Abstract

A detailed study of two-photon exchange in unpolarized and polarized elastic electron–nucleon scattering is presented, taking particular account of nucleon finite size effects. Contributions from nucleon elastic intermediate states are found to have a strong angular dependence, which leads to a partial resolution of the discrepancy between the Rosenbluth and polarization transfer measurements of the proton electric to magnetic form factor ratio, $G_E/G_M$. The two-photon exchange contribution to the longitudinal polarization transfer $P_L$ is small, whereas the contribution to the transverse polarization transfer $P_T$ is enhanced at backward angles by several percent, increasing with $Q^2$. This gives rise to a small, $\lesssim 3\%$ suppression of $G_E/G_M$ obtained from the polarization transfer ratio $P_T/P_L$ at large $Q^2$. We also compare the two-photon exchange effects with data on the ratio of $e^+p$ to $e^-p$ cross sections, which is predicted to be enhanced at backward angles. Finally, we evaluate the corrections to the form factors of the neutron, and estimate the elastic intermediate state contribution to the $^3$He form factors.

I. INTRODUCTION

Electromagnetic form factors are fundamental observables which characterize the composite nature of the nucleon. Several decades of elastic form factor experiments with electron beams, including recent high-precision measurements at Jefferson Lab and elsewhere, have provided considerable insight into the detailed structure of the nucleon.

In the standard one-photon exchange (Born) approximation, the electromagnetic current operator is parameterized in terms of two form factors, usually taken to be the Dirac ($F_1$) and Pauli ($F_2$) form factors,

$$\Gamma^\mu = F_1(q^2) \gamma^\mu + \frac{i\sigma^{\mu\nu} q_\nu}{2M} F_2(q^2),$$

where $q$ is the momentum transfer to the nucleon, and $M$ is the nucleon mass. The resulting cross section depends on two kinematic variables, conventionally taken to be $Q^2 \equiv -q^2$ (or $\tau \equiv Q^2/4M^2$) and either the scattering angle $\theta$, or the virtual photon polarization $\varepsilon = (1 + 2(1 + \tau) \tan^2(\theta/2))^{-1}$. In terms of the Sachs electric and magnetic form factors, defined as

$$G_E(Q^2) = F_1(Q^2) - \tau F_2(Q^2),$$

$$G_M(Q^2) = F_1(Q^2) + F_2(Q^2),$$

the reduced Born cross section can be written

$$\sigma_R = G_M^2(Q^2) + \frac{\varepsilon}{\tau} G_E^2(Q^2).$$

The standard method which has been used to determine the electric and magnetic form factors, particularly those of the proton, has been the Rosenbluth, or longitudinal-transverse (LT), separation method. Since the form factors in Eq. (4) are functions of $Q^2$ only, studying the cross section as a function of the polarization $\varepsilon$ at fixed $Q^2$ allows one to extract $G_M^2$ from the $\varepsilon$-intercept, and the ratio $R \equiv \mu G_E/G_M$ from the slope in $\varepsilon$, where $\mu$ is the nucleon magnetic moment. The results of the Rosenbluth measurements for the proton have generally been consistent with $R \approx 1$ for $Q^2 \lesssim 6$ GeV$^2$ \cite{1, 2, 3}. The “Super-Rosenbluth” experiment at Jefferson Lab \cite{4}, in which smaller systematic errors were achieved by detecting the recoiling proton rather than the electron, as in previous measurements, is also consistent with the earlier LT results.
An alternative method of extracting the ratio $R$ has been developed recently at Jefferson Lab \[5\], in which a polarized electron beam scatters from an unpolarized target, with measurement of the polarization of the recoiling proton. From the ratio of the transverse to longitudinal recoil polarizations one finds

$$R = -\mu \frac{E_1 + E_3}{2M} \tan \theta \frac{P_T}{P_L} = -\mu \sqrt{\frac{\tau(1 + \varepsilon)}{2\varepsilon}} \frac{P_T}{P_L},$$

(5)

where $E_1$ and $E_3$ are the initial and final electron energies, and $P_T$ ($P_L$) is the polarization of the recoil proton transverse (longitudinal) to the proton momentum in the scattering plane. The polarization transfer experiments yielded strikingly different results compared with the LT separation, with $R \approx 1 - 0.135(Q^2/\text{GeV}^2 - 0.24)$ over the same range in $Q^2 \[2\]$. Recall that in perturbative QCD one expects $F_1 \sim Q^2 F_2$ at large $Q^2$ (or equivalently $G_E \sim G_M$ \[6\]), so that these results imply a strong violation of scaling behavior (see also Refs. \[7, 8\]).

The question of which experiments are correct has been debated over the past several years. Attempts to reconcile the different measurements have been made by several authors \[9, 10, 11, 12\], who considered whether $2\gamma$ exchange effects, which form part of the radiative corrections (RCs), and which are treated in an approximate manner in the standard RC calculations \[13\], could account for the observed discrepancy. An explicit calculation \[10\] of the two-photon exchange diagram, in which nucleon structure effects were for the first time fully incorporated, indeed showed that around half of the discrepancy could be removed just by the nucleon elastic intermediate states. A partonic level calculation \[11, 12\] subsequently showed that the deep inelastic region can also contribute significantly to the box diagram.

In this paper we further develop the methodology introduced in Ref. \[10\], and apply it to systematically calculate the $2\gamma$ exchange effects in a number of electron–nucleon scattering observables. We focus on the nucleon elastic intermediate states; inelastic contributions are discussed elsewhere \[14\]. In Sec. II we examine the effects of $2\gamma$ exchange on the ratio of electric to magnetic form factors in unpolarized scattering. In contrast to the earlier analysis \[10\], in which simple monopole form factors were utilized at the internal $\gamma NN$ vertices, here we parameterize the vertices by realistic form factors, and study the model-dependence of effects on the ratio $R$ due to the choice of form factors. We also compare the results with data on the ratio of $e^+p$ to $e^-p$ scattering cross sections, which is directly sensitive to $2\gamma$ exchange effects.

In Sec. III we examine the effects of $2\gamma$ exchange on the polarization transfer reaction,
\[ \vec{e}p \rightarrow e\vec{p}, \] for both longitudinally and transversely polarized recoil protons. We also consider the case of proton polarization normal to the reaction plane, which depends on the imaginary part of the box diagram. Since this is absent in the Born approximation, the normal polarization provides a clean signature of $2\gamma$ exchange effects, even though it does not directly address the $G^p_{E}/G^p_{M}$ discrepancy. Following the discussion of the proton, in Sec. IV we consider $2\gamma$ exchange corrections to the form factors of the neutron, both for the LT separation and polarization transfer techniques. Applying the same formalism to the case of the $^3$He nucleus, in Sec. V we compute the elastic contribution from the box diagram to the ratio of charge to magnetic form factors of $^3$He. In Sec. VI we summarize our findings, and discuss future work.

II. TWO-PHOTON EXCHANGE IN UNPOLARIZED SCATTERING

In this section we outline the formalism used to calculate the $2\gamma$ exchange contribution to the unpolarized electron–nucleon cross section, and examine the effect on the $G^p_{E}/G^p_{M}$ ratio extracted using LT separation. Since there are in general three form factors that are needed to describe elastic $eN$ scattering beyond $1\gamma$ exchange, we also evaluate the $2\gamma$ contributions to each of the form factors separately. In the final part of this section, we examine the effect of the $2\gamma$ correction on the ratio of $e^+p$ to $e^-p$ elastic cross sections, which is directly sensitive to $2\gamma$ exchange effects.

