO$_3$ peaks are masked out. For consistency the mask locations are determined by superlattice reflections of a uniform film stack to the SrNbO$_3$ and LaAlO$_3$ Bragg peaks whose positions were determined by Gaussian fit. The background is subtracted as the radial median value from the centre of the diffraction pattern. To quantify the increase in the superlattice peak intensity, the mean value was calculated within the X-shaped region shown overlaid on the (100) peak images in Supplementary Fig. 8 while the mean value outside is taken as the zero value. The resulting value is then normalized by the sample thickness, h/2 (that is, thickness measured in units of the inelastic mean free electron scattering distance, λ, see below and Supplementary Fig. 9) giving a superlattice intensity measure of 19.16, 92.91 and 317.04 for lp-SNO, mp-SNO and hp-SNO, respectively. From this increase in the superlattice reflection intensity from lp-SNO, to mp-SNO, to hp-SNO, it is straightforward to infer an increase in oxygen defect plane density and an increase in oxygen incorporation.

Atomic resolution scanning TEM and energy-filtered TEM are performed on the TEAMOS, a Cs aberration-corrected FIPE Titan operating at 300 kV. For high-resolution imaging TEM, simultaneously collected images are acquired using a high-angle annular dark-field (HAADF) detector and a bright-field detector. The former, used in all panels of Fig. 3, produces Z-contrast images with intensities approximately proportional to the square of the atomic number (Z) and atomic nuclei appearing bright. The bright-field images, used in the top half of Fig. 3c, are useful for identifying oxygen-rich regions in the films. Figure 6d shows that the atomic oxygen walls (Fig. 6d and Supplementary Fig. 20). As a first approximation, the plasmonic confinement of oxygen walls (Fig. 6d and Supplementary Fig. 20).

Density functional theory calculations. The atomic and electronic structure of SrNbO$_3$ and NbO$_3$ compounds are computed by spin-polarized DFT calculations using the Perdew–Burke–Ernzerhof (PBE96) exchange–correlation potential and the projector-augmented wave (PAW) method$^{28}$ as implemented in the Vienna ab initio simulation program$^{29}$. In these calculations, Sr 4s4p5s, Nb 4s4p5d and O 2s2p orbitals are treated as valence states, employing the PAW potentials labelled as Sr$^{sv}$, Nb$^{pv}$ and O$^{pv}$ in the Vienna ab initio simulation program PBE library. The cutoff energy for the plane-wave basis set is set to 450 eV, and DFT + U approach is employed to treat the Nb 4d orbitals occupied in the Nb$^{4+}$ ions, with the value of U − J set to 4 eV. SrNbO$_3$, SrNbO$_{3.33}$, SrNbO$_{3.4}$ and SrNbO$_{3.5}$ are modelled by supercells containing, respectively, 20 atoms with space group Pnam, 64 atoms with space group Comm, 54 atoms with space group Pnmm and 44 atoms with space group Cmcm. In the structural relaxations, 8 × 8 × 4, 4 × 8 × 6, 6 × 4 × 8 and 1 × 8 × 16 unit cells are employed for SrNbO$_3$, SrNbO$_{3.33}$, SrNbO$_{3.4}$ and SrNbO$_{3.5}$, respectively. The Nb 4d valence electron densities of SrNbO$_3$ and SrNbO$_{3.4}$ are shown in Fig. 6a,b, while those of SrNbO$_{3.33}$ and SrNbO$_{3.5}$ are shown in Supplementary Fig. 18 and discussed in Supplementary Note 8. The valence electron densities are calculated using electron states with energies ranging from −10 eV to −2 eV below the Fermi level. The conduction electron densities are calculated using electron states with energies ranging from 0 eV to 10 eV above the Fermi level. The samples used in Fig. 2a (main batch) and Supplementary Fig. 16a (second batch) were measured by a LEO Gemini500 microscope using both the bright-field and energy-dispersive X-ray spectroscopy (EDX) detectors.

