CHAPTER 6

Two-photon intravital multi-color imaging combined with inducible gene expression to distinguish metastatic behaviour of breast cancer cells in vivo

Running title: Intravital imaging of differential metastatic behaviours

ABSTRACT

The aim of this study is to use multi-color intravital imaging together with an inducible cell model to compare metastatic behaviour of control and genetically modified breast cancer cell populations within the intact primary tumor of a mouse. GFP-MTLn3-ErbB1 cells were generated with doxycycline-regulated conditional transgene expression using lentiviral TREAutoR3-CFP. CFP expression together with tumor cell motility are monitored in vitro and in vivo. Effective and tight control of doxycycline-induced CFP expression was observed both in vitro and in vivo. Intravital multiphoton microscopy on intact orthotopic tumors allowed a clear discrimination between GFP only and (GFP+CFP) cell populations, which enables direct comparison of the motility behaviour of two different cell populations in the same microenvironment in vivo. This system is robust and versatile for conditional gene expression and can be used to study the role of individual candidate metastases genes in vitro and in vivo. This technology will allow investigations of cellular events in cancer metastasis and in particular intravasation within a primary tumor.
1. Introduction

Despite many years of laboratory and clinical research, still a large number of women die of breast cancer metastasis formation. Therefore, it is crucial to understand the underlying mechanisms of metastasis formation and especially tumor cell intravasation. Improved models are required to study the role of individual candidate metastases genes involved in this individual steps and in particular in the intravasation steps.

So far constitutive ectopic expression of wild type genes, their deletion mutants or shRNA-mediated knockdown are typically used to study the role of candidate metastases genes. Often this by itself affects already the tumor formation and/or is toxic to cells. Indeed, overexpression of a deletion mutant or knock down of a protein may affect cell proliferation or survival, and consequently the tumor growth in vivo, so no conclusion can be drawn on the effect of the candidate gene on tumor cell invasion capacity. In that case, the choice for an experimental metastasis assay is made to still assess the metastatic capacity of the cells. To circumvent this problem, conditional gene expression strategies allowing the expression of target gene only when desired are invaluable tools for cancer research. For example, after orthotopic injection of the transgenic cell-line, ideally one waits until the tumor reaches a certain size and at a desired moment induces overexpression of a deletion mutant and study its affect by quantifying the lung burden. An inducible system is relevant not only for studying the effect of gene candidates on metastasis formation but also when combined with dual-colour imaging for observing at the same time in the same microenvironment the motility behaviours of the control cells and the genetically modified cells.

Currently available systems often have limited in vivo functionality because of leakiness, insufficient levels of induction, lack of tissue specificity or complicated designs. We evaluated the use of a highly versatile lentiviral vector-based tool that allows conditional expression of any candidate metastasis gene of interest. This approach allows one to analyze the behaviour of different manipulated cell populations in the same tumor microenvironment by optical imaging. Two-photon intravital imaging of fluorescent protein-expressing tumors enables cell motility to be observed with great details and at great depth within tissue. In addition to detecting tumor cells, two-photon intravital imaging can provide information about cell movement and interactions between cells and the microenvironment. Our ultimate goal is to compare the metastatic behaviour (e.g. number of tumor cells in blood and number and size of lung metastases) of two distinct tumor cell populations (control cells and modified cells with overexpression or knock down of a target gene) within the same primary tumor. Since, there is a correlation between patterns in gene expression in cells with varying metastatic potential and differences in cell motility and polarization, our aim is to relate the motility cell behaviour of the two cell subpopulations and their metastatic capacity. For this purpose, we use two-photon intravital
microscopy combined with fluorescently labeled cells. The use of green fluorescent protein (GFP) and cyan fluorescent protein (CFP) can be simultaneously imaged in a living tumor\textsuperscript{12,16}. In this proof of concept study, we chose for this fluorophore combination to be able to discriminate between control GFP-labeled cells and GFP-labeled cells that also harbor conditional expression of CFP alone in the same tumor microenvironment.