A. Formalism

For the elastic scattering process we define the momenta of the initial electron and nucleon as $p_1$ and $p_2$, and of the final electron and nucleon as $p_3$ and $p_4$, respectively, $e(p_1) + p(p_2) \rightarrow e(p_3) + p(p_4)$. The four-momentum transferred from the electron to the nucleon is given by $q = p_4 - p_2 = p_1 - p_3$ (with $Q^2 \equiv -q^2 > 0$), and the total electron and proton invariant mass squared is given by $s = (p_1 + p_2)^2 = (p_3 + p_4)^2$. In the Born approximation, the amplitude can be written

\[ \mathcal{M}_0 = -i\frac{e^2}{q^2} \bar{u}(p_3) \gamma_\mu u(p_1) \bar{u}(p_4) \Gamma^\mu(q) u(p_2), \] (6)
where $e$ is the electron charge, and $\Gamma^\mu$ is given by Eq. (1). In terms of the amplitude $\mathcal{M}_0$, the corresponding differential Born cross section is given by

$$
\frac{d\sigma_0}{d\Omega} = \left( \frac{\alpha}{4Mq^2 E_1} \frac{E_3}{E_1} \right)^2 |\mathcal{M}_0|^2 = \sigma_{\text{Mott}} \frac{\tau}{\varepsilon (1 + \tau)} \sigma_R ,
$$

where $\sigma_R$ is the reduced cross section given in Eq. (4), and the Mott cross section for the scattering from a point particle is

$$
\sigma_{\text{Mott}} = \frac{\alpha^2 E_3 \cos^2 \frac{\theta}{2}}{4E_1^2 \sin^4 \frac{\theta}{2}} ,
$$

with $E_1$ and $E_3$ the initial and final electron energies, and $\alpha = e^2/4\pi$ the electromagnetic fine structure constant. Including radiative corrections to order $\alpha$, the elastic scattering cross section is modified as

$$
\frac{d\sigma_0}{d\Omega} \rightarrow \frac{d\sigma}{d\Omega} (1 + \delta) ,
$$

where $\delta$ includes one-loop virtual corrections (vacuum polarization, electron and proton vertex, and two photon exchange corrections), as well as inelastic bremsstrahlung for real photon emission [13].

According to the LT separation technique, one extracts the ratio $R^2$ from the $\varepsilon$ dependence of the cross section at fixed $Q^2$. Because of the factor $\varepsilon/\tau$ multiplying $G_E^2$ in Eq. (4), the cross section becomes dominated by $G_M^2$ with increasing $Q^2$, while the relative contribution of the $G_E^2$ term is suppressed. Hence understanding the $\varepsilon$ dependence of the radiative correction $\delta$ becomes increasingly important at high $Q^2$. As pointed out in Ref. [2], for example, a few percent change in the $\varepsilon$ slope in $d\sigma$ can lead to a sizable effect on $R$. In contrast, as we discuss in Sec. III below, the polarization transfer technique does not show the same sensitivity to the $\varepsilon$ dependence of $\delta$.

If we denote the amplitude for the one-loop virtual corrections by $\mathcal{M}_1$, then $\mathcal{M}_1$ can be written as the sum of a “factorizable” term, proportional to the Born amplitude $\mathcal{M}_0$, and a non-factorizable part $\overline{\mathcal{M}}_1$,

$$
\mathcal{M}_1 = f(Q^2, \varepsilon) \mathcal{M}_0 + \overline{\mathcal{M}}_1 .
$$

The ratio of the full cross section (to order $\alpha$) to the Born can therefore be written as

$$
1 + \delta = \frac{|\mathcal{M}_0 + \mathcal{M}_1|^2}{|\mathcal{M}_0|^2} ,
$$
with $\delta$ given by
\[
\delta = 2f(Q^2, \varepsilon) + \frac{2\text{Re}\{M_0^\dagger M_1\}}{|M_0|^2}.
\] (12)

In practice the factorizable terms parameterized by $f(Q^2, \varepsilon)$, which includes the electron vertex correction, vacuum polarization, and the infrared (IR) divergent parts of the nucleon vertex and two-photon exchange corrections, are found to be dominant. Furthermore, these terms are all essentially independent of hadronic structure.

However, as explained in Ref. [10], the contributions to the functions $f(Q^2, \varepsilon)$ from the electron vertex, vacuum polarization, and proton vertex terms depend only on $Q^2$, and therefore have no relevance for the LT separation aside from an overall normalization factor. Hence, of the factorizable terms, only the IR divergent two-photon exchange contributes to the $\varepsilon$ dependence of the virtual photon corrections.

The terms which do depend on hadronic structure are contained in $M_1$, and arise from the finite nucleon vertex and two-photon exchange corrections. For the case of the proton, the hadronic vertex correction was analyzed by Maximon and Tjon [15], and found to be $< 0.5\%$ for $Q^2 < 6$ GeV$^2$. Since the proton vertex correction does not have a strong $\varepsilon$ dependence, it will not affect the LT analysis, and can be safely neglected.

For the inelastic bremsstrahlung cross section, the amplitude for real photon emission can also be written in the form of Eq. (10). In the soft photon approximation the amplitude is completely factorizable. A significant $\varepsilon$ dependence arises due to the frame dependence of the angular distribution of the emitted photon. These corrections, together with external bremsstrahlung, contain the main $\varepsilon$ dependence of the radiative corrections, and are usually accounted for in the experimental analyses. They are generally well understood, and in fact enter differently depending on whether the electron or proton are detected in the final state. Hence corrections beyond the standard $\mathcal{O}(\alpha)$ radiative corrections which can lead to non-negligible $\varepsilon$ dependence are confined to the $2\gamma$ exchange diagrams, illustrated in Fig. and are denoted by $M^{2\gamma}$, which we will focus on in the following. The $2\gamma$ exchange correction $\delta^{2\gamma}$ which we calculate is then essentially
\[
\delta^{2\gamma} \rightarrow \frac{2\text{Re}\{M_0^\dagger M^{2\gamma}\}}{|M_0|^2}.
\] (13)

In principle the two-photon exchange amplitude $M^{2\gamma}$ includes all possible hadronic intermediate states in Fig. Here we consider only the elastic contribution to the full response
function, and assume that the proton propagates as a Dirac particle (excited state contributions are considered in Ref. [14]). We also assume that the structure of the off-shell current operator is similar to that in Eq. (1), and use phenomenological form factors at the $\gamma NN$ vertices. This is of course the source of the model dependence in the problem. Clearly this also creates a tautology, as the radiative corrections are also used to determine the experimental form factors. However, because $\delta$ is a ratio, the model dependence cancels somewhat, provided the same phenomenological form factors are used for both $M_0$ and $M^{2\gamma}$ in Eq. (13).

The total $2\gamma$ exchange amplitude, including the box and crossed box diagrams in Fig. 1, has the form

\[
\mathcal{M}^{2\gamma} = e^4 \int \frac{d^4k}{(2\pi)^4} \frac{N_{\text{box}}(k)}{D_{\text{box}}(k)} + e^4 \int \frac{d^4k}{(2\pi)^4} \frac{N_{\text{x-box}}(k)}{D_{\text{x-box}}(k)},
\]

where the numerators are the matrix elements

\[
N_{\text{box}}(k) = \bar{u}(p_3)\gamma_\nu(p_1 - k + m)\gamma_\mu u(p_1) \times \bar{u}(p_4)\Gamma^\mu(q - k)(p_2 + k + M)\Gamma^\nu(k)u(p_2),
\]

\[
N_{\text{x-box}}(k) = \bar{u}(p_3)\gamma_\nu(p_3 + k + m)\gamma_\mu u(p_1) \times \bar{u}(p_4)\Gamma^\mu(q - k)(p_2 + k + M)\Gamma^\nu(k)u(p_2),
\]

and the denominators are products of propagators

\[
D_{\text{box}}(k) = [k^2 - \lambda^2][(k - q)^2 - \lambda^2]
\times[(p_1 - k)^2 - m^2][(p_2 + k)^2 - M^2],
\]

\[
D_{\text{x-box}}(k) = D_{\text{box}}(k)|_{p_1 - k \rightarrow p_3 + k}.
\]

An infinitesimal photon mass $\lambda$ has been introduced in the photon propagator to regulate the IR divergences. The IR divergent part is of interest since it is the one usually included in the standard RC analyses. The finite part, which is typically neglected, has been included in Ref. [10] and found to have significant $\varepsilon$ dependence.

