(Dated: March 27, 2002)

We analyze the enhancement of the superconducting critical temperature of superconducting/ferromagnetic bilayers due to the appearance of localized superconducting states in the vicinity of magnetic domain walls in the ferromagnet. We consider the case when the main mechanism of the superconductivity destruction via the proximity effect is the exchange field. We demonstrate that the influence of the domain walls on the superconducting properties of the bilayer may be quite strong if the domain wall thickness is of the order of superconducting coherence length.

I. INTRODUCTION

The coexistence of singlet superconductivity and ferromagnetism is very improbable in bulk compounds but may be easily achieved in artificially fabricated hybrid superconductor (S)-ferromagnet (F) structures.

There are two basic mechanisms responsible for interaction of superconducting order parameter with magnetic moments in the ferromagnet: the electromagnetic mechanism (interaction of Cooper pairs with magnetic field induced by magnetic moments) and the exchange interaction of magnetic moments with electrons in Cooper pairs. The second mechanism enters into play due to the proximity effect, when the Cooper pairs penetrate into the F layer and induce superconductivity there. In S/F bilayers it is possible to study the interplay between superconductivity and magnetism in a controlled manner, since we can change the relative strength of two competing orderings by varying the layer thicknesses and magnetic content of F layers. Naturally, to observe the influence of the ferromagnetism on the superconductivity, the thickness of S layer must be small. This influence is most pronounced if the S layer thickness is smaller than the superconducting coherence length \(\xi\). Recently, the observation of many interesting effects in S/F systems became possible due to the great progress in the preparation of high-quality hybrid F/S systems - see the reviews\textsuperscript{1,2,3}.

In practice, the domains appear in ferromagnets and, near the domain walls, a special situation occurs for proximity effect. For the purely orbital (electromagnetic) mechanism of the superconductivity destruction, the nucleation of the superconductivity in the presence of domain structure has been theoretically studied in\textsuperscript{4,5} for the case of magnetic film with perpendicular anisotropy. The conditions of the superconductivity appearance occur to be more favorable near the domain walls due to the partial compensation of the magnetic induction. Recently, the manifestation of such domain wall superconductivity (DWS) was revealed on experiment\textsuperscript{6} where Nb film was deposited on top of the single crystal ferromagnetic BaFe\textsubscript{12}O\textsubscript{19} covered with a thin Si buffer layer.

As the typical value of the exchange field in the ferromagnets \(h \sim (100 - 1000)K\) exceeds many times the superconducting critical temperature \(T_c\), the exchange mechanism prevails the orbital one in the superconductivity destruction when the electrical contact between S and F layers is good. For the proximity effect mediated by the exchange interaction, the Cooper pairs feel the exchange field averaged over the superconducting coherence length. Naturally, it will be smaller near the domain wall and we may expect that superconductivity would be more robust near them. The local increase of the critical temperature in presence of magnetic domains was observed experimentally in Nb\textsubscript{0.80}Fe\textsubscript{0.20}/Nb bilayers (with Nb thickness around 20 nm)\textsuperscript{7}, and it was attributed to DWS formation.

In the present paper we study theoretically the conditions of the localized superconductivity appearance near the domain wall taking into account exchange mechanism of the proximity effect. In Sec. \textsuperscript{II} we demonstrate that, in the case of thin F layer and small domain wall thickness, the problem is somewhat similar to that of the domain wall superconductivity in ferromagnetic superconductors\textsuperscript{8,9}. For the case when the superconducting coherence length \(\xi\) exceeds the DW thickness \(w\), we expect a very strong local increase of \(T_c\) (see Sec. \textsuperscript{III}). In Sec. \textsuperscript{IV} we obtain the analytical expression for the critical temperature of the DWS for the case when the DW thickness \(w\) exceeds the superconducting coherence length \(\xi\). The Appendix presents an extension of this result to arbitrary thickness of the F layers and transparency of the S/F interface. We discuss our results in Sec. \textsuperscript{V}. In particular, we predict the realization of the situation when superconductivity appears only near the DW.

II. EQUATION FOR THE CRITICAL TEMPERATURE IN THIN BILAYERS

We introduce the Usadel equations\textsuperscript{10} which are very convenient when dealing with S/F systems with critical temperatures \(T_c\) and exchange fields \(h\) such as \(T_c\tau \ll 1\) and \(h\tau \ll 1\), where \(\tau\) is the elastic scattering time.

Near the second order transition into superconducting
state, Usadel equations can be linearized with respect to the amplitude of the superconducting gap. In the S region, the linearized Usadel equation is:

$$-D_s \nabla^2 \tilde{s}_s + 2|\omega|\tilde{s}_s = 2\Delta_s(r)\tilde{\sigma}_z,$$  
(1)

where $D_s$ is the diffusion constant in the superconductor and $\omega = (2n + 1)\pi T$ is a Matsubara frequency at temperature $T$. (Notations are similar to the ones used in Ref. 2, except for the factor $i$ in front of $\Delta_s$). Eq. 11 relates the anomalous Green’s function $\tilde{f}_s$, which is a matrix in spin space, to the superconducting gap $\Delta_s(x)$, $\tilde{\sigma}_{x(y,z)}$ are Pauli matrices in spin space. In the absence of supercurrent, the gap can be taken as real.

In F region, an exchange field $h_f = (h_{f,x}, h_{f,y}, h_{f,z})$ is acting on the spins of conduction electrons and the linearized Usadel equation for anomalous function $\tilde{f}_f$ is

$$-D_f \nabla^2 \tilde{f}_f + 2|\omega|\tilde{f}_f + is_\omega \left(h_{f,x}[\tilde{\sigma}_x, \tilde{f}_f] + h_{f,y}[\tilde{\sigma}_y, \tilde{f}_f] + h_{f,z}[\tilde{\sigma}_z, \tilde{f}_f]\right) = 0. \quad (2)$$

Here, $D_f$ is the diffusion constant in the ferromagnet and we used the abbreviation $s_\omega \equiv \text{sgn}(\omega)$.