Here as a concept, we generated a GFP- MTLn3- ErbB1 cell-line that harbors the lentiviral TREAutoR3-CFP construct and established the functionality of this lentiviral vector-based tool that allows conditional expression for both \textit{in vitro} and \textit{in vivo} study. We systematically characterized the induction kinetics of CFP expression and demonstrated that doxycycline-induced CFP expression does not influence cell proliferation and motility properties \textit{in vitro} or \textit{in vivo}. Our data clearly show that two-photon intravital imaging can be used to simultaneously image cell migration of GFP only and CFP-labeled tumor cells, collagen fibers and macrophages in established tumors in the living animal. Thus, in the very same tumor microenvironment, we can study the effect of the expression of a gene candidate on the metastatic behaviour of individual tumor cells since both control and modified cells can be tracked simultaneously by using two-photon intravital imaging. In the context of metastasis formation, this model will allow the future evaluation of candidate metastasis target genes on tumor cell dissemination programs to the lung.

2. Materials and Methods

2.1 Reagents

Mouse anti-human ErbB1 was purchased from Calbiochem (EMD Biosciences, San Diego, CA). Goat anti-mouse APC was purchased from Cedarlane (Ontario, CA). Alpha modified minimal essential medium (a-MEM), Fetal Bovine Serum (FBS), phosphate buffered saline (PBS) and trypsin were from Life Technologies (Rockville, MD, USA).

2.2 Cloning and lentivirus production

The lentiviral vector TREAutoR3 was kindly provided by Dr. Jurgen Seppen\textsuperscript{9}. An AgeI-PstI digest of TREAutoR3 released the d2eGFP fragment. The CFP fragment from Clontech vector CFP-C1 was cloned into the AgeI-PstI digest of TREAutoR3 to create the TREAutoR3-CFP vector. Lentiviral vectors were prepared as reported previously\textsuperscript{17}. 
2.3 Transfection and stable cell-line selection

MTLn3 rat mammary adenocarcinoma cells were cultured as previously described. MTLn3-GFP-ErbB1 cell-lines were kindly provided by Dr. Jeffrey E. Segall and were maintained in αMEM (Life Technologies, Inc., Gaithersburg, MD) supplemented with 5% fetal bovine serum (Life Technologies). TREautoR3 virus containing supernatant was added to the medium of the MTLn3 cells. After 24 hours transduction, the medium was refreshed and after 48 hours the cells were cultured to be frozen at -80°C and selected for CFP expression after doxycycline exposure.

2.4 Immunofluorescence

Cells were cultured on 12 mm collagen-coated glass coverslips and fixated in 4% (w/v) formaldehyde in PBS. Subsequently coverslips were mounted in Aqua PolyMount (Polysciences, Warrington, PA). Imaging occurred using a Bio-Rad Radiance 2100 MP confocal laser scanning system with a Nikon Eclipse TE2000-U inverted fluorescence microscope and a x60 Nikon objective.

2.5 Cell Proliferation and motility assays

GFP-MTLn3-ErbB1-TREautoR3-CFP cells were cultured in 24 well plates in the absence or presence of doxycycline for 5 days. Cells were washed with PBS and subsequently scanned with a Typhoon Imager 9400 (Amersham Biosciences) with both 457 nm and 488 nm laser lines. Total GFP fluorescence which is equivalent with total number of cells was determined with ImageQuant 5.2 software. For cell motility assays, cells were plated onto collagen coated 24 wells glass bottom plates (Sensoplate, Greiner Bio-One) and after 2 hours of serum starvation stimulated with either EGF (10 mM) or HGF (10 ng/ml) and followed with time lapse microscopy for 2 hours. Image acquisition was performed using a Nikon TE2000 combined with a Prior stage and controlled by NIS Element Software. Using GFP and CFP filters for epifluorescence microscopy, time-lapse videos were recorded using a CCD camera controlled by NIS Element Software.