The IR divergent part of the amplitude $\mathcal{M}^{2\gamma}$ can be separated from the IR finite part by analyzing the structure of the photon propagators in the integrand of Eq. (14). The two poles, where the photons are soft, occur at $k = 0$ and at $k = q$. The dominant (IR divergent) contribution to the integral (14) comes from the poles, and one therefore typically makes
the approximation
\[
\mathcal{M}_{\text{IR}}^{2\gamma} \approx e^4 N_{\text{box}}(0) \int \frac{d^4k}{(2\pi)^4} \frac{1}{D_{\text{box}}(k)} + e^4 N_{x-\text{box}}(0) \int \frac{d^4k}{(2\pi)^4} \frac{1}{D_{x-\text{box}}(k)},
\]
with
\[
N_{\text{box}}(q) = N_{\text{box}}(0) = 4i p_1 \cdot p_2 \frac{q^2 M_0}{c^2},
\]
\[
N_{x-\text{box}}(q) = N_{x-\text{box}}(0) = 4i p_3 \cdot p_2 \frac{q^2 M_0}{c^2}.
\]

In this case the IR divergent contribution is proportional to the Born amplitude, and the corresponding correction to the Born cross section is independent of hadronic structure.

The remaining integrals over propagators can be done analytically. In the target rest frame the total IR divergent two-photon exchange contribution to the cross section is found to be
\[
\delta_{\text{IR}} = -\frac{2\alpha}{\pi} \ln \left( \frac{E_1}{E_3} \right) \ln \left( \frac{Q^2}{\lambda^2} \right),
\]
a result given by Maximon and Tjon [15]. The logarithmic IR singularity in \( \lambda \) is exactly cancelled by a corresponding term in the bremsstrahlung cross section involving the interference between real photon emission from the electron and from the nucleon.

By contrast, in the standard treatment of Mo and Tsai (MT) [13] a different approximation for the integrals over propagators is introduced. Here, the IR divergent contribution to the cross section is
\[
\delta_{\text{IR}}(\text{MT}) = -2\frac{\alpha}{\pi} (K(p_1, p_2) - K(p_3, p_2)),
\]
where \( K(p_i, p_j) = p_i \cdot p_j \int_0^1 dy \ln \left( \frac{p_y^2/\lambda^2}{p_y^2} \right) \) and \( p_y = p_i y + p_j (1 - y) \). The logarithmic dependence on \( \lambda \) is the same as Eq. (22), however.

As mentioned above, the full expression in Eq. (14) includes both finite and IR divergent terms, and form factors at the \( \gamma NN \) vertices. In Ref. 10 the proton form factors \( F_1 \) and \( F_2 \) were expressed in terms of the Sachs electric and magnetic form factors,
\[
F_1(Q^2) = \frac{G_E(Q^2) + \tau G_M(Q^2)}{1 + \tau},
\]
\[
F_2(Q^2) = \frac{G_M(Q^2) - G_E(Q^2)}{1 + \tau},
\]
with \( G_E \) and \( G_M \) both parameterized by a simple monopole form, \( G_{E,M}(Q^2) \sim \Lambda^2/(\Lambda^2 + Q^2) \), with the mass parameter \( \Lambda \) related to the size of the proton. In the present analysis
we generalize this approach by using more realistic form factors in the loop integration, consistent with the actual $G_{E,M}$ data. The functions $F_1$ and $F_2$ are parameterized directly in terms of sums of monopoles, of the form

$$F_{1,2}(Q^2) = \sum_{i=1}^{N} \frac{n_i}{d_i + Q^2},$$

where $n_i$ and $d_i$ are free parameters, and $n_N$ is determined from the normalization condition, $n_N = d_N(F_{1,2}(0) - \sum_{i=1}^{N-1} n_i/d_i)$. The parameters $n_i$ and $d_i$ for the $F_1$ and $F_2$ form factors of the proton and neutron are given in Table I. The normalization conditions are $F_1^p(0) = 1$ and $F_2^p(0) = \kappa_p$ for the proton, and $F_1^n(0) = 0$ and $F_2^n(0) = \kappa_n$ for the neutron, where $\kappa_p = 1.793$ and $\kappa_n = -1.913$ are the proton and neutron anomalous magnetic moments, respectively.

In practice we use the parameterization from Ref. [16], and fit the parameterized form factors a sum of three monopoles, except for $F_2^n$, which is fitted with $N = 2$. As discussed in the next section, the sensitivity of the results to the choice of form factor is relatively mild. Of course, one should note that the data to which the form factors are fitted were extracted under the assumption of $1\gamma$ exchange, so that in principle one should iterate the data extraction and fitting procedure for self-consistency. However, within the accuracy of the data and of the $2\gamma$ calculation the effect of this will be small.

To obtain the radiatively corrected cross section for unpolarized electron scattering the polarizations of the incoming and outgoing electrons and nucleons in Eqs. (15) and (16) need to be averaged and summed, respectively. The resulting expression involves a product of traces in the Dirac spaces of the electron and nucleon. The trace algebra is tedious but straightforward. It was carried out using the algebraic program FORM [17] and verified independently using the program Tracer [18]. We also used two independent Mathematica packages (FeynCalc [19] and FormCalc [20]) to carry out the loop integrals. The packages gave distinct but equivalent analytic expressions, which gave identical numerical results. The loop integrals in Eq. (14) can be expressed in terms of four-point Passarino-Veltman functions [21], which have been calculated using Spence function [22] as implemented by Veltman [23]. In the actual calculations we have used the FF program [24]. The results of the proton calculation are presented in the following section.
B. 2γ Corrections to Proton Form Factors

In typical experimental analyses of electromagnetic form factor data [1], radiative corrections are implemented using the prescription of Ref. [13], including using Eq. (23) to approximate the $2\gamma$ contribution. To investigate the effect of our results on the data analyzed in this manner, we will therefore compare the $\varepsilon$ dependence of the full calculation with that of $\delta_{\text{IR}}(\text{MT})$. To make the comparison meaningful, we will consider the difference

$$\Delta \equiv \delta_{\text{full}} - \delta_{\text{IR}}(\text{MT}),$$

in which the IR divergences cancel, and which is independent of $\lambda$.

The results for the difference $\Delta$ between the full calculation and the MT approximation are shown in Fig. 2 for several values of $Q^2$ from 1 to 6 GeV$^2$. The additional corrections are most significant at low $\varepsilon$, and essentially vanish at large $\varepsilon$. At the lower $Q^2$ values $\Delta$ is approximately linear in $\varepsilon$, but significant deviations from linearity are observed with increasing $Q^2$, especially at smaller $\varepsilon$.

In Fig. 3(a) we illustrate the model dependence of the results by comparing the results in Fig. 2 at $Q^2 = 1$ and 6 GeV$^2$ with those obtained using a dipole form for the $F_1^p$ and $F_2^p$ form factors, with mass $\Lambda = 0.84$ GeV. At the lower, $Q^2 = 1$ GeV$^2$, value the model dependence is very weak, with essentially no change at all in the slope. For the larger value $Q^2 = 6$ GeV$^2$ the differences are slightly larger, but the general trend of the correction remains unchanged. We can conclude therefore that the model dependence of the calculation is quite modest. Also displayed is the correction at $Q^2 = 12$ GeV$^2$, which will be accessible in future experiments, showing significant deviations from linearity over the entire $\varepsilon$ range.

The results are also relatively insensitive to the high-$Q^2$ behavior of the $G_E^p/G_M^p$ ratio, as Fig. 3(b) illustrates. Here the correction $\Delta$ is shown at $Q^2 = 6$ GeV$^2$ calculated using various form factor inputs, from parameterizations obtained by fitting only the LT-separated data [16, 25], and those in which $G_E^p$ is constrained by the polarization transfer data [25, 26]. The various curves are almost indistinguishable, and the dependence on the form factor inputs at lower $Q^2$ is expected to be even weaker than that in Fig. 3(b).