In addition, the boundary conditions at the interfaces with vacuum yield $\partial_z \tilde{s}_s(z = d_s) = 0$ and $\partial_z \tilde{f}_f(z = -d_f) = 0$, where $d_s$ and $d_f$ are the thicknesses of S and F layers, respectively, and $z = 0$ defines the plane of the interface between both layers. We also consider that S and F layers are separated by a thin insulating tunnel barrier. Therefore, the boundary conditions at the interface $z = 0$ are:

$$\sigma_s \partial_z \tilde{s}_s(0) = \sigma_f \partial_z \tilde{f}_f(0), \quad \tilde{s}_s(0) = \tilde{f}_f(0) + \gamma_B \xi_s \partial_z \tilde{f}_f \bigg|_{z=0}, \quad (3)$$

where $\sigma_s$ and $\sigma_f$ are conductivities in the layers, and $\gamma_B$ is related to the boundary resistance per unit area $R_b$ through $\gamma_B \eta_s = R_b/\sigma_f$, where $\xi_s$ is the superconducting coherence length.

The critical temperature $T = T_c$ at the second order transition is now obtained from the self consistency equation for the gap:

$$\Delta(r) \ln \frac{T_c}{T_{c0}} + \pi T \sum_\omega \left( \frac{\Delta(r)}{|\omega|} - f^{11}_s(r, \omega) \right) = 0 \quad (4)$$

($f^{11}$ is a matrix element of $\tilde{f}$, where $T_{c0}$ is the bare transition temperature of the S layer.

In the ferromagnet, the magnitude $h_f$ of the exchange field $h_f$ is fixed. However, its orientation can rotate in the presence of a magnetic domain wall structure. In the following, we assume a one-dimensional domain wall structure, along $x$-axis. In order to find the critical temperature of the bilayer in the presence a domain wall, we must find the $x$- and $z$-dependence of the gap and anomalous functions $\tilde{s}_s$ and $\tilde{f}_f$ which solve Eqs. 11-4. Proximity effect can significantly affect the transition temperature only when the thickness of S layer is comparable with the superconducting coherence length $\xi_s = \sqrt{D_s/2\pi T_{c0}}$. In order to get tractable expressions, we will only consider the case $d_s \ll \xi_s$. Such regime is also well achievable experimentally. Then, $\tilde{s}_s$ and $\Delta_s$ are almost constant along $z$-axis. Therefore, we can average Eq. 11 on the thickness of S layer and make use of the boundary condition at the interface with vacuum. Finally, we get the following equation at $z = 0$:

$$-D_s \partial_z^2 \tilde{s}_s + \frac{D_s}{d_s} \partial_z \tilde{s}_s + 2|\omega|\tilde{s}_s = 2\Delta_s\tilde{\sigma}_z. \quad (5)$$

The characteristic scale for the proximity effect in F layer is rather set by coherence length $\xi_f = \sqrt{D_f/h_f}$, where $h_f$ is the typical amplitude of the exchange field in the ferromagnet. In this section, we will address the case of very thin F layer: $d_f \ll \xi_f$. Then, from Eq. 2, we can derive similarly the Usadel equation averaged over the thickness $d_f$, at $z = 0$:

$$-D_f \partial_z^2 \tilde{f}_f - \frac{D_f}{d_f} \partial_z \tilde{f}_f + 2|\omega|\tilde{f}_f + is_\omega \left(h_{f,x}[\tilde{\sigma}_x, \tilde{f}_f] + h_{f,y}[\tilde{\sigma}_y, \tilde{f}_f] + h_{f,z}[\tilde{\sigma}_z, \tilde{f}_f]\right) = 0. \quad (6)$$

Let us note right now that the assumption of very thin F layer is quite hard to achieve experimentally, as we will discuss at the end of Sec. X. In Appendix, we will consider the case of arbitrary thickness for the F layer.

For simplicity, we also consider the case of low interface resistance ($\gamma_B \rightarrow 0$) where the proximity effect is maximal. In this regime, $\tilde{f}_f(x) \approx \tilde{s}_s(x) = \tilde{f}(x)$. By proper linear combination Eqs. 3-4, we can form a single equation on $\tilde{f}(\tilde{x})$:

$$-D \partial^2_{\tilde{x}} \tilde{f} + 2|\omega|\tilde{f} + is_\omega \left(h_{\tilde{x}}[\tilde{\sigma}_x, \tilde{f}] + h_{\tilde{y}}[\tilde{\sigma}_y, \tilde{f}] + h_{\tilde{z}}[\tilde{\sigma}_z, \tilde{f}]\right) = 2\Delta \tilde{\sigma}_z, \quad \Delta = \frac{\eta_s}{\eta_s + \eta_f} \Delta_s, \quad (7)$$

where $\eta_s = \sigma_s d_s/\Delta_s$ and $\eta_f = \sigma_f d_f/D_f$. Therefore, the thin bilayer is described by the same equations as for a magnetic superconductor with effective diffusion constant, exchange field, and BCS coupling constant:

$$D = \frac{D_s \eta_s + D_f \eta_f}{\eta_s + \eta_f}, \quad h = \frac{\eta_f}{\eta_s + \eta_f} h_f, \quad \tilde{\lambda} = \frac{\eta_s}{\eta_s + \eta_f} \lambda, \quad (8)$$

respectively. An equation similar to Eq. 7 was derived for a thin normal-metal/superconductor bilayer, in the absence of exchange field ($h = 0$) in Ref. 12. There, it was shown that the reduction of the coupling constant $\tilde{\lambda}$ leads to a rapid decrease of the bilayer critical temperature. In the following, we do not consider these effects. Rather, we dwell with the case when $\tilde{\lambda} \approx \lambda$, and the reduction of $T_c$ is mainly due to effective exchange field $h$. Such situation occurs at $\eta_s \gg \eta_f$. (When S and F layers have comparable diffusion constant and conductivity, the renormalization factors in Eq. 8 receive a simple interpretation in terms of volume ratios. In particular, the
condition $\eta_s \gg \eta_f$ results in $d_s \gg d_f$.) Thus, $D \approx D_s$ and $h \approx (\eta_f/\eta_s) h_f$. Let us note that the amplitude of $h$ is strongly reduced compared to $h_f$, eventually it is of the order of $\Delta_s$, and thus it leads to the possible coexistence of magnetism and superconductivity in the bilayer.

