2Kavli Institute for Particle Astrophysics and Cosmology,
There is abundant astrophysical evidence for the existence of dark matter [1–4], a nonrelativistic and non-baryonic matter component of the Universe that has so far eluded direct detection through interaction with ordinary matter [5]. Weakly interacting massive particles (WIMPs), which obtain their relic abundance by thermal freeze-out through weak interactions [6], are postulated in a wide variety of viable extensions to the standard model of particle physics [7–9]. They are a leading candidate to explain dark matter, despite strong constraints from many searches completed and ongoing at colliders [10–14], with telescopes [15–21], and in underground laboratories [22–29]. This Letter reports the first search for dark matter from the LUX-ZEPLIN (LZ) experiment, with the largest target mass of any WIMP detection experiment to date.

The LZ experiment [30, 31] is located 4850 ft underground in the Davis Cavern at the Sanford Underground Research Facility (SURF) in Lead, South Dakota, USA, shielded by an overburden of 4300 m

The LUX-ZEPLIN experiment is a dark matter detector centered on a dual-phase xenon time projection chamber operating at the Sanford Underground Research Facility in Lead, South Dakota, USA, with the largest target mass of any WIMP detection experiment to date.

This Letter reports the first search for dark matter from the LUX-ZEPLIN (LZ) experiment, with the largest target mass of any WIMP detection experiment to date.
water-equivalent [32]. It is a low-background, multidetector experiment centered on a dual-phase time projection chamber (TPC) mounted in a double-walled titanium cryostat [33] filled with 10 t of liquid xenon (LXe). The TPC is a vertical cylinder approximately 1.5 m in diameter and height, lined with reflective polytetrafluoroethylene, and instrumented with 494 3-inch photomultiplier tubes (PMTs) in two arrays at top and bottom. Energy depositions above approximately 1 keV in the 7 t active xenon region produce two observable signals: vacuum ultraviolet (VUV) scintillation photons (S1) and ionization electrons that drift under a uniform electric field to the liquid surface, where they are extracted and produce secondary scintillation in the xenon gas (S2). The ratio of S2 to S1 differentiates interactions with a xenon nucleus (producing a nuclear recoil, or NR) from interactions with the atomic electron cloud (producing an electron recoil, or ER).

The TPC is surrounded by two detectors, which provide veto signals to reject internal and external backgrounds. A LXe “skin” detector between the TPC field cage and the cryostat wall is instrumented with 93 1-inch and 38 2-inch PMTs. The outer detector (OD) is a near-hermetic system of acrylic tanks containing 17 t of gadolinium-loaded (0.1% by mass) liquid scintillator [34] to detect neutrons. The entire LZ detector system is in a tank filled with 238 t of ultrapure water to shield from the ambient radioactive background, and 120 8-inch PMTs are submerged in the water to record OD and water Cherenkov signals.

The data reported here were collected from December 23, 2021 to May 11, 2022, under stable detector conditions. The cathode and gate electrodes [35] established a drift field of 193 V/cm, determined by electrostatic simulation to vary by 4% over the volume considered in this analysis. The gate and anode electrodes established a gas extraction field of 7.3 kV/cm at radial position r = 0. Twelve TPC and two skin PMTs, with no specific position correlation, developed malfunctioning connections or excessive noise during commissioning and were disabled prior to the run. The temperature and pressure of the LXe were stable to within 0.2%, at 174.1 K (at the TPC bottom) and 1.791 bar(a). The liquid level was stable to within 10 µm, measured by precision capacitance sensors. The full xenon complement of 10 t was continuously purified at 3.3 t/day through a hot getter system, and the observed electron lifetime against attachment on electronegative impurities was between 5000 µs and 8000 µs, much longer than the 951 µs maximum drift time in the TPC.

The data acquisition (DAQ) system records events triggered by a digital filter sensitive to S2 signals in the TPC, reaching full efficiency for S2 pulses with six extracted electrons at a typical rate of 5 Hz. A time window of 2 ms before and 2.5 ms after each trigger is recorded, constituting an event. Zero-suppressed waveforms from all PMT channels, including low- and high-gain amplification paths for TPC and OD PMTs, are recorded for every trigger with single photoelectron efficiencies averaging 94%, 86%, and >95% for the TPC, skin, and OD PMTs, respectively.

Event properties are reconstructed through analysis of the PMT waveform shapes, timings, and distributions. Raw waveform amplitudes are normalized by the PMT and amplifier gains and summed separately within the TPC, skin, and OD. Integrated waveform area is reported in photons detected (phd) at each PMT, accounting for the double photoelectron effect in response to vacuum ultraviolet photons [36, 37]. Pulse boundaries are identified on the summed waveforms using filters tuned for prototypical pulse shapes in each detector. Pulses in the TPC are further classified as S1 or S2 based on their hit pattern and pulse shape. S1 pulses are required to have signals above the electronic noise threshold in at least three PMTs. The time ordering of the most prominent S1 and S2 pulses in each event is then used to identify single-scatter (one S1 preceding one S2) and multiscatter (one S1 preceding multiple S2s) events. The transverse (x, y) location of events is determined by the PMT hit pattern of S2 light from the extracted electrons, using the MERCURY algorithm [38]. The algorithm was tuned using uniformly distributed radioactive sources in the TPC and has a 1σ resolution of 4 mm for S2 signals of 3000 phd. The resolution worsens by approximately a factor of 2 near the TPC wall due to asymmetric light collection at the TPC edge. The location along the cylinder (z) axis is inferred from the drift time, and has a 1σ resolution of 0.7 mm for events near the cathode electrode.