The effect of the $2\gamma$ corrections on the cross sections can be seen in Fig. 4, where the reduced cross section $\sigma_R$, scaled by the square of the dipole form factor,

$$G_D = \left(1 + \frac{Q^2}{0.71 \text{ GeV}^2}\right)^{-2},$$

is given as a function of $Q^2$.
is plotted as a function of $\varepsilon$ for several fixed values of $Q^2$. In Fig. 4(a) the results are compared with the SLAC data \cite{27} at $Q^2 = 3.25, 4, 5$ and $6$ GeV$^2$, and with data from the “Super-Rosenbluth” experiment at JLab \cite{4} in Fig. 4(b). In both cases the Born level results (dotted curves), which are obtained using the form factor parameterization of Ref. \cite{26} in which $G_E^p$ is fitted to the polarization transfer data \cite{5}, have slopes which are significantly shallower than the data. With the inclusion of the $2\gamma$ contribution (solid curves), there is a clear increase of the slope, with some nonlinearity evident at small $\varepsilon$. The corrected results are clearly in better agreement with the data, although do not reproduce the entire correction necessary to reconcile the Rosenbluth and polarization transfer measurements.

To estimate the influence of these corrections on the electric to magnetic proton form factor ratio, the simplest approach is to examine how the $\varepsilon$ slope changes with the inclusion of the $2\gamma$ exchange. Of course, such a simplified analysis can only be approximate since the $\varepsilon$ dependence is only linear over limited regions of $\varepsilon$, with clear deviations from linearity at low $\varepsilon$ and high $Q^2$. In the actual data analyses one should apply the correction $\Delta$ directly to the data, as in Fig. 4. However, it is still instructive to obtain an estimate of the effect on $R$ by taking the slope over several ranges of $\varepsilon$.

Following Ref. \cite{10}, this can be done by fitting the correction $(1 + \Delta)$ to a linear function of $\varepsilon$, of the form $a + b\varepsilon$, for each value of $Q^2$ at which the ratio $R$ is measured. The corrected reduced cross section in Eq. (4) then becomes

$$\sigma_R \approx a G_M^2(Q^2) \left[ 1 + \frac{\varepsilon}{\mu^2 \tau} \left( R^2 [1 + \varepsilon b/a] + \mu^2 \tau b/a \right) \right],$$

(29)

where

$$R^2 = \frac{\tilde{R}^2 - \mu^2 \tau b/a}{1 + \varepsilon b/a}$$

(30)

is the “true” form factor ratio, corrected for $2\gamma$ exchange effects, and $\tilde{R}$ is the “effective” ratio, contaminated by $2\gamma$ exchange. Note that in Eqs. (29) and (30) we have effectively linearized the quadratic term in $\varepsilon$ by taking the average value of $\varepsilon$ (i.e., $\bar{\varepsilon}$) over the $\varepsilon$ range being fitted. In contrast to Ref. \cite{10}, where the approximation $a \approx 1$ was made and the quadratic term in $\varepsilon$ neglected, the use of the full expression in Eq. (30) leads to a small decrease in $R$ compared with the approximate form.

The shift in $R$ is shown in Fig. 5 together with the polarization transfer data. We consider two ranges for $\varepsilon$: a large range $\varepsilon = 0.2 - 0.9$, and a more restricted range $\varepsilon = 0.5 - 0.8$. The approximation of linear $\varepsilon$ dependence of $\Delta$ should be better for the latter, even though
in practice experiments typically sample values of $\varepsilon$ near its lower and upper bounds. A proposed experiment at Jefferson Lab \cite{28} aims to test the linearity of the $\varepsilon$ plot through a precision measurement of the unpolarized elastic cross section.

The effect of the $2\gamma$ exchange terms on $R$ is clearly significant. As observed in Ref. \cite{10}, the $2\gamma$ corrections have the proper sign and magnitude to resolve a large part of the discrepancy between the two experimental techniques. In particular, the earlier results in Ref. \cite{10} using simple monopole form factors found a shift similar to that in for the $\varepsilon = 0.5 \rightarrow 0.8$ range in Fig. 5, which resolves around 1/2 of the discrepancy. The nonlinearity at small $\varepsilon$ makes the effective slope somewhat larger if the $\varepsilon$ range is taken between 0.2 and 0.9. The magnitude of the effect in this case is sufficient to bring the LT and polarization transfer points almost to agreement, as indicated in Fig. 5.

While the $2\gamma$ corrections clearly play a vital role in resolving most of the form factor discrepancy, it is instructive to understand the origin of the effect on $R$ with respect to contributions to the individual $G_E^p$ and $G_M^p$ form factors. In general the amplitude for elastic scattering of an electron from a proton, beyond the Born approximation, can be described by three (complex) form factors, $\tilde{F}_1$, $\tilde{F}_2$ and $\tilde{F}_3$. The generalized amplitude can be written as \cite{9, 11}

$$
\mathcal{M} = -ie^2 q^2 \bar{u}(p_3) \gamma_\mu u(p_1) \bar{u}(p_4) \left( \tilde{F}_1 \gamma^\mu + \tilde{F}_2 \frac{i\sigma^{\mu\nu} q_\nu}{2M} + \tilde{F}_3 \frac{\gamma \cdot K}{M^2} \right) u(p_2),
$$

where $K = (p_1 + p_3)/2$ and $P = (p_2 + p_4)/2$. The functions $\tilde{F}_i$ (both real and imaginary parts) are in general functions of $Q^2$ and $\varepsilon$. In the $1\gamma$ exchange limit the $\tilde{F}_{1,2}$ functions approach the usual (real) Dirac and Pauli form factors, while the new form factor $\tilde{F}_3$ exists only at the $2\gamma$ level and beyond,

$$
\tilde{F}_{1,2}(Q^2, \varepsilon) \rightarrow F_{1,2}(Q^2),
$$

$$
\tilde{F}_3(Q^2, \varepsilon) \rightarrow 0.
$$

Alternatively, the amplitude can be expressed in terms of the generalized (complex) Sachs electric and magnetic form factors, $\tilde{G}_E = G_E + \delta G_E$ and $\tilde{G}_M = G_M + \delta G_M$, in which case the reduced cross section, up to order $\alpha^2$ corrections, can be written \cite{11}

$$
\tilde{\sigma}_R = G_M^2 + \frac{\varepsilon}{\tau} G_E^2 + 2G_M^2 \text{Re} \left\{ \frac{\delta G_M}{G_M} + \varepsilon Y_{2\gamma} \right\} + \frac{2\varepsilon}{\tau} G_E^2 \text{Re} \left\{ \frac{\delta G_E}{G_E} + \frac{G_M}{G_E} Y_{2\gamma} \right\},
$$

(34)
where the form factor $\bar{F}_3$ has been expressed in terms of the ratio

$$Y_{2\gamma} = \bar{\nu} \frac{\bar{F}_3}{G_M},$$

with $\bar{\nu} \equiv K \cdot P/M^2 = \sqrt{\tau(1 + \tau)(1 + \varepsilon)/(1 - \varepsilon)}$. We should emphasize that the generalized form factors are not observables, and therefore have no intrinsic physical meaning. Thus the magnitude and $\varepsilon$ dependence of the generalized form factors will depend on the choice of parametrization of the generalized amplitude. For example, the axial parametrization introduces an effective axial vector coupling beyond Born level, and is written as

$$\mathcal{M} = -i\frac{e^2}{q^2} \left\{ \bar{u}(p_3)\gamma_\mu u(p_1) \bar{u}(p_4) \left( F'_1 \gamma^\mu + F'_2 \frac{i\sigma^{\mu\nu}q_\nu}{2M} \right) u(p_2) + G'_A \bar{u}(p_3)\gamma_\mu\gamma_5 u(p_1) \bar{u}(p_4)\gamma^\mu\gamma_5 u(p_2) \right\}.$$ 

(36)