The phase diagram of magnetic superconductors with constant exchange field was studied long ago. Second order transition line from normal to superconducting state at the critical temperature $T = T_c(h)$ is given by equation

$$\ln \frac{T}{T_c} + 2\pi T e^{\sum_{\omega>0}} \left\{ \frac{1}{\omega} - \frac{1}{\omega + ih} \right\} = 0,$$

where $h$ is the amplitude of $h$. At zero temperature, the critical field is $h_c^{(2)} = \Delta_0/2$, where $\Delta_0 \approx 1.76 T_c$ is the superconducting gap. However, at $T < T^* \approx 0.56 T_c$, the transition into superconducting state is of the first order and the critical field at zero temperature is rather $h_c = \Delta_0/\sqrt{2}$.

In the presence of a domain structure in the ferromagnet, the average exchange field felt by the electrons near domain walls is smaller than in the domains. This may lead to the enhancement of the superconducting critical temperature. On the basis of the Usadel equation \#17 with self consistency equation \#18, we consider now this problem in the case of narrow domain walls in Sec. \#11 and large domain walls in Sec. \#14.

### III. NARROW DOMAIN WALL

In this section, we consider the case of thin domain walls characterized by the domain wall thickness $w \ll \xi_s$. In Ref. \#3 the zero temperature critical field was obtained in the context of magnetic superconductors. Here, we revise the result and obtain the phase diagram at finite temperature.

We model the exchange field $h$ acting on the electrons with a step function: $h_z(x) = h sgn(x)$, $h_y = h_z = 0$. The structure of Usadel equation \#17 in spin space simplifies greatly and we have:

$$-\frac{D}{2} \partial_x^2 f^{11} + (|\omega| + is_e h_z(x)) f^{11} = \Delta,$$  

while $f^{12} = f^{21} = 0$ and $f^{22} = -f^{11}$. Its solution for a given $\Delta$ is

$$f^{11}(x) = \int dy \mathcal{G}(x,y) \Delta(y),$$

where $\mathcal{G}$ is the Green’s function associated with the homogeneous differential equation \#19; $\mathcal{G}$ is defined by:

$$\mathcal{G}(x,y) = \frac{e^{-\kappa x}}{D \kappa} \left( e^{\kappa y} + \frac{\kappa - \kappa^*}{\kappa + \kappa^*} e^{-\kappa y} \right) \text{ for } x > y > 0,$$

$$\mathcal{G}(x,y) = \frac{2}{D(\kappa + \kappa^*)^2 e^{\kappa x} e^{\kappa^* y}} \text{ for } x > 0 > y,$$

where $\kappa = \sqrt{2(|\omega| + is_e h)/D}$, while $\mathcal{G}(x,y) = \mathcal{G}(y,x)$ and $\mathcal{G}(x,y) = \mathcal{G}(-x,-y)$.

We look for a symmetric solution $\Delta(-x) = \Delta(x)$. Writing the self consistency equation \#11 in Fourier space, we get the equation defining the critical temperature $T = T_{cw}$ for DWS formation:

$$\left( \ln \frac{T}{T_{cw}} + 2\pi T Re \sum_{\omega>0} \frac{1}{\omega} - \frac{1}{\omega + ih + \overline{D} p^2} \right) \Delta_p = 0,$$

$$2T \sum_{\omega>0} dk \sqrt{D} \left[ |\omega^2 + h^2| (\sqrt{\omega^2 + h^2} - \omega) \right] \Delta_k.$$

Close to $T_c$, at $h \ll T_c$, the critical temperature for the transition into uniform superconducting state can be obtained analytically from Eq. \#21:

$$\frac{T_c - T_c(h)}{T_c} = \frac{7 \zeta(3) h^2}{4 \pi^2 T_c} \frac{31 \zeta(5) h^4}{16 \pi^4 T_c^2} + \ldots$$

On the other hand, Eq. \#24 for the DWS can be simplified:

$$\left( \frac{T_{cw}(h) - T_c(h)}{T_{cw}} + \frac{\pi D p^2}{8 T_{cw}} \right) \Delta_p = A \frac{h^2}{T_{cw}} \sqrt{\frac{D}{\pi T_{cw}}} \int dk \Delta_k,$$

where $A = (8\sqrt{2} - 1)\zeta(3)/4 \pi^3$. Such equation is solved straightforwardly and we get the increase of critical temperature near $T_c$ due to DWS:

$$\frac{T_{cw}(h) - T_c(h)}{T_{cw}} \approx 8 A^2 \frac{h^4}{T_{cw}^2}.$$

The corresponding shape of the order parameter near the transition is given by

$$\Delta(x) \sim \exp \left[ -B \frac{|x|}{\xi_s} \frac{T_{cw} - T_{cw}(h)}{T_{cw}} \right],$$

where $B = 16 \pi \sqrt{2} A/(7 \zeta(3))$. Thus, near $T_c$, the localized superconductivity is characterized by exponential decay without oscillation of the superconducting order parameter, with its maximum at the domain wall position.

Away from $T_c$, Eq. \#25 does not contain any small parameter. Its structure is that of a linear integral equation whose kernel is a superposition of separable terms. Such form of the kernel is known to be convenient for numerical calculation. As a result, we obtained the second order critical line at any temperature (cf. Fig. \#11). The critical line is significantly increased compared to the critical line for the transition into uniform superconducting state. In particular, at zero temperature, the critical field for localized superconductivity at $T = 0$ is $h_{cw} \approx 1.33 T_c \approx 0.76 \Delta_0$ and lies above the critical field for the first order transition into uniform state, $h_c \approx 0.71 \Delta_0$. It is of interest to note that, if the effective exchange field in the bilayer is between $h_c$ and $h_{cw}$, then the special situation occurs when only DWS can be
is of the first order, with the critical line $h$ order transition into uniform superconducting state is plotted in black. At $T < T^* = 0.56T_{c0}$, transition into uniform state is of the first order, with the critical line $h_c(T)$ plotted in blue. The critical line $h_{cw}(T)$ corresponding to domain wall superconductivity is of the second order and is plotted in red.

realized in the system, but no superconductivity faraway from the domain walls.