2.6 In vivo tumor growth and metastasis formation

6-week old Rag2-/- γc-/- mice were obtained from in house breeding. Animals were housed in individually ventilated cages under sterile conditions containing 3 mice per cage. Sterilised food and water were provided ad libitum. To measure spontaneous metastasis, tumor cells were grown to 70% to 85% confluence before being harvested for cell counting. Cells (5 x 10^5) were injected into the right thoracic mammary fat pads. The cells were injected in a volume of 100 μL of PBS with Ca^{2+} (1 mM) and Mg^{2+} (2 mM) through a 25-gauge needle. Tumor growth rate was monitored at weekly intervals after inoculation of tumor cells. Horizontal (h)
and vertical (v) diameters were determined, and tumor volume (V) was calculated 
\[ V = \frac{4}{3}\pi(\frac{1}{2}\sqrt[3]{h*v})^3 \]. After 4 weeks, the animals were anesthetized with 
isoﬂurane and the lungs were excised and rinsed in ice-cold PBS after having 
performed intravital imaging (see below). The right lung was used to count the 
tumor burden. For rough estimation, the right lungs were imaged with the 
Fluorescence Imaging unit IVIS (see below). And for detailed quantification, the 
flat side of the right lung was analysed with the immunofluorescence microscope. 
With a x10 objective lens (NA 0.25), we screened the flat surface of the lobe and 
counted the number of GFP or CFP positive metastases. Following that step, the 
right lung was cut into two pieces and ﬁxated in 4% paraformaldehyde. The left 
lung was injected with ink solution and thereafter destained in water and ﬁxated 
in Fekete’s (4.3% (v/v) acetic acid, 0.35% (v/v) formaldehyde in 70% ethanol). 
Lung tumor burden was also determined by counting the number of surface 
metastases. The primary tumors and lungs from each mouse were used for 
histologic analysis. Samples were ﬁxed in formalin and embedded in parafﬁn, and 
5-μm sections were stained with H&E.

2.7 Intravital Imaging by multiphoton microscopy

Tumor imaging was done as described previously\textsuperscript{10,12,16,20}. Cells (5 x 10\textsuperscript{5}) were 
injected into the mammary fat pads of Rag2\textsuperscript{-/-}γc\textsuperscript{-/-} mice as described above and 
allowed to grow for 4 weeks. The animal was placed under isoﬂurane anesthesia, 
and the tumor was exposed using a simple skin ﬂap surgery, with as little 
disruption of the surrounding vasculature as possible. Eventually, by injecting 200 
μl of 20 mg/mL of Texas red-dextran in PBS 2 hours prior imaging, we can also 
visualize the blood vessels and the macrophages in the primary tumor\textsuperscript{12,15}. The 
animal was then placed in a 30°C temperature chamber on an inverted Nikon 
TE2000-U microscope and imaged using a x20 Nikon objective (Plan Apo, NA 
0.75). Briefly a 5-W Tsunami laser (Spectra Physics, Mountain View, CA) was used 
to run a Radiance 2100 multiphoton system (Bio-Rad, Hercules, CA) at 860 nm 
using a 450/480-nm filter to image matrix and CFP and a 515/530-nm filter to 
image CFP and GFP. Time lapse images of CFP and GFP-labeled MTLn3-ErbB1 
generated tumors were taken at 1-minute interval for 30 minutes. The images were 
collected using Bio-Rad’s Lasersharp 2000 software. During each 1-minute interval, 
a z series of 10 images was taken at a spacing of 10 μm between images, beginning 
at the periphery of the tumor and moving into the tumor. For each tumor, this 
image acquisition process was repeated for 30 minutes, resulting in a time lapse 
three dimensional z series for analysis of tumor cell motility. Image analysis and 
cell tracking were done with Image Pro Software.
2.8 Fluorescence imaging (FLI)

Fluorescence imaging was performed with a highly sensitive, cooled CCD camera mounted in a light-tight specimen box (IVISTM; Xenogen). Imaging was controlled by the acquisition and analysis software Living Image® (Xenogen). The light emitted from the biofluorescent metastases or cells were detected by the IVISTM camera system, integrated, digitized, and displayed. For ex vivo imaging, lungs were excised, placed into a petri dish, and imaged for 1–2 min.

2.9 Statistical analysis

Student’s t test was used to determine if there was a significant difference between two means (P < 0.05). When multiple means were compared, significance was determined by one-way analysis of variance (P < 0.05). Significant differences are marked in the graphs.