Following Ref. [12], one finds the relationships

$$F'_1 = \bar{F}_1 + \bar{\nu}\bar{F}_3,$$

(37)

$$F'_2 = \bar{F}_2,$$

(38)

$$G'_A = -\tau\bar{F}_3.$$ 

(39)

In Fig. 6 we show the contributions of $2\gamma$ exchange to the (real parts of the) proton $\bar{G}_E$ and $\bar{G}_M$ form factors, and the ratio $Y_{2\gamma}$ evaluated at $Q^2 = 1, 3$ and $6$ GeV$^2$. One observes that the $2\gamma$ correction to $\bar{G}_M$ is large, with a positive slope in $\varepsilon$ which increases with $Q^2$. The correction to $\bar{G}_E$ is similar to that for $\bar{G}_M$ at $Q^2 = 1$ GeV$^2$, but becomes shallower at intermediate $\varepsilon$ values for larger $Q^2$. Both of these corrections are significantly larger than the $Y_{2\gamma}$ correction, which is weakly $Q^2$ dependent, and has a small negative slope in $\varepsilon$ at larger $Q^2$. The contribution to $Y_{2\gamma}$ is found to be about 5 times smaller than that extracted in phenomenological analyses under the assumption that the entire form factor discrepancy is due to the new $\bar{F}_3$ contribution (see also Ref. [30]).

C. **Comparison of $e^+p$ to $e^-p$ cross sections**

Direct experimental evidence for the contribution of $2\gamma$ exchange can be obtained by comparing $e^+p$ and $e^-p$ cross sections through the ratio

$$R^{e^+e^-} \equiv \frac{d\sigma(e^+)}{d\sigma(e^-)}.$$
\[ \left| \mathcal{M}_0(e^+) \right|^2 + 2 \Re \left\{ \mathcal{M}_0(e^+) \dagger \mathcal{M}^{2\gamma}(e^+) \right\} \approx \left| \mathcal{M}_0(e^-) \right|^2 + 2 \Re \left\{ \mathcal{M}_0(e^-) \dagger \mathcal{M}^{2\gamma}(e^-) \right\}. \]  \quad (40)

Whereas the Born amplitude \( \mathcal{M}_0 \) changes sign under the interchange \( e^- \leftrightarrow e^+ \), the \( 2\gamma \) exchange amplitude \( \mathcal{M}^{2\gamma} \) does not. The interference of the \( \mathcal{M}_0 \) and \( \mathcal{M}^{2\gamma} \) amplitudes therefore has the opposite sign for electron and positron scattering. Since the finite part of the \( 2\gamma \) contribution is negative over most of the range of \( \varepsilon \), one would expect to see an enhancement of the ratio of \( e^+ \) to \( e^- \) cross sections,

\[ R_{e^+e^-} \approx 1 - 2\Delta, \]  \quad (41)

where \( \Delta \) is defined in Eq. (27).

Although the current data on elastic \( e^-p \) and \( e^+p \) scattering are sparse, there are some experimental constraints from old data taken at SLAC \[31, 32\], Cornell \[33\], DESY \[34\] and Orsay \[35\] (see also Ref. \[36\]). The data are predominantly at low \( Q^2 \) and at forward scattering angles, corresponding to large \( \varepsilon (\varepsilon > 0.7) \), where the \( 2\gamma \) exchange contribution is small (\( \lesssim 1\% \)). Nevertheless, the overall trend in the data reveals a small enhancement in \( R_{e^+e^-} \) at the lower \( \varepsilon \) values, as illustrated in Fig. 4 (which shows a subset of the data, from the SLAC experiments \[31, 32\]).

The data in Fig. 4 are compared with our theoretical results, calculated for several fixed values of \( Q^2 \) (\( Q^2 = 1, 3 \) and \( 6 \) GeV\(^2 \)). The results are in good agreement with the data, although the errors on the data points are quite large. Clearly better quality data at backward angles, where an enhancement of up to \( \sim 10\% \) is predicted, would be needed for a more definitive test of the \( 2\gamma \) exchange mechanism. An experiment \[37\] using a beam of \( e^+e^- \) pairs produced from a secondary photon beam at Jefferson Lab will make simultaneous measurements of \( e^-p \) and \( e^+p \) elastic cross sections up to \( Q^2 \sim 2 \) GeV\(^2 \). A proposal to perform a precise (\( \sim 1\% \)) comparison of \( e^-p \) and \( e^+p \) scattering at \( Q^2 = 1.6 \) GeV\(^2 \) and \( \varepsilon \approx 0.4 \) has also been made at the VEPP-3 storage ring \[38\].

III. POLARIZED ELECTRON–PROTON SCATTERING

The results of the \( 2\gamma \) exchange calculation in the previous section give a clear indication of a sizable correction to the LT-separated data at moderate and large \( Q^2 \). The obvious question which arises is whether, and to what extent, the \( 2\gamma \) exchange affects the polarization
transfer results, which show the dramatic fall-off of the $G_E^p/G_M^p$ ratio at large $Q^2$. In this section we examine this problem in detail.

The polarization transfer experiment involves the scattering of longitudinally polarized electrons from an unpolarized proton target, with the detection of the polarization of the recoil proton, $e^+ + p \rightarrow e^- + p'$. (The analogous process whereby a polarized electron scatters elastically from a polarized proton leaving an unpolarized final state gives rise to essentially the same information.) In the Born approximation the spin dependent amplitude is given by

$$
\mathcal{M}_0(s_1, s_4) = -i \frac{e^2}{q^2} \bar{u}(p_3) \gamma_\mu u(p_1, s_1) \bar{u}(p_4, s_4) \Gamma^\mu(q) u(p_2),
$$

(42)

where $s_1 = (s_1^0; \vec{s}_1)$ and $s_4 = (s_4^0; \vec{s}_4)$ are the spin four-vectors of the initial electron and final proton, respectively, and the spinor $u(p_1, s_1)$ is defined such that $u(p_1, s_1)\bar{u}(p_1, s_1) = (\gamma_1 + m)(1 + \gamma_5\gamma_1)/2$, and similarly for $\bar{u}(p_4, s_4)$. The spin four-vector (for either the electron or recoil proton) can be written in terms of the 3-dimensional spin vector $\vec{\zeta}$ specifying the spin direction in the rest frame (see e.g. Ref. [39]),

$$
s^\mu = \left( \frac{\vec{\zeta} \cdot \vec{p}}{m}; \vec{\zeta} + \vec{p}\frac{\vec{\zeta} \cdot \vec{p}}{m(m + E)} \right),
$$

(43)

where $m$ and $E$ are the mass and energy of the electron or proton. Clearly in the limit $\vec{p} \rightarrow 0$, the spin four-vector $s \rightarrow (0; \vec{\zeta})$. Since $\zeta$ is a unit vector, one has $\vec{\zeta}^2 = 1$, and one can verify from Eq. (43) that $s^2 = -1$ and $p \cdot s = 0$. If the incident electron energy $E_1$ is much larger than the electron mass $m$, the electron spin four-vector can be related to the electron helicity $h = \vec{\zeta}_1 \cdot \vec{p}_1$ by

$$
s_1 \approx h \frac{p_1}{m}.
$$

(44)

The coordinate axes are chosen so that the recoil proton momentum $\vec{p}_4$ defines the $z$ axis, in which case for longitudinally polarized protons one has $\vec{\zeta} = \vec{p}_4$. In the $1\gamma$ exchange approximation the elastic cross section for scattering a longitudinally polarized electron with a recoil proton polarized longitudinally is then given by

$$
\frac{d\sigma^{(L)}}{d\Omega} = h \sigma_{\text{Mott}} \frac{E_1 + E_3}{M} \sqrt{\frac{\tau}{1 + \tau}} \tan^2 \frac{\theta}{2} G_M^2.
$$

(45)

For transverse recoil proton polarization we define the $x$ axis to be in the scattering plane, $\hat{x} = \hat{y} \times \hat{z}$, where $\hat{y} = \hat{p}_1 \times \hat{p}_3$ defines the direction perpendicular, or normal, to the scattering
plane. The elastic cross section for producing a transversely polarized proton in the final state, with \( \vec{\zeta} \cdot \vec{p}_4 = 0 \), is given by

\[
\frac{d\sigma^{(T)}}{d\Omega} = \hbar \sigma_{\text{Mott}} 2 \sqrt{1 + \frac{\tau}{\tan \frac{\theta}{2}}} G_E G_M .
\]  

(46)

Taking the ratio of the transverse to longitudinal proton cross sections then gives the ratio of the electric to magnetic proton form factors, as in Eq. (5). Note that in the 1\( \gamma \) exchange approximation the normal polarization is identically zero.