We also plot the self consistent order parameter at different temperatures in Fig. 2. In addition to the decay, it shows small oscillations along the direction perpendicular to the domain wall at low temperatures.

As it was pointed out in Sec. III, transition into uniform superconducting state happens to be of the first order at $T < T^*$ in the bilayer. Therefore, one should also worry about the possibility of the change of the transition order along the critical line corresponding to DWS. We considered this possibility by solving the nonlinear Usadel equations perturbatively up to the third order terms in the gap $\Delta$. We found that such equation corresponds to the saddle-point of the free energy density (per unit thickness of the bilayer and per unit length of the magnetic domain wall) functional:

$$\mathcal{F} = \mathcal{F}_2 + \mathcal{F}_4 + \ldots$$

(18)

$$\mathcal{F}_2 = \nu \int dx \left\{ |\Delta|^2 \ln \frac{T}{T_{c0}} + \frac{2\pi T \Re}{\omega} \sum_{\omega > 0} |\Delta|^2 - \Delta^* f_{11} \right\}$$

$$\mathcal{F}_4 = \frac{\pi T \nu}{2} \Re \int dx \left[ \frac{D}{2} (\partial_x f_{11})^2 + \Delta f_{11} \right] (f_{11}^*)^2,$$

where $\nu$ is the density of states at the Fermi level in the normal state, and $f_{11}^*$ is given by Eq. (11). At the second order transition, the term $\mathcal{F}_2$, which is quadratic in $\Delta$, vanishes when Eq. (11) is satisfied. The phase transition is stable provided that the term $\mathcal{F}_4$, which is quartic in $\Delta$, remains positive along the transition line. We checked numerically that this was indeed the case. In particular, at $T = 0$ and $h$ close to $h_{cw}$, we found:

$$\mathcal{F}_2 = \nu \ln \frac{h}{h_{cw}} \int dx |\Delta(x)|^2$$

$$\simeq 2.87\nu \sqrt{\frac{D}{2h_{cw}}} \ln \frac{h}{h_{cw}} \Delta(x = 0)^2,$$

$$\mathcal{F}_4 = 0.26\nu \int dx \Delta(x = 0)^4.$$  (19)

Thus we found that the transition into DWS remains of the second order at all temperatures.

IV. LARGE DOMAIN WALL

In this section, we consider the case of a large domain wall with thickness $w \gg \xi_s$. The domain wall can be described with an exchange field $h = h(\cos\phi, \sin\phi, 0)$, the rotation angle $\phi(x)$ varies monotonously between $\phi(-\infty) = -\pi/2$ and $\phi(\infty) = \pi/2$. We find that the critical temperature at DWS nucleation is given by a Schrödinger equation for a particle in the presence of a potential well whose profile is proportional to $-(\partial_x \phi)^2$. This result is not specific to the thin bilayer considered in this Section. In the Appendix, we extend it to bilayers with arbitrary thickness of the F layer and arbitrary transparency of the S/F interface.

At the transition, the linearized Usadel equation must be solved, that is:

$$-\frac{D}{2} \frac{\partial_x^2 f_{11}^{\pm}}{\omega} + |\omega| f_{12}^{\pm} - \frac{ih s \omega}{2} e^{i\phi} \left( e^{i\phi} f_{21}^{\pm} - e^{-i\phi} f_{12}^{\pm} \right) = \Delta$$

$$\frac{D}{2} \frac{\partial_x^2 f_{12}^{\pm}}{\omega} + |\omega| f_{22}^{\pm} + ihs \omega e^{i\phi} f_{12}^{\pm} = 0$$

$$\frac{D}{2} \frac{\partial_x^2 f_{21}^{\pm}}{\omega} + |\omega| f_{21}^{\pm} - ihs \omega e^{-i\phi} f_{21}^{\pm} = 0.$$  (20)

while $f_{22} = -f_{11}$. If the spatial dependence of $\phi$ is neglected, the gap $\Delta$ is uniform along the layer and the solutions are readily found:

$$f_{11}^{\pm} = \frac{\Delta |\omega|}{\omega^2 + h^2}, \quad f_{12}^{\pm} = \frac{i\Delta hs \omega e^{-i\phi}}{\omega^2 + h^2} = -e^{-2i\phi} f_{21}^{\pm}.$$  (21)
As a result, the critical temperature \( T_c \) into uniform superconducting state naturally does not depend on \( \phi \) and is again given by Eq. (19). Now, let us assume that \( \phi \) varies slowly. We solve Usadel equation (20) perturbatively by looking for a solution \( f \approx f_0 + f_1 \). In first approximation, \( f_0 \) is still given by Eq. (21), where \( \phi \), and, possibly, \( \Delta \), now slowly depend on \( x \). The correction \( f_1 \) induced by their spatial dependence is determined by the set of equations:

\[
|\omega|f_1^{11} - \frac{h s_\omega}{2} (e^{-i\phi} f_1^{21} - e^{-i\phi} f_1^{12}) = \frac{D}{2} \partial_x^2 f_0^{11},
\]

\[
|\omega|f_1^{12} + ih s_\omega e^{-i\phi} f_1^{11} = \frac{D}{2} \partial_x^2 f_0^{12},
\]

\[
|\omega|f_1^{21} - ih s_\omega e^{i\phi} f_1^{11} = \frac{D}{2} \partial_x^2 f_0^{21}.
\]

(22)