3. Results

3.1 Conditional transgene expression in vitro

To study two different cell populations (with differential transgene expression) in the same microenvironment in vivo, a model is required that uses two different fluorescent proteins in order to discriminate these populations. Moreover, given the possible effect of transgene expression or knockdown on tumor growth and the microenvironment, such a transgene expression should be conditional. Here, we chose to work with GFP and CFP, two fluorescent proteins that can be visualized by two-photon intravital imaging and thus in vivo16. Furthermore, to test whether a cell line with inducible expression of candidate metastasis controlling genes can be used for in vivo studies, we used the established GFP-MTLn3-ErbB1 cell line and verified first the functionality of the lentiviral vector TREAuroR3 in vitro9,20,21. We generated a TREAuroR3 lentiviral vector that expresses CFP after doxycycline-mediated induction to create breast cancer cells that either lack or express a transgene upon treatment with doxycyclin (Fig. 1A). We transduced GFP-MTLn3-ErbB1 cells and directly after transduction, we added doxycycline to sort the positive cells by FACS analysis for both CFP and GFP expression (data not shown). In addition, similar levels of ErbB1 were observed in both the original cell-line (GFP-MTLn3-ErbB1) and the new cell-line (GFP-MTLn3-ErbB1-TREAuroR3-CFP) (data not shown). Next, we determined whether the expression of the transgene was tightly and effectively controlled by doxycycline. CFP expression was upregulated after 24 hours of doxycycline treatment with all concentrations. The most optimal concentration was 1000 ng/ml at which over 90% of the cells were CFP positive (Fig. 1B). In the absence of doxycycline no CFP expression was observed indicating that transgene expression was tightly and effectively controlled by doxycycline (Fig. 1B). We also checked the kinetics of the CFP
transgene expression over time. After 8 hours around 50% of the cells were CFP positive, while after 24 hours already approximately 90% of the cells were CFP positive (Fig. 1C). Together, these data show that the autoregulatory lentiviral vector TREautoR3 does not leak at all in the absence of the drug and that the regulation of the transgene expression is sensitive, fast and tight. Moreover, with this one cell-line with inducible expression of CFP, we generated a versatile tool to study the effect of transgene expression compared to control situation in one experiment where all conditions are exactly the same.

**Figure 1A:** *In vitro* drug-controllable transgene expression. (A) Schematic representation of the constructed lentiviral vector.
Figure 1 continued: *In vitro* drug-controllable transgene expression. (B) Doxycycline (dox) dose-response of the TRE-autoR3-CFP vector. Transduced GFP-MTLn3-ErbB1 cells were cultured in the absence or presence of doxycycline at different concentrations for 24 hours (from 50 until 1000 ng/ml doxy) and visualized by confocal microscope. In this titration experiment, the percentage of CFP positive cells was calculated. (C) Induction kinetics of the CFP expression of GFP-MTLn3 cells transduced with TREautoR3 vector. Dual-color imaging of cells exposed to 1000 ng/ml of doxycycline after different time points. The number of CFP expressing cells after doxycycline induction was counted. Scale bars for B, C = 100 µm.
3.2 Doxycycline-mediated expression of CFP in MTLn3 cells does not affect cell proliferation and cell motility

The use of such an inducible system together with CFP expression might affect cell properties. Therefore, we carefully checked whether doxycycline-mediated expression of CFP alone affects two important aspects in the breast cancer progression: cell proliferation and cell motility. To determine the effect of doxycycline-mediated CFP expression on cell proliferation, our conditional cell-line was cultured in 24 wells for 5 days either untreated or treated with doxycycline to induce CFP expression. At indicated time-points the increase in GFP and CFP fluorescence was determined as a measurement of proliferation using a fluorescence imager. After 5 days, no significant effect was observed in cell proliferation rate when cells were exposed to doxycycline (Fig. 2A). Next, we verified whether cell motility remains the same after doxycycline-induced CFP expression. Cell motility of GFP only or GFP/CFP cells was determined using a random cell migration assay with wide field fluorescence microscopy. No significant difference was observed in cell motility between GFP and GFP/CFP cells under control conditions or after stimulation of the cells with either EGF or HGF (Fig. 2B). Thus doxycycline-mediated expression of CFP does not affect in vitro cell proliferation and motility.
3.3 Effective doxycycline-induced CFP expression in vivo does not affect tumor growth and lung metastasis formation