The amplitude for the 2\( \gamma \) exchange diagrams in Fig. 1 with the initial electron and final proton polarized can be written as

\[
\mathcal{M}^{2\gamma}(s_1, s_4) = e^4 \int \frac{d^4k}{(2\pi)^4} \frac{N_{\text{box}}(k, s_1, s_4)}{D_{\text{box}}(k)} + e^4 \int \frac{d^4k}{(2\pi)^4} \frac{N_{x-\text{box}}(k, s_1, s_4)}{D_{x-\text{box}}(k)} ,
\]  

(47)

where the numerators are the matrix elements

\[
N_{\text{box}}(k, s_1, s_4) = \bar{u}(p_3) \gamma_\mu (p_1 - \frac{p}{k} + m) \gamma_\nu u(p_1, s_1) \times \bar{u}(p_4, s_4) \Gamma^\mu(q - k)(p_2 + \frac{p}{k} + M) \Gamma^\nu(k) u(p_2) ,
\]  

(48)

\[
N_{x-\text{box}}(k, s_1, s_4) = \bar{u}(p_3) \gamma_\nu(p_2 + \frac{p}{k} + M) \gamma_\mu u(p_1, s_1) \times \bar{u}(p_4, s_4) \Gamma^\mu(q - k)(p_2 + \frac{p}{k} + M) \Gamma^\nu(k) u(p_2) ,
\]  

(49)

and the denominators are given in Eqs. (17) and (18). The traces in Eqs. (48) and (49) can be evaluated using the explicit expression for the spin-vectors \( s_1 \) and \( s_4 \) in Eqs. (43) and (44).

In analogy with the unpolarized case (see Eq. (27)), the spin-dependent corrections to the longitudinal (\( \Delta_L \)) and transverse (\( \Delta_T \)) cross sections are defined as the finite parts of the 2\( \gamma \) contributions relative to the IR expression from Mo & Tsai [13] in Eq. (23), which are independent of polarization,

\[
\Delta_{L,T} = \delta_{L,T}^{\text{full}} - \delta_{L,T}^{\text{IR}} .
\]  

(50)

Experimentally, one does not usually measure the longitudinal or transverse cross section per se, but rather the ratio of the transverse or longitudinal cross section to the unpolarized cross section, denoted \( P_L \) or \( P_T \), respectively. Thus the 2\( \gamma \) exchange correction to the polarization transfer ratio can be incorporated as

\[
\frac{P_{L,T}^{1\gamma+2\gamma}}{P_{L,T}^{1\gamma}} = \frac{1 + \Delta_{L,T}}{1 + \Delta} ,
\]  

(51)
where $\Delta$ is the correction to the unpolarized cross section considered in the previous section.

The $2\gamma$ exchange contribution relative to the Born term is shown in Fig. 8. The correction to the longitudinal polarization transfer ratio $P_L$ is small overall. This is because the correction $\Delta_L$ to the longitudinal cross section is roughly the same as the correction $\Delta$ to the unpolarized cross section. The corrections $\Delta$ and $\Delta_L$ must be exactly the same at $\theta = 180^{\circ}$ ($\varepsilon = 0$), and our numerical results bear this out. By contrast, the correction to the transverse polarization transfer ratio $P_T$ is enhanced at backward angles, and grows with $Q^2$. This is due to a combined effect of $\Delta_T$ becoming more positive with increasing $Q^2$, and $\Delta$ becoming more negative.

In the standard radiative corrections using the results of Mo & Tsaï [13], the corrections for transverse polarization are the same as those for longitudinal polarization, so that no additional corrections beyond hard bremsstrahlung need be applied [39]. Because the polarization transfer experiments [3] typically have $\varepsilon \approx 0.7–0.8$, the shift in the polarization transfer ratio in Eq. (5) due to the $2\gamma$ exchange corrections is not expected to be dramatic.

If $R$ is the corrected (“true”) electric to magnetic form factor ratio, as in Eq. (29), then the measured polarization transfer ratio is

$$\tilde{R} = R \left( \frac{1 + \Delta_T}{1 + \Delta_L} \right). \tag{52}$$

Inverting Eq. (52), the shift in the ratio $R$ is illustrated in Fig. 9 by the filled circles (offset slightly for clarity). The unshifted results are indicated by the open circles, and the LT separated results are labeled by diamonds. The effect of the $2\gamma$ exchange on the form factor ratio is a very small, $\lesssim 3\%$ suppression of the ratio at the larger $Q^2$ values, which is well within the experimental uncertainties.

Note that the shift in $R$ in Eq. (52) does not include corrections due to hard photon bremsstrahlung (which are part of the standard radiative corrections). Since these would make both the numerator and denominator in Eq. (52) even larger, the correction shown in Fig. 9 would represent an upper limit on the shift in $R$.

Finally, the $2\gamma$ exchange process can give rise to a non-zero contribution to the elastic cross section for a recoil proton polarized normal to the scattering plane. This contribution is purely imaginary, and does not exist in the $1\gamma$ exchange approximation. It is illustrated in Fig. 10 where the ratio $\Delta_N$ of the $2\gamma$ exchange contribution relative to the unpolarized Born contribution is shown as a function of $\varepsilon$ for several values of $Q^2$. (For consistency in notation
we denote this correction $\Delta_N$ rather than $\delta_N$, even though there is no IR contribution to the normal polarization.)

The normal polarization contribution is very small numerically, $\Delta_N \lesssim 1\%$, and has a very weak $\varepsilon$ dependence. In contrast to $\Delta_L$ and $\Delta_T$, the normal polarization ratio is smallest at low $\varepsilon$, becoming larger with increasing $\varepsilon$. Although not directly relevant to the elastic form factor extraction, the observation of protons with normal polarization would provide direct evidence of $2\gamma$ exchange in elastic scattering. Figure 11 shows the normal polarization asymmetry $A_y$ as a function of the center of mass scattering angle, $\Theta_{cm}$, for several values of $Q^2$. The asymmetry is relatively small, of the order of $1\%$ at small $\Theta_{cm}$ for $Q^2 \sim 3 \text{ GeV}^2$, but grows with $Q^2$.

The imaginary part of the $2\gamma$ amplitude can also be accessed by measuring the electron beam asymmetry for electrons polarized normal to the scattering plane [40]. Knowledge of the imaginary part of the $2\gamma$ exchange amplitude could be used to constrain models of Compton scattering, although relating this to the real part (as needed for form factor studies) would require a dispersion relation analysis.

**IV. ELECTRON–NEUTRON SCATTERING**

In this section we examine the effect of the $2\gamma$ exchange contribution on the form factors of the neutron. Since the magnitude of the electric form factor of the neutron is relatively small compared with that of the proton, and as we saw in Sec. III the effects on the proton are significant at large $Q^2$, it is important to investigate the extent to which $G^E_n$ may be contaminated by $2\gamma$ exchange.

Using the same formalism as in Secs. II and III, the calculated $2\gamma$ exchange correction for the neutron is shown in Fig. 12 for $Q^2 = 1, 3$ and $6 \text{ GeV}^2$. Since there is no IR divergent contribution to $\delta$ for the neutron, the total $2\gamma$ correction $\delta_{\text{full}}$ is displayed in Fig. 12. In the numerical calculation, the input neutron form factors from Ref. [16] are parameterized using the pole fit in Eq. (26), with the parameters given in Table II. For comparison, the correction at $Q^2 = 6 \text{ GeV}^2$ is also computed using a 3-pole fit to the form factor parameterization from Ref. [41]. The difference between these is an indication of the model dependence of the calculation.