By appropriate linear combination of these equations, one finds that

\[
f^{11} \approx \frac{|\omega|}{\omega^2 + h^2} \Delta + \frac{Dh^2}{2(\omega^2 + h^2)^2} (\phi')^2 \Delta + \frac{D}{2} \frac{\omega^2 - h^2}{(\omega^2 + h^2)^2} \Delta''.
\]

(23)

Here, primes stand for derivative along \( x \). Inserting this solution in the self consistency equation (19) we obtain the equation for the gap

\[-\frac{1}{2m} \Delta''(x) + U(x) \Delta(x) = E \Delta(x),
\]

(24)

where

\[E = -\ln \frac{T}{T_c}, \quad \frac{1}{2m} = D \pi T \sum_{\omega>0} \frac{(\omega^2 - h^2)}{(\omega^2 + h^2)^2}, \]

\[U(x) = -D \pi T (\phi')^2 \sum_{\omega>0} \frac{h^2}{(\omega^2 + h^2)^2}.
\]

(25)

Equation (24) is a linearized Ginzburg-Landau equation for a magnetic superconductor in the presence of a domain wall. It can be easily checked that effective mass \( m \) is always positive and \( U(x) \) is negative. Therefore, Eq. (24) looks like a one-dimensional Schrödinger equation for a particle in potential well \( U(x) \). It is well known that a bound state with \( E < 0 \) always forms in such potential. As a result, second order transition into localized superconducting state always appears more favorable than into uniform state.

Let us estimate now the magnitude of critical temperature increase.

Close to \( T_{c0} \), the spatial variation for \( \Delta \) is set by the temperature-dependent coherence length \( \xi(T) = \xi_s \sqrt{T_{c0}/(T_{c0} - T)} \) which diverges at the transition. Therefore, \( \xi_s \ll w \ll \xi(T) \) and the potential well can be approximated by a delta-potential: \( U(x) \approx -\pi D h^2/48 T_{c0}^3 w \delta(x) \), while \( 1/2m \sim (\pi D/8 T_{c0}) \). Therefore we get the estimate:

\[
\frac{T_{cw} - T_{c}}{T_{c}} \approx \frac{\pi^6}{36} \left( \frac{h}{2 \pi T_{c0}} \right)^4 \frac{\xi_s^2}{w^2} \times \frac{\xi_s^2}{w^2} \frac{(T_{c0} - T_{c})^2}{T_{c0}^2}.
\]

(26)

Such increase is small in the ratio \((\xi_s/w)^2\), and another reduction factor comes from the smallness of critical exchange field \( h \) near \( T_{c0} \), see Eq. (19).

At \( T \to 0 \), the second order transition into uniform state occurs at exchange field \( h_c^{(2)} = \Delta_0/2 \). On the other hand, the effective mass in Eq. (24) diverges as \( 1/2m \sim (\pi D/T)c^{-h/T} \). The fact that \( m \) remains positive at finite temperatures is related to the absence of instability toward a modulated superconducting (Fulde-Ferrell-Larkin-Ovchinnikov) state in magnetic superconductors in the presence of strong disorder, \( \tau T_{c0} \ll 1 \).

Due to its large inertia, the particle now resides in the minimum of the potential well (zero point fluctuations can be neglected): \( U_{\text{min}} = -(\pi D/16hw^2) \). The corresponding increase in critical exchange field at \( T = 0 \) is \((h_{cw} - h_c^{(2)}) = \pi D/16w^2 \). Such increase is of the order of magnitude \((\xi_s/w)^2 h_c^{(2)} \ll h_c^{(2)} \). Actually, at low temperature the transition into the superconducting state in the uniform exchange field is a first order. We may expect that the domain wall superconductivity in such situation also appears by a first order transition.

At intermediate temperature, we may obtain the critical temperature \( T = T_{cw} \) with a specific choice of the spatial dependence of rotation angle \( \phi \). Assuming that \( \phi(x) = 2 \arctan[\tanh(\xi/2w)] \), we get

\[
\ln \frac{T_{cw}}{T_c} = \frac{9}{8} \frac{T_{c0}}{w^2} F(\frac{h}{2 \pi T_c}),
\]

(27)

where

\[
F(u) = \Re \psi_1(Z) \left[ -1 + \sqrt{1 - \frac{2 \Re(i \psi(Z) + w \psi_1(Z))^2}{w \Re \psi_1(Z)}} \right]^2,
\]

(28)

where \( \psi \) and \( \psi_1 \) are digamma functions, and \( Z = 1/2 + iu \).

We should note however that transition into uniform superconducting state becomes of the first order at \( T < T^* \) and results in significant increase of the critical line \( h_c(T) \). Most probably, such change of the transition order should also be considered for localized superconductivity.

V. DISCUSSION

The qualitative picture of the effect of domains walls on the superconducting properties now emerges from our calculations.

First, the electrons of the Cooper pairs which travel across the S/F interface feel the exchange field \( h_f \) in the F layer. This proximity effect results in an effective pair breaking that weakens superconductivity in S layer. As a result, the critical temperature \( T_c \) of the bilayer gets suppressed in comparison with the critical temperature \( T_{c0} \) of the bare S film: \( T_{c0} - T_c \sim \gamma_s^{-1} \). There, the pair-breaking time \( \gamma_s \) can be estimated from Eq. (19), at \( h \ll T_{c0}, \gamma_s^{-1} \sim h^2/T_{c0} \), where \( h \) is the effective exchange field that would act directly in the bare S layer to yield
the same pair breaking effect due to $h_f$ in the bilayer. In particular, when the S/F interface is transparent and F layer is thin, we found that $h \sim h_f d_f/(d_s + d_f)$, where $d_f$ and $d_s$ are the thicknesses of F and S layers, respectively. On the other hand, when $h \gg T_{c0}$, there is no superconducting transition in the bilayer.