Conventional and correlated plasmons theoretical calculations. The theoretical z(o), LF, and conventional plasmon of lp-SNO shown in Fig. 6e,f are calculated using DFT + U approach in the following modified form of the Drude model$^{28}$:

\[
\alpha(k, \omega) = \frac{-\omega}{\varepsilon_{\text{re}}(k, \omega)}
\]

where \( \varepsilon_{\text{re}}(k, \omega) = \varepsilon_{\text{re}} - i\frac{\omega_p^2}{\varepsilon_{\text{re}}} \) and \( \omega_p \) is the plasma frequency. The calculation results are in a very good agreement with experimental data up to 4 eV, below the onset energy of the interband transitions, confirming that lp-SNO is a metal with conventional plasmonic characteristics.
higher peak intensity as energy increases. To improve this, we find that the increasing intensity trend can only be achieved if the charges are assumed to be distributed with alternating signs, that is, $q_1 = -e$, $q_2 = +e$, $q_3 = -e$ and so on. Third, the number of plasmonic peaks appearing in the theoretical $\varepsilon(\omega)$ and LF of hp-SNO is tuned by varying the number of oscillators in one chain. In analogy with a string with $N$ oscillators, a string with $N$ natural oscillation modes. Since the number of observed plasmonic peaks in Fig. 1d is three, this gives an indication that $N$ should be an odd number. We start with the case of $N = 3$. A three-body oscillator has three intrinsic oscillation modes, but there is one mode that has zero polarization. This zero-polarization mode cannot show up in $\varepsilon(\omega)$, leaving only two non-zero peaks and inconsistent with the three peaks observed in Fig. 1d. Next, for $N = 5$ the five-body oscillator has five eigenmodes, but two of them have zero polarization, leaving three non-zero peaks surviving, which is what the experimental results require. The calculation results (Supplementary Figure 21) show that for $N = 5$ the peak positions and the increasing intensity trend are in a rough agreement with experimental results, but the calculated relative peak intensities are not very satisfactory because the first and the second peaks are too low compared to the third peak. The calculation for the case of $N = 7$ is next performed with the same approach as discussed above. The results show that not only does it give three appearing peaks (Fig. 6e and Supplementary Fig. 21), with only an additional negligibly small peak close to 0 eV, but also it provides a peak intensity profile that much better resembles the theoretical results. For this particular case, the parameter values are set as follows: $m_0 = 2.0 eV$, $Z = 25$, $\varepsilon(\omega) = 4.0$, $1/r = 0.5 eV$, $m_1 = m_2 = \cdots = m_N = Z m_0$, $k_1 = 0.4 k_0$, $k_2 = 0.5 k_0$, $k_3 = 1.0 k_0$ and $k_4 = 1.1 k_0$, and the rest of the spring constants follow a mirror symmetry, that is, $k_5 = k_1$, $k_6 = k_2$, $k_7 = k_3$, $k_8 = k_4$, and $k_9 = k_5$. The calculations are also performed for $N = 9$ and $N = 11$, although Supplementary Fig. 21 shows that these two cases result in too many peaks. In Fig. 1d it can be seen that, in addition to the three main peaks of $C_5$, $C_5$ and $C_9$, there is a relatively high peak at $2.4 eV$ that appears in both $\varepsilon(\omega)$ and LF spectra of thick hp-SNO, which means this peak is also a correlated plasmon peak. From the analysis of Supplementary Fig. 21, this small peak could come from the excitation of these higher-order modes (that is, $N = 9$ and/or $N = 11$), although its low intensity compared the three main peaks of $C_5$, $C_9$ and $C_9$ means that the seven-oscillator mode should still be the dominant mode of oscillation.

For more details, the in-depth theoretical calculations of the conventional plasmon of lp-SNO and correlated plasmons of hp-SNO are discussed further in Supplementary Note 3.

Data availability. The data that support the findings of this study are available from the corresponding authors on reasonable request.