The most notable difference with respect to the proton results is the sign and slope of the
2\(\gamma\) exchange correction. Namely, the magnitude of the correction \(\delta_{\text{full}}(\varepsilon, Q^2)\) for the neutron is \(\sim 3\) times smaller than for the proton. The reason for the sign change is the negative anomalous magnetic moment of the neutron. The \(\varepsilon\) dependence is approximately linear at moderate and high \(\varepsilon\), but at low \(\varepsilon\) there exists a clear deviation from linearity, especially at large \(Q^2\).

Translating the \(\varepsilon\) dependence to the form factor ratio, the resulting shift in \(\mu_n G_E^n / G_M^n\) is shown in Fig. 13 at several values of \(Q^2\), assuming a linear 2\(\gamma\) correction over two different \(\varepsilon\) ranges (\(\varepsilon = 0.2 - 0.9\) and \(\varepsilon = 0.5 - 0.8\)). The baseline (uncorrected) data are from the global fit in Ref. [16]. The shift due to 2\(\gamma\) exchange is small at \(Q^2 = 1\) GeV\(^2\), but increases significantly by \(Q^2 = 6\) GeV\(^2\), where it produces a 50–60% rise in the uncorrected ratio. These results suggest that, as for the proton, the LT separation method is subject to large corrections from 2\(\gamma\) exchange at large \(Q^2\).

While the 2\(\gamma\) corrections to the form factor ratio from LT separation are significant, particularly at large \(Q^2\), in practice the neutron \(G_E^n\) form factor is commonly extracted using the polarization transfer method. To compare the 2\(\gamma\) effects on the ratio \(\mu_n G_E^n / G_M^n\) extracted by polarization transfer, in Fig. 14 we plot the same “data points” as in Fig. 13, shifted by the \(\delta_{L,T}\) corrections as in Eq. (52) at two values of \(\varepsilon\) (\(\varepsilon = 0.3\) and 0.8). The shift is considerably smaller than that from the LT method, but nevertheless represents an approximately 4% (3%) suppression at \(\varepsilon = 0.3\) (0.8) for \(Q^2 = 3\) GeV\(^2\), and \(\approx 10\%\) (5%) suppression for \(Q^2 = 6\) GeV\(^2\) for the same \(\varepsilon\). In the Jefferson Lab experiment [42] to measure \(G_E^n / G_M^n\) at \(Q^2 = 1.45\) GeV\(^2\) the value of \(\varepsilon\) was around 0.9, at which the 2\(\gamma\) correction was \(\approx 2.5\%\). In the recently approved extension of this measurement to \(Q^2 \approx 4.3\) GeV\(^2\) [43], the 2\(\gamma\) correction for \(\varepsilon \approx 0.82\) is expected to be around 3%. While small, these corrections will be important to take into account in order to achieve precision at the several percent level.

V. 3\(^{\text{He}}\) Elastic Form Factors

In this section we extend our formalism to the case of elastic scattering from 3\(^{\text{He}}\) nuclei. Of course, the contribution of 3\(^{\text{He}}\) intermediate states in 2\(\gamma\) exchange is likely to constitute only a part of the entire effect – contributions from break-up channels may also be important. However, we can obtain an estimate on the size of the effect on the 3\(^{\text{He}}\) form factors, in comparison with the effect on the nucleon form factor ratio.
The expressions used to evaluate the $2\gamma$ contributions are similar to those for the nucleon, since $^3\text{He}$ is a spin-$\frac{1}{2}$ particle, although there are some important differences. For instance, the charge is now $Ze$ (where $Z = 2$ is the atomic number of $^3\text{He}$), the mass $M_{^3\text{He}}$ is $\approx 3$ times larger than the nucleon mass, and the anomalous magnetic moment is $\kappa_{^3\text{He}} = -4.185$. In addition, the internal $\gamma^3\text{He}$ form factor is somewhat softer than the corresponding nucleon form factor (since the charge radius of the $^3\text{He}$ nucleus is $\approx 1.88$ fm). Using a dipole shape for the form factor gives a cut-off mass of $\Lambda_{^3\text{He}} \approx 0.37$ GeV.

The $2\gamma$ exchange correction is shown in Fig. 15 as a function of $\varepsilon$ for several values of $Q^2$. The $\varepsilon$ dependence illustrates the interesting interplay between the Dirac and Pauli contributions to the cross section. At low $Q^2$ ($Q^2 \sim 1$ GeV$^2$), the $F_1$ contribution is dominant, and the effect has the same sign and similar magnitude as in the proton. The result in fact reflects a partial cancellation of 2 opposing effects: the larger charge squared $Z^2$ of the $^3\text{He}$ nucleus makes the effect larger (by a factor $\sim 4$), while the larger mass squared of the $^3\text{He}$ nucleus suppresses the effect by a factor $\sim 9$. In addition, the form factor used is much softer than that of the nucleon, so that the overall effect turns out to be similar in magnitude as for the proton.

With increasing $Q^2$ the Pauli $F_2$ term becomes more important, so that for $Q^2 \gtrsim 3$ GeV$^2$ the overall sign of the contribution is positive. Interestingly, over most of the region between $\varepsilon \approx 0.2$ and 0.9 the slope in $\varepsilon$ is approximately constant. This allows us to extract the correction to the ratio of charge to magnetic form factors, $F_C/F_M$, which we illustrate in Fig. 16. The effect is a small, $\lesssim 0.5\%$ reduction in the ratio for $Q^2 \lesssim 3$ GeV$^2$, which turns into an enhancement at large $Q^2$. However, the magnitude of the effect is small, and even for $Q^2 = 6$ GeV$^2$ the $2\gamma$ effect only gives $\lesssim 2\%$ increase in the form factor ratio. Proposed experiments at Jefferson Lab [44] would measure the $^3\text{He}$ form factors to $Q^2 \approx 4$ GeV$^2$.

VI. CONCLUSION

We have presented a comprehensive analysis of the effects of $2\gamma$ exchange in elastic electron–nucleon scattering, taking particular account of the effects of nucleon structure. Our main purpose has been to quantify the $2\gamma$ effect on the ratio of electric to magnetic form factors of the proton, which has generated controversy recently stemming from conflicting results of measurements at large $Q^2$. 
Consistent with the earlier preliminary investigation [10], we find that inclusion of $2\gamma$ exchange reduces the $G_E^p/G_M^p$ ratio extracted from LT-separated cross section data, and resolves a significant amount of the discrepancy with the polarization transfer results. At higher $Q^2$ we find strong deviations from linearity, especially at small $\varepsilon$, which can be tested in future high-precision cross section measurements. There is some residual model-dependence in the calculation of the $2\gamma$ amplitude arising from the choice of form factors at the internal $\gamma^* NN$ vertices in the loop integration. This dependence, while not overwhelming, will place limitations on the reliability of the LT separation technique in extracting high-$Q^2$ form factors. On the other hand, the size of the $2\gamma$ contributions to elastic scattering could be determined from measurement of the ratio of $e^- p$ to $e^+ p$ elastic cross sections, which are uniquely sensitive to $2\gamma$ exchange effects.

We have also generalized our analysis to the case where the initial electron and recoil proton are polarized, as in the polarization transfer experiments. While the $2\gamma$ corrections can be as large as $\sim 4-5\%$ at small $\varepsilon$ for $Q^2 \sim 6$ GeV$^2$, because the polarization transfer measurements are performed typically at large $\varepsilon$ we find the impact on the extracted $G_E^p/G_M^p$ ratio to be quite small, amounting to $\lesssim 3\%$ suppression at the highest $Q^2$ value.