Second, in the vicinity of magnetic domain walls in the F layer, such pair breaking mechanism becomes less effective. Therefore, localized superconductivity may appear with critical temperature $T_{cw} > T_c$. When the domain wall width $w$ is large in comparison with superconducting coherence length $\xi_s$, the exchange field rotates by the angle $\theta \sim \xi_s/w$ on the scale of proximity effect. Therefore, the decrease of the average exchange field close to the wall is estimated as $h \sim h_{aw} \sim \theta^2 h$. Correspondingly, the pair-breaking time is increased by $\Delta \tau_s/\tau_s \sim \theta^2$. In analogy with the theory of superconductivity at twin-plane boundaries, one can estimate the increase of $T_c$:

$$
\Delta T \equiv T_{cw} - T_c \sim \frac{\theta^2 w}{\tau_s \xi(T)}.
$$

Here, the temperature dependent correlation length $\xi(T) \sim \xi_s \sqrt{T_c/\Delta T}$ is the spatial extension of the superconducting gap and it diverges close to the superconducting transition; the pair breaking is only reduced on the small portion of the gap corresponding to the width $w$ of the domain wall. On the end, the formula yields the estimate $\Delta T/T_c \sim (\xi_s/w)^2/(\tau_s T_c)^2$. Combining this result with the estimates for $\tau_s$ given in the preceding paragraph, we finally retrieve Eq. (26) qualitatively. This result holds when the width $w$ is much larger than $\xi_s$. At smaller domain wall width, weakening of pair breaking effect works on the characteristic scale $\xi_s$ of the proximity effect and $w$ should be replaced by $\xi_s$ in the estimate. Therefore, the large enhancement of $T_{cw}$, (of the order of $T_c$), can be expected when $w \lesssim \xi_s$ and $h \sim T_{c0}$.

In the present work, we confirmed quantitatively this estimate in a number of situations. In particular, we obtained that, in the case of strong enhancement of $T_{cw}$ (at $w \lesssim \xi_s$), for a thin F layer, transition into DWS state remains of the second order, with critical line above the transition into uniform superconducting state of the second order at $T > T^* = 0.56 T_{c0}$, and of the first order at $T < T^*$. We predicted that only DWS could appear in bilayers with appropriate parameters.

Let us now come back to the assumption of very thin F layer that was taken in the calculations. Usually, the exchange field in a ferromagnet is much larger than the gap in a superconductor. Therefore, the coherence length $\xi_f$ is much smaller than $\xi_s$ (1–5 nm for the former, compared to 10–50 nm for the latter). Therefore, the regime $d_f \ll \xi_f$ is quite hard to achieve with real samples of diffusive ferromagnets. Extending the calculation for thin F layer to arbitrary thickness of the layer and arbitrary transparency (characterized by $\gamma_f$) of the interface is quite straightforward when domain walls are large, as we show in the Appendix. As it is well known, the behavior of the critical temperature of the transition into uniform superconducting state is quite rich in such case and may even oscillate as a function of the parameters such as $d_f$ or $\gamma_f$. However, the physics of DWS appears to be quite similar to the one derived for thin bilayer. In particular, in the case of thick F layer ($d_f \gg \xi_f = \sqrt{D_f/h_f}$), the effective exchange field that would enter the above qualitative estimates would be $h \sim (\xi_s/d_s) \sqrt{h_f T_{c0}}$. Clearly, at $\xi_s \gg d_s$, as we assumed from the beginning, such field is much larger than $T_{c0}$ and leads therefore to superconductivity suppression. However, $h$ is strongly reduced if the S/F interface is opaque, which may lead to the F/S coexistence and to DWS appearance, as studied in this work. Nevertheless, the enhancement of $T_c$ still is small by the factor $\xi_s/w \ll 1$ in the situation described in the Appendix.

These considerations suggest two possible directions to extend the range of existence of DWS. In the present work, DWS was analyzed for S layers with thickness $d_s$ much smaller than coherence length $\xi_s$. On the other hand, DWS should not appear when the superconductor is hardly affected by proximity effect, at $d_s \gg \xi_s$. It would be of interest to consider the intermediate case when $d_s$ and $\xi_s$ are of the same order. This was studied for instance in the absence of magnetic domains in Ref. [17]. Maybe a more important point would be to address the case of DWS in S/F bilayer with narrow domain wall and large thickness of the F layer. However, both problems require considerably more numerical work, which goes beyond the scope of this paper.

A lot of attention has been devoted to the study of long range triplet proximity effect which develops in S/F structures when the direction of exchange field in the ferromagnet varies spatially. In our calculation, such long range triplet component is also present, as it is clear from the Appendix: in Eq. (A6), the term $\gamma_0 \chi_0 \tilde{z}$ in the direction transverse to the bilayer is generated only because of the presence of domain wall, and it decays with typical length $\xi_T \sim \sqrt{D_f/T} \gg \xi_f$. However, $\gamma_0$ does not enter $f_1$ and, therefore, is not important for the determination of the critical temperature of transition into DWS. In all the calculations we presented, there is no long range triplet component in the direction transverse to the wall either: the typical length for the superconducting gap is determined by conventional short range proximity effect with decay length $\sim \xi_s$. We would like to emphasize also that the $T_c$ enhancement due to the appearance of DWS is maximized for narrow domain wall (see Sec. III), when the matrix elements of the anomalous Green’s function that would give rise to long range triplet component are exactly zero. Therefore, the physics of DWS discussed here is not directly related to such phenomenon.

This observation is in agreement with Ref [16], where the calculation of critical temperature of S/F bilayers in the presence of spiral magnetic order in the F layer was presented. There also, long range triplet component was found not to contribute to the result. On the other hand,
long range triplet component may be important for other properties such as density of state in the ferromagnetic layer with domain structure deposited on top of a bulk superconducting substrate [14].