We also checked whether doxycycline-mediated expression of CFP alone affects tumor growth and lung metastasis formation. We used inbred Rag2/-γc/- mice and injected orthotopically in the fat pad 500,000 GFP-MTLn3-ErbB1-TREAutoR3-CFP cells. Three groups were defined based on the doxycycline administration time point. The control group received sucrose drinking water without doxycycline. The second group received doxycycline sucrose drinking water starting from day 1 and the third group starting from day 28, which is approximately 48 hours before sacrificing the animals (Fig. 3A). We measured the tumor progression with a calliper during the entire length of the experiment and no significant difference was found in tumor growth rate between the three groups (data not shown). After sacrifice, tumor volume and weight were measured with no differences observed between different treatments (Fig. 3B). Also histological analysis of tumor tissue sections is similar in the three test groups (Fig. 3C). Next, we quantified with both fluorescence imaging (FLI) (Fig. 4A) and fluorescence microscopy (Fig. 4B) the lung tumor burden. In all the three groups, an average number of 400 lung metastases were counted showing no difference in metastasis formation after doxycycline-
induced CFP expression. Histological observations of the lungs did not reveal any
difference between the three groups (Fig. 4C). In conclusion, tumor growth and
lung metastasis formation are not affected by doxycycline-induced CFP expression.

Figure 3: Doxycycline mediated CFP expression does not affect tumor cell growth in vivo. (A) Schedule of in vivo doxycycline treatment. We defined in total three groups: control group (n=5) which gets only sucrose drinking water, group 2 (n=5) which gets doxycycline in the drinking water from day 0 and group 3 (n=5) which gets doxycycline in the drinking water 48 hours before sacrifice. (B) At sacrifice the tumor was isolated and the weight measured. (C) Sectioned tumors were stained with H&E and representative pictures are shown.

3.4 Tightly controlled CFP expression in both tumor and lung metastases

Since we want to use this inducible system in vivo it was essential to evaluate the
effectiveness of doxycycline-induced CFP expression. With two-photon intravital imaging, we checked whether doxycycline CFP induction was successful in the tumor and in the lung metastases. No CFP expression at all was detected in the control group, yet robust CFP expression was detected in over 90% of the whole tumor when doxycycline was added in the drinking water from day 1 and in more than 70% of the tumor when doxycycline was added 48 hours before sacrificing the animals (Fig. 5A). We observed the same CFP induction when analysing the lung metastases with two-photon excitation after sacrifice (Fig. 5B): in the control group, only GFP positive and no CFP positive metastasis could be observed throughout the entire lung. When doxycycline was added in the drinking water from day 1, almost all the lung metastases were CFP positive. A period of 48 hours doxycycline exposure resulted in approximately 70% CFP-positive lung metastasis. Together
Intravital imaging of differential metastatic behaviours these data demonstrate that our GFP-MTLn3-ErbB1-TREAutoR3 model allows for the effective, fast and tightly controlled transgene expression. Moreover, we can easily discriminate the GFP only and GFP/CFP positive lung metastases which is a prerequisite to evaluate the effect of transgene expression on lung metastasis formation.

**Figure 4:** Doxycycline mediated CFP expression does not affect the number of lung metastases. (A) Fresh isolated lungs were visualized with FLI. Control group is ‘– doxy’ and group 2 is ‘+ doxy’. (B) Using epifluorescence, we counted the number of fluorescent lung metastases only on one side of the small lobe. (C) Part of the isolated lungs was injected with inkt and the rest of the lungs were stained with H&E and representative pictures are shown.

### 3.5 Two distinct tumor cell subpopulations can be tracked in the same tumor microenvironment and doxycycline-induced CFP expression does not affect cell motility in vivo

Multiphoton imaging technology can be used to get an insight into the microenvironment and understand its role in the invasion and intravasation steps of metastasis inside living mammary tumors. Results show that the tumor microenvironment is a dynamic place where interactions between tumor cells, macrophages, blood vessels, and extracellular matrix fibers define the metastatic phenotype. In our set-up, we used a Biorad Radiance 2100 multiphoton microscope with an inverted Nikon TE2000 connected to a Spectra Physics Tsunami Ti-Sapphire laser of 5 W. As previously shown by E. Sahai and colleagues, wavelengths around 880 nm were most suitable for simultaneous imaging of GFP and CFP. We used for all experiments 860 nm. The selected
emission filters enabled us to visualise at the same time CFP (480/30), GFP (515/30) and the extracellular matrix (450/80) simultaneously (Fig. 7 and supplementary movie M1). Collagen type I which is very abundant in the tumor microenvironment can be visualised with second harmonic generation generated by the pulsed laser used in two-photon microscopy\textsuperscript{23-25}. In addition, when injecting Texas-Red dextran (620/60) in the tail vein of the animal two hours prior imaging, the blood flow and the macrophage in the tumor can be visualized. Together this provides information about the tumor microenvironment and its host cells (Fig. 6A and supplementary movie M2).