Extending the formalism to the case of the neutron, we have calculated the $2\gamma$ exchange corrections to the neutron $G_E^n/G_M^n$ ratio. While numerically smaller than for the proton, the corrections are nonetheless important since the magnitude of $G_E^n$ itself is small compared with $G_E^p$. Furthermore, because of the opposite sign of the neutron magnetic moment relative to the proton, the $2\gamma$ corrections to the LT-separated cross section give rise to a sizable enhancement of $G_E^n/G_M^n$ at large $Q^2$. The analogous effects for the polarization transfer ratio are small, on the other hand, giving rise to a few percent suppression for $Q^2 \lesssim 6$ GeV$^2$.

Finally, we have also obtained an estimate of the $2\gamma$ exchange contribution to the elastic form factors of $^3$He from elastic intermediate states. The results reveal an interesting interplay between an enhancement from the larger charge of the $^3$He nucleus and a suppression due to the larger mass. Together with softer form factor (larger radius) compared with that of the nucleon, the net effect is $\lesssim 1\%$ over the $Q^2$ range accessible to current and upcoming experiments.

Contributions from excited states, such as the $\Delta$ and heavier baryons, may modify the quantitative analysis presented here. Naively, one could expect their effect to be suppressed because of the larger masses involved, at least for the real parts of the form factors. An
investigation of the inelastic excitation effects is presented in Ref. [14].

TABLE I: Parameters for the proton and neutron form factor fits in Eq. [26] used in this work, with $n_i$ and $d_i$ in units of GeV$^2$.

|   | $F_1^p$ | $F_2^p$ | $F_1^n$ | $F_2^n$ |
|---|---------|---------|---------|---------|
| $N$ | 3       | 3       | 3       | 2       |
| $n_1$ | 0.38676 | 1.01650 | 24.8109 | 5.37640 |
| $n_2$ | 0.53222 | –19.0246 | -99.8420 |
| $d_1$ | 3.29899 | 0.40886 | 1.98524 | 0.76533 |
| $d_2$ | 0.45614 | 2.94311 | 1.72105 | 0.59289 |
| $d_3$ | 3.32682 | 3.12550 | 1.64902 | —       |

FIG. 1: Two-photon exchange box and crossed box diagrams for elastic electron–proton scattering.
FIG. 2: Difference between the full two-photon exchange correction to the elastic cross section (using the realistic form factors in Eq. (26)) and the commonly used expression (23) from Mo & Tsai [13] for $Q^2 = 1–6$ GeV$^2$. The numbers labeling the curves denote the respective $Q^2$ values in GeV$^2$. 
FIG. 3: Model dependence of the difference between the full two-photon exchange correction and the Mo & Tsai approximation: (a) at $Q^2 = 1$, 6 and 12 GeV$^2$, using realistic (solid) [16] and dipole (dashed) form factors; (b) at $Q^2 = 6$ GeV$^2$ using the form factor parameterizations from Refs. [16] (solid), [26] (dashed), and [25] with $G_E^o$ constrained by the LT-separated (dot-dashed) and polarization transfer (long-dashed) data.
FIG. 4: Reduced cross section $\sigma_R$ (scaled by the dipole form factor $G_D^2$) versus $\varepsilon$ for several values of $Q^2$: (a) SLAC data [27] at $Q^2 = 3.25$ (open squares), 4 (filled circles), 5 (open circles) and 6 GeV$^2$ (filled squares); (b) JLab data [4] at $Q^2 = 2.64$ (filled squares), 3.2 (open squares) and 4.1 GeV$^2$ (filled circles). The dotted curves are Born cross sections evaluated using a form factor parameterization [26], with $G_E^p$ fitted to the polarization transfer data [5], while the solid curves include $2\gamma$ contributions. The curves in the bottom panel have been shifted by (+1.0%, +2.1%, +3.0%) for $Q^2 = (2.64, 3.2, 4.1)$ GeV$^2$. 
FIG. 5: The ratio of proton form factors $\mu_p G_E/G_M$ measured using LT separation (open diamonds) and polarization transfer (PT) (open circles). The LT points corrected for $2\gamma$ exchange are shown assuming a linear slope for $\varepsilon = 0.2 - 0.9$ (filled squares) and $\varepsilon = 0.5 - 0.8$ (filled circles) (offset for clarity).
FIG. 6: Finite $2\gamma$ contributions (defined with respect to the Mo-Tsai IR result \[13\]) to the real parts of the $G_M$ (dashed), $G_E$ (dot-dashed) and $Y_{2\gamma}$ (solid) form factors of the proton at $Q^2 = 1$, 3 and 6 GeV$^2$. Note the larger scale in the bottom figure.
FIG. 7: Ratio of elastic $e^+p$ to $e^-p$ cross sections. The data are from SLAC [31, 32], with $Q^2$ ranging from 0.01 to 5 GeV$^2$. The results of the $2\gamma$ exchange calculations are shown by the curves for $Q^2 = 1$ (dotted), 3 (dashed) and 6 GeV$^2$ (solid).
FIG. 8: Ratio of the finite part (with respect to the IR contribution in Eq. (22)) of the Born+2γ correction relative to the Born term, for (a) longitudinal and (b) transverse recoil proton polarization, at $Q^2 = 1$ (dotted), 3 (dashed) and 6 GeV$^2$ (solid). Note the different scales on the vertical axes.
FIG. 9: Proton electric to magnetic form factor ratio obtained from the polarization transfer measurements, with (solid circles) and without (open circles) the $2\gamma$ exchange corrections. The corrected values have been offset for clarity. The LT-separated ratio (open diamonds) from Fig. 5 is shown for comparison.
FIG. 10: Ratio of the $2\gamma$ contribution to the normal polarization, to the unpolarized Born contribution, as a function of $\varepsilon$, for $Q^2 = 1$ (dotted), 3 (dashed) and 6 GeV$^2$ (solid).

FIG. 11: Normal polarization asymmetry, expressed as a percentage, as a function of the center of mass scattering angle, $\Theta_{\text{cm}}$, for $Q^2 = 1$ (dotted), 3 (dashed) and 6 GeV$^2$ (solid).
FIG. 12: $2\gamma$ contribution to the unpolarized electron–neutron elastic scattering cross section, at $Q^2 = 1$ (dotted), 3 (dashed) and 6 GeV$^2$ (solid and dot-dashed). The dot-dashed curve corresponds to the form factor parameterization of Ref. [41], while the others are from Ref. [16] (as fitted by the parameters in Table I).
FIG. 13: Effect of $2\gamma$ exchange on the ratio of neutron form factors $\mu_n G_E^n/G_M^n$ using LT separation. The uncorrected points (open circles) are from the form factor parameterization in Ref. [16], while the points corrected for $2\gamma$ exchange are obtained from linear fits to $\delta^{\text{full}}$ in Fig. 12 for $\varepsilon = 0.2 - 0.9$ (filled squares) and $\varepsilon = 0.5 - 0.8$ (filled circles) (offset for clarity).
FIG. 14: Effect of $2\gamma$ exchange on the ratio of neutron form factors $\mu_n G_E^n/G_M^n$ using polarization transfer. The uncorrected points (open circles) are from the parameterization in Ref. [16], and the points corrected for $2\gamma$ exchange correspond to $\varepsilon = 0.3$ (filled squares) and $\varepsilon = 0.8$ (filled circles) (offset for clarity).
FIG. 15: $2\gamma$ contribution to the unpolarized electron–$^3$He elastic scattering cross section, with the $^3$He elastic intermediate state, as a function of $\varepsilon$, for $Q^2 = 1$ (dotted), 2 (dot-dashed), 3 (dashed) and 6 GeV$^2$ (solid).
FIG. 16: Relative change (in percent) in the ratio of the charge to magnetic form factors of $^3$He due to $2\gamma$ exchange, obtained from linear fits to $\Delta$ in Fig. 15 for $\varepsilon = 0.2 - 0.9$ (filled squares) and $\varepsilon = 0.5 - 0.8$ (open circles) (offset for clarity).