We would also like to emphasize that our calculations differ from the study of S/F bilayers in the presence of spiral magnetic order in the F layer [15]. These works can be interpreted as considerations on magnetic domain structure only in as much that the width of the domains $L$ and the width of the walls $w$ are identical. A consequence is that the superconducting gap is spatially uniform along the bilayer in Ref. [15]. In contrast, our theory really shows that, in the more realistic case when $w \ll L$, truly localized superconducting states can appear. In addition, consideration on the effect of spiral magnetic order corresponding to $\phi(x) = Qx$ in Eqs. (24,25), where $Q$ is the wavevector of the spiral, can be immediately calculated from the Schrödinger-like equation [27], at least when $Q\zeta \ll 1$. Critical temperature enhancement due to spiral magnetic order and corresponding to uniform gap $\Delta(x)$ follows straightforwardly from the observation that $\phi'(x) = Q$ which enters Eq. (24) is constant.

In conclusion, we analyzed in this work the enhancement of the superconducting critical temperature of superconducting/ferromagnetic bilayers due to the appearance of localized superconducting states in the vicinity of magnetic domain walls in the ferromagnet. We considered the case when the main mechanism of the superconductivity destruction via the proximity effect is the exchange field. We demonstrated that the influence of the domain walls on the superconducting properties of S layer may be quite strong if the domain wall thickness is of the order of superconducting coherence length.

We interpreted qualitatively and quantitatively the amplitude of this effect, and we pointed out the special case when parameters of the bilayer are such that only localized superconductivity may form in these systems.

For magnetic film with perpendicular anisotropy, the orbital effect provides an additional mechanism for the domain wall superconductivity and it may be easily taken into account. On the other hand for the film with the easy plane magnetic anisotropy the domain wall will be a source of the magnetic field in the adjacent S layer and locally weakens the superconductivity. The role of the orbital mechanism in the domain wall superconductivity may be important only if the magnetic induction is comparable with the upper critical field of the superconducting film.

The domain wall superconductivity in S/F bilayers opens an interesting way to manipulate the superconducting properties through the domain structure. In particular the motion of the domain wall in F layer may be accompanied by the displacement of the narrow superconducting region in S layer.

We are grateful to J. Aarts for attracting our attention to the problem of the domain wall superconductivity in S/F bilayers and useful discussions.

**APPENDIX A: THICK F LAYER**

As mentioned previously, $h_f$ is usually large in ferromagnets. Therefore the condition of thin F layer, $d_f \ll \xi_f$, is hardly reached. We would like to extend the results of the previous section to the more realistic situation of a finite size F layer. The difficulty is that the set of differential equations (11-14) to be solved are now two-dimensional. We managed to solve it for the case of large domain wall only. In the F layer, we parametrize the exchange field rotation with a slowly varying angle $\phi(x)$ such as $h_f = h_f(\cos \phi, \sin \phi, 0)$. Linearized Usadel equations (2) in F layer are:

$$
\frac{D_f}{2} \Delta f^{11} + |\omega| f^{11} - \frac{h_f s \omega}{2} (e^{-i \phi} f^{21} - e^{-i \phi} f^{12}) = 0,
$$

$$
\frac{D_f}{2} \Delta f^{12} + |\omega| f^{12} + ih_f s \omega e^{-i \phi} f^{11} = 0,
$$

$$
\frac{D_f}{2} \Delta f^{21} + |\omega| f^{21} - ih_f s \omega e^{i \phi} f^{11} = 0.
$$

(A1)

where $\Delta = \partial^2_x + \partial^2_z$, while $f^{22} = -f^{11}$. When the spatial dependence of $\phi$ is neglected, the general form of the solutions which satisfy boundary condition at the F/vacuum interface are:

$$
f^{11}_{0} = F_{+} \text{ch} q_z \tilde{z} + F_{-} \text{ch} q_z \tilde{z},
$$

(A2)

$$
f^{12}_{0} = s_{\omega} e^{-i \phi} \left( F_f \text{ch} q_z \tilde{z} + F_c \text{ch} q_z \tilde{z} - F_{-} \text{ch} q_z \tilde{z} \right),
$$

$$
f^{21}_{0} = -s_{\omega} e^{i \phi} \left( -F_f \text{ch} q_z \tilde{z} + F_c \text{ch} q_z \tilde{z} - F_{-} \text{ch} q_z \tilde{z} \right),
$$

where $\tilde{z} = z + d_f$, $q_0 = \sqrt{2|\omega|/D_f}$, and $q_{\pm} = \sqrt{2(|\pm i h_f + |\omega|)|/D_f}$.

We determine now the amplitudes of the eigenmodes $F_0$ and $F_{\pm}$. For this, we first determine $f_{11}$ and $\partial_z f_{11}$ at $z = 0$ in F layer. Making use of the boundary conditions (3), we can now insert them in the Usadel equation (2) in the S layer. We proceed similarly for $f_{12}$ and $f_{21}$. On the end, we get from the three equations which determine the amplitudes we are looking for. We find $F_0 = 0$, while

$$
F_{\pm} = \frac{\Delta}{2\Omega_{\pm}}, \quad \Omega_{\pm} = |\omega| C_{\pm} + \alpha q_{\pm} s \text{sh} q_{\pm} d_f,
$$

(A3)

where $C_{\pm} = c \text{ch} q_d d_f + \gamma B \xi_s q_{\pm} s \text{sh} q_{\pm} d_f$ and $\alpha = D_s \sigma_f / 2 d_s \sigma_s$.