To get a better insight into metastasis mechanisms, we want to be able to track two cell subpopulations within a primary tumor which differentially express a candidate metastasis target gene by using two-photon intravital imaging. For this purpose, we checked firstly whether we were able to discriminate the GFP only and GFP/CFP cells, and secondly whether the tumor cell motility \textit{in vivo} was not affected by doxycycline induced CFP expression. We performed two-photon intravital imaging in primary tumors of both control and doxycycline groups. We could easily detect, discriminate and track the two tumor cell subpopulations: GFP only and GFP/CFP cells (Fig. 6B). We also observed equal amount of cell migration events in both groups. The very few observed migrating cells were solitary with an amoeboid morphology. Protrusion, crawling and host cell events were equally observed in the three animal groups. These cells were often observed moving linearly in association with the extracellular matrix (ECM) fibers. Figure 6B (and supplementary movies M3 to 5) shows time-series of both GFP only cells (green) and GFP-CFP (cyan) cells moving along collagen fibers as imaged by second harmonic generation (blue). After tracking the cells with image analysis software, we could determine the cell speed of both cell types. This speed was approximately 7.5 µm/min, which is nearly ten times faster as normally observed on two dimensional substrates \textit{in vitro} (Fig. 2B). Doxycycline-induced CFP expression did not affect average migration speed of individual tumor cells (Fig. 6C). These data fit with the identical metastatic spread to the lungs under both conditions (Fig. 4A and B). In summary, we can directly compare the behaviour of cells with different phenotype that can be tightly controlled by doxycycline induction in the same tumor environment \textit{in vivo}.
Figure 5: Tightly controlled CFP expression in both tumor and lung metastases. Fresh isolated lungs and tumors were imaged with multiphoton microscopy. Control group is ‘- doxy’ and group 2 is ‘+ doxy’. Simultaneous capture of GFP, CFP and collagen second harmonic fluorescence (blue) in the mammary tumors (A) and lung metastases (B) of control group and group. Scale bar for a-b = 100 µm.
Figure 6: The microenvironment of a mammary tumor can be imaged using multiphoton microscopy. (A) Simultaneous imaging of macrophages (red) that are seen outside dextran-labeled vessels (arrow) and the tumor cells mass (green). (B) Differences in motility can be determined by imaging cells with different transgene expression in the same tumor. The panels show time series of images of mammary tumor with cells either expressing GFP only or combined GFP/CFP after doxycycline induction. (C) Doxycycline induced CFP expression does not affect cell motility in vivo. The tumor cells move at a rate of around 7.5 µm/min over the course of the 30-min time-lapse. Scale bars are 100 µm (A) and 20 µm (B).

4. Discussion

A better understanding of the mechanisms of increased tumor cell motility and migration within the primary breast tumor is required. Constitutive expression of a transgene or knock down of a gene in breast cancer cells may affect critical processes that are required for primary tumor growth. To study the role of specific candidate metastasis genes on tumor cell motility and subsequent metastasis formation a model is needed in which gene expression can be induced after a primary tumor is formed. Here we set-up and describe a breast cancer model in which gene expression can be induced at any time point during tumor progression using a doxycycline-dependent conditional gene expression breast cancer cell line combined with two-photon intravital imaging. This model enabled us to study
Intravital imaging of differential metastatic behaviours.

tumor cell motility and intravasation processes of the control and manipulated breast cancer cell populations within the same primary tumor environment.