Inserting Eqs. (A2)-(A6) into (9) to determine $f_{11}$, and then inserting $f_{11}$ in the self consistency equation (2), we get the equation defining the critical temperature $T = T_c(h)$ for uniform superconducting state:

$$
0 = \ln \frac{T}{T_c 0} + 2\pi T \text{Re} \sum_{\omega > 0} \left\{ \frac{1}{|\omega|} - \frac{1}{|\omega| + \Gamma_+} \right\},
$$

$$
\Gamma_+ = \frac{\alpha q_{\pm} \text{coth} q_{\pm} d_f + \gamma B \xi_s q_{\pm}}{\text{coth} q_{\pm} d_f + \gamma B \xi_s q_{\pm}}.
$$

(A4)

This result is the same as Eq. (47) of Ref. [1]. Whether transition is of the second order (as described by Eq. (A3)) or of the first order was considered in Ref. [21].
Let us now consider the effect of a domain wall. As in section IV, we will look for a solution $f \approx f_0 + f_1$. In leading order, the spatial dependence of $\phi$ and the gap $\Delta$ is ignored, and $f_0$ is still given by Eqs. (A2)–(A5). The correction $f_1$ accounts for the slow variations of $\phi$ and $\Delta$ along $x$-axis; it is determined by the set of equations:

$$
-\frac{D_f}{2} \partial_x^2 f_1^{11} + |\omega| f_1^{11} - \frac{h_f s_w}{2} \left(e^{-i\phi} f_1^{21}\right) - e^{-i\phi} f_1^{12} = \frac{D_f}{2} \partial_x^2 f_0^{11},
$$

$$
-\frac{D_f}{2} \partial_x^2 f_1^{12} + |\omega| f_1^{12} + i h_f s_w e^{-i\phi} f_1^{11} = \frac{D_f}{2} \partial_x^2 f_0^{12},
$$

$$
-\frac{D_f}{2} \partial_x^2 f_1^{21} + |\omega| f_1^{21} - i h_f s_w e^{i\phi} f_1^{11} = \frac{D_f}{2} \partial_x^2 f_0^{21}.
$$

Ignoring $x$-dependence of the right-hand-side of the above differential equations, we can find the exact $x$-dependent function $f_1$ which solves them. We obtain:

$$
f_1^{11} = \sum_{a = \pm} \left[ \chi q a \hat{z}^\ast \left( \frac{\Delta}{2\Omega_a} + \frac{i D_f \phi^2 \Delta}{16 h_f \Omega_a} + \gamma_a \right) - \hat{z} \chi q a \hat{z} \frac{\Delta'}{\Delta} - \frac{1}{\gamma} \frac{\phi^2 \Delta}{\Delta} \right],
$$

$$
f_1^{12,21} = \pm s_w e^{i\phi} \left[ \pm \gamma_0 \chi q a \hat{z}^\ast \sum_{a = \pm} \left[ \left( \frac{\Delta}{2\Omega_a} + \frac{i D_f \phi^2 \Delta}{16 h_f \Omega_a} \right) \chi q a \hat{z}^\ast - \chi q a \hat{z} \frac{\Delta'}{\Delta} - \frac{1}{\gamma} \frac{\phi^2 \Delta}{\Delta} \right] \right],
$$

where the integration constants $\gamma_0$ and $\gamma_\pm$ still remain to be determined. For this purpose, we insert Eqs. (A6) into (8) in order to get $f_s$ and $\partial_x^2 f_s$. Inserting them in Eq. (5), we thus obtain a set of three equations which allow to determine them. In particular, we find:

$$
\gamma_\pm = \pm \frac{i D_f \phi^2 \Delta}{16 h_f \Omega_\pm} + \frac{\Xi_\pm}{4 q s \Omega_\pm^2} \left( \Delta' - \frac{1}{2} \phi^2 \Delta \right) + \frac{D_s (C_{1 \pm} \Delta' + \frac{i \phi^2 \Delta}{\Omega_\pm^2} + \frac{C_{1 \pm}}{\Omega_\pm})}{4 \Omega_\pm}
$$

where $\Xi_\pm = |\omega| S_\pm + \alpha (s q d_f f_d + d f s_q \chi q d_f)$ and $S_\pm = d f s q d_f + \gamma B \xi (s q d_f + d f q s d_f)$.

Finally, we can insert Eqs. (A7) into (A6), and then into (9), in order to obtain $f_1^{11}$ in the S layer. Then, we insert it the self consistency equation (10). On the end, we find that the superconducting gap at the transition into DWS state is still determined by the Schrödinger equation (21), with effective coefficients:

$$
E = -\ln \frac{T}{T_c},
$$

$$
\frac{1}{2m} = \pi T \Re \sum_{\omega > 0} \left( \frac{D_s + \alpha (s h_2 d_f + 2 q s d_f)}{2 q_s \Omega_+^2} \right),
$$

$$
U(x) = -\pi T (\phi')^2 \sum_{\omega > 0} \left( D_s \left[ \frac{3}{\omega} \right]^2 - \frac{D_f}{2 h_f \Omega_+} - \frac{1}{\omega_+} \right),
$$

where $\omega_+ = \omega + \Gamma_+$.

In the limit of thin F layer ($q_s d_f \rightarrow 0$) and large transparency of S/F interface ($\gamma_B \rightarrow 0$), we note that $\Gamma_+ \approx \eta_f h_f$, and it is easily checked that the above formulas for $1/2m$ and $U(x)$ reduce to Eq. (26) from Sec. IV when $\eta_f \ll \eta_s$.

For large F films and transparent S/F interface, we find that the critical temperature is given by Eq. (A1), where $\Gamma_+ = (1 + i)h$ and $\Gamma = \alpha \sqrt{h_f / D_f}$; $\Gamma$ can be interpreted as a combination of both exchange field and spin-flip terms with equal weight. In such case, it is known that transition into uniform state is of the second order. The coefficients of Eq. (A8) also simplify to the form

$$
E = -\ln \frac{T}{T_c}, \quad \frac{1}{2m} = \pi T D_s \Re \sum_{\omega > 0} \left( \frac{1}{\omega + (1 + i)h} \right)^2,
$$

$$
U(x) = -\pi T D_s (\phi')^2 \sum_{\omega > 0} \left[ \frac{3}{\omega} - \frac{1}{\omega + (1 + i)h} \right]^2.
$$

Let us note that effective exchange field and spin-flip parameter scale is $\sim (\xi_s / d_s) \sqrt{h_f / T_c}$ if S and F layers have comparable diffusion constants and conductivities. When $d_s \ll \xi_s$, as we assumed from beginning, this leads to $\sim T_c$, and therefore to complete superconductivity suppression. However, we expect that our results hold qualitatively in more general case $\xi_s \lesssim d_s$ when superconductivity is not completely suppressed.