Currently available drug-inducible systems have often limited in vivo functionality because of leakiness and insufficient levels of induction\textsuperscript{7,8}. Our results demonstrate a high degree of robustness and versatility in allowing drug-controllable transgene expression in comparison to classical systems based on transactivation of synthetic promoters\textsuperscript{7,8}. A similar system for conditional transgene expression and gene knockdown has been recently described for its efficiency and versatility but not yet in the dual-colour imaging model we are aiming for\textsuperscript{6,26}. Indeed, Szulc J. and coworkers designed a lentiviral vector-based that controls conditionally the regulation of endogenous proteins in vitro and in vivo. They were able to perform in vivo doxycycline switches to turn endogenous tp53 expression off in a primary tumor at both RNA and protein levels. The GFP marker contained in the same vector was used to track the cells with a knockdown. Since GFP could be replaced by CFP, we also could use this construct to track the cells with a knockdown of a specific metastasis related protein using two-photon intravital microscopy.

Cancer cell migration in primary tumors can be directly observed by multiphoton microscopy\textsuperscript{11,13}. Two-photon laser scanning microscopy (TPLSM) offers important advantages over laser scanning microscopy, such as deep tissue penetration and three-dimensionally localised excitation. Here we used an already well described pair of fluorescent proteins in dual-color imaging with TPLSM, GFP and CFP. Nowadays, EGFP and the monomeric version of DsRed (mRFP1) are widely used for dual-color imaging experiments using laser scanning confocal microscopy\textsuperscript{27-35}. Nonetheless, this combination of fluorophores is not yet very suitable for two-photon intravital imaging. Indeed, the high intensity pulsed infrared lasers still commonly used for two photon microscopy produce light in the 750-980 nm range and are unable to excite RFPs efficiently in deep tissue since the output of most of Ti-Sapphire lasers drops off significantly with the increasing wavelength. Thus the combination of fluorophores GFP/CFP to track two different subpopulations is still the most suitable for the common two-photon microscope set-ups. More importantly, with this pair of fluorophores, there is still a free window to use fluorescent molecules in the far red spectrum such as Texas-red conjugated dextran to detect blood vessels in the primary tumor which is crucial for visualising intravasation events. So during image acquisition, we are able to visualise and track tumor cell subpopulations, the blood vessels and macrophages and the extra cellular matrix, all the different components indispensable to understand mechanisms of metastasis formation. The group of E. Sahai is using this dual-colour imaging to monitor tumour motility of two cell subpopulations in vivo. For instance, using multi-photon confocal imaging in a mixed tumor population MDA-MB-231 C15-4–GFP parental control cells were more motile than the MDA-MB-231 15-20-CFP MRTF-depleted cells\textsuperscript{36}. Very recently, they also performed intravital imaging of a ‘mosaic’ tumor containing MTLn3 CFP-
expressing control cells and MTLn3 TGFβR-DN-GFP expressing cells\textsuperscript{37}. Analysis of time-lapses made in the ‘mosaic’ tumors revealed that the overexpression of a dominant negative of the TGFβ receptor completely inhibits single cell movement while control cells still exhibit both single and cohesive cell migrations. Our approach combines both a relevant inducible breast cancer model together with a successful dual-color imaging. In this way we can quantify the effect of targeting a certain gene in metastasis formation and correlate those data with the distinct motility behaviour analysed with intravital imaging. In the case of an overexpression of a dominant negative protein (Fig. 7), a potential experimental set-up would include 1) a control group which is not exposed to doxycycline and which cells metastasize to the lungs, 2) a series of treatment groups exposed at different times to doxycycline to evaluate the reduction of lung metastases and 3) a final group exposed only at the end of the experiment to doxycycline so that not all the cells are CFP positive which allow intravital imaging to determine the motility behaviour of both cell types and correlate it to their metastatic capacity. We anticipate no problem in discriminating GFP and (GFP+CFP) cells due to the relative expression of the fluorophores since an even low CFP signal can be easily detected.

Our presently described methodology is based on an end-point observation of the tumor. It would be more efficient to know exactly at what time point the angiogenic switch, thereby allowing and facilitating intravasation of tumor cells, takes place so that the intravital imaging of the primary tumor would reveal many cell events of intravasation. A combination of monitoring the tumor progression with a non-invasive method (whole body imaging with fluorescence or bioluminescence) and TPLSM where tumors can be visualized at the single cell resolution would be very powerful, thus predicting the most optimal moment to monitor a maximum number of intravasation events within the primary tumor. Still whole body imaging using fluorescence is not yet as optimal as bioluminescence although promising results have described the use of a new fluorescent variant tdTomato\textsuperscript{38,39}. The latter could also be used for TPLSM since its brightness and photostability are much better than mRFP or mCherry. Recently a new fluorophore pair EGFP-mKeima has been also described as optimal for two-photon dual-color imaging\textsuperscript{40}. If mKeima is as performant for whole body imaging as tdTomato, this new pair EGFP-mKeima could suit both whole body imaging and TPLSM.
Figure 7: Schematic view of the methodology illustrated with an example (conditional expression of a CFP-tagged dominant negative protein that alters cell migration). Control cells are injected in the mammary fat pad and allowed to grow in a primary tumor without doxycycline exposure. In general three groups of animals can be included in the experimental set-up: 1) a control group to assess the metastatic capacity of the control GFP-MTLn3-ErbB1 cells (lungs full of GFP-positive metastases), 2) a series of animals where expression of the CFP-tagged dominant negative protein can be induced at different time points during the experiment (the earlier the induction, the lower the number of GFP-positive lung metastases), 3) a final group to perform intravital imaging in which CFP expression is induced half-way the experiment (not all the cells are CFP positive so that we can compare the motility behaviours of the control and the modified cells).

To avoid the end-point experiment due to the skin flap surgery needed to access the primary tumor for visualization; Kedrin and coworkers just published a new technique perfectly adapted for monitoring tumor cell migration within a mammary primary tumor for prolonged time \(^\text{41}\). They design a mammary imaging window so that there is no need any more to perform a skin flap surgery and most of all to sacrifice the mouse after imaging. Moreover, it is now possible to monitor tumor cell migration for more than 24 hours and at different time points during tumorogenesis. A perfect model for understanding metastatic behaviour of breast cancer cells would be the use of this new technique combined with our doxycycline-dependent conditional gene expression cell-line.

Currently, our established multi-color tumor model system allows visualization of tumor cells with two different phenotypes that may interact with
their microenvironment such as the extra-cellular matrix and other tumor host such as macrophages. Tumors with distinct cell populations and its microenvironment (macrophages and ECM) are uniquely identified by their fluorescence colors. The multi-color, tumor cell-environment interaction model system allows observations at the single-cell level in fresh tissue, affording further insights into the role of a specific protein in relation with the tumor microenvironment in tumor growth and progression and especially tumor cell motility. This is particularly very important for understanding the intravasation process. The model will now be used to elucidate the role of target genes within tumor cells with predicted roles in breast cancer progression. Our model is also excellently suited to evaluate the effect of targeted therapeutics that should block cell motility and consequently intravasation and thereby tumor cell dissemination.

Acknowledgments

We thank J. Wyckoff and J. Segall for helpful suggestion for our intravital imaging work and M. de Graauw for valuable discussion and critically reading the manuscript. This work was financially supported by grants from the Dutch Cancer Society (UL 2006-3538 and UL 2007-3860), the EU FP7 Health Program Metafight (Grant agreement no.201862), the Dutch Organization for Scientific Research (902-21-229 and 911-02-022) and TI Pharma (T3-107).

SUPPLEMENTAL DATA

Supplementary movie M1: Simultaneous capture of GFP, CFP and collagen second harmonic fluorescence in a living mammary tumor. Z-scan with multiphoton through a tumor with both GFP and CFP-labeled MTLn3 cells. Scan starts from the outside (ECM in blue) and go through the tumor 120 µm further with a step of 10 µm.

Supplementary movie M2: Imaging of blood vessels and macrophages following intravenous injection of Texas Red-dextran. Time lapse movie of 30 min.

Supplementary movies M 3 to 5: Time-lapse z-series of tumor cells GFP-MTLn3-ErbB1-TREAutoR3. Movie 3 shows GFP only tumor cells (-doxy) using ECM fibers for high velocity migration while movies 4 and 5 show GFP/CFP tumor cells (+doxy) also extending protrusions and crawling on collagen fibers. Movies are 50 µm thick projection and 30 min long.
Intravital imaging of differential metastatic behaviours