LZ uses radioactive sources to correct for spatial variation in response across the TPC and to calibrate the detector response to ER and NR events. ER calibration events are obtained using dispersed sources 83Kr and 131mXe before and during the WIMP search and tritiated methane (CH3T) postsearch. The tritium source is important for understanding the response to low-energy ER events, the most prominent background component in the run. Localized NR calibration events are created using a deuterium-deuterium (DD) generator that emits monoenergetic 2.45 MeV neutrons [39–41] along a conduit through the water tank at approximately 10 cm below the liquid surface and AmLi sources [42] deployed between the walls of the cryostat vessels in three azimuthal positions and three z positions, a total of nine positions.

Using the dispersed sources, the S1 signal is normalized to the geometric center of the detector, using a correction in x, y, and drift time; this normalized value is called S1c. The S2 signal is normalized to a signal at the radial center and top (shortest drift time) of the detector; this normalized value is called S2c. The size of the S1 corrections is on average 9% and comes primarily from variations in light collection efficiency and PMT quantum efficiency. The size of the S2 corrections is on
average 11% in the \((x, y)\) plane and comes primarily from nonoperational PMTs and extraction-field nonuniformity caused by electrostatic deflection of the gate and anode electrodes. The S2 correction in \(z\) is due to electron attachment on impurities and averages 7%. Corrected parameters are uniform across the TPC to within 3%.

To reproduce the TPC response to ER and NR events, detector and xenon response parameters of the nesT 2.3.7 [43] ER model are tuned to match the median and widths of the tritium calibration data in log_{10}S2c-S1c space, and to match the reconstructed energies of the \(^{83}\text{Kr}\) (41.5 keV), \(^{129}\text{Xe}\) (236 keV), and \(^{131}\text{Xe}\) (164 keV) peaks. The photon detection efficiency \(q_1\) is determined to be 0.114 ± 0.002 phd/photon and the gain of the ionization channel \(g_2\) to be 47.1 ± 1.1 phd/electron [44]. The tritium data are best modeled with the nesT recombination skewness model [45] disabled, and comparisons between the tuned model and tritium data using several statistical tests show consistency throughout the full tritium ER distribution [46–49]. The nesT ER model also includes effects from electron capture decays [50] when making predictions from electron capture background sources. The parameters of the ER model were propagated to the nesT NR model and found to be in good agreement with DD calibration data, matching NR band means and widths to better than 1% and 4% in log_{10}S2c, respectively. Further checks comparing DD and AmLi neutron calibrations agree to 1%. Figure 1 shows the tritium and DD neutron data compared to the calibrated model.

The WIMP signal considered in this analysis is expected to produce low-energy, single-scatter NR signals uniformly distributed in the TPC, with no additional signals in the TPC, skin, or OD. The following strategy is used to obtain a clean sample of such events: exclude time periods of elevated TPC activity or electronics interference; remove multiscatter interactions in the TPC; remove events outside an energy region of interest (ROI); remove events due to accidental coincidence of S1 and S2 pulses; remove events with coincident signals in the TPC and skin or OD; remove events near the TPC active volume boundaries. Methods of bias mitigation that involve obscuring the data, such as blinding the signal region or adding fake events (“salting”), were avoided to allow control over larger sources of systematic errors that may be presented by a new detector. To mitigate bias in this result, all analysis cuts were developed and optimized on sideband selections and calibration data.

The search dataset totals 89 live days after removing periods for detector maintenance and calibration activity, as well as a 3% loss due to DAQ dead time and a 7% loss to periods excised due to anomalous trigger rates. Because dual-phase xenon TPCs experience elevated rates of activity after large S2 pulses [25, 28, 51, 52], a time hold-off is imposed to remove data taken after large S2s and after cosmic-ray muons traversing the TPC. These omissions result in a final search live time of 60 ± 1 d where a WIMP interaction could be reconstructed. In future searches, the hold-off can be relaxed by optimization with respect to analysis cuts and detector operating conditions.

The ROI is defined as S1c in the range 3 – 80 phd, uncorrected S2 greater than 600 phd (>10 extracted electrons), and S2c less than 10^5 phd, ensuring that signal efficiencies are well understood and background ER sources are well calibrated by the tritium data. Events classified as multiple scatters in the TPC are removed, as are events with poor reconstruction due to noise, spurious pulses, or other data anomalies.

A suite of analysis cuts targets accidental coincidence events, henceforth called “accidentals,”, where an isolated S1 and an isolated S2 are accidentally paired to mimic a physical single-scatter event. Isolated S1s can be generated from sources such as particle interactions in charge-insensitive regions of the TPC, Cherenkov and fluorescent light in detector materials, or dark-noise pileup. Isolated S2s can be generated from sources such as radioactive or electron emission from the cathode or gate electrodes, particle interactions in the gas phase or in the liquid above the gate electrode, or drifting electrons trapped on impurities and released with \(\mathcal{O}(100\text{ ms})\) time delay [52]. Analysis cuts to remove accidentals target individual sources of isolated S1s and S2s using the expected behavior of the S1 and S2 pulses with respect to quantities such as drift time, top-bottom asymmetry of light, pulse width, timing of PMT hits within the pulse, and hit pattern of the photons in the PMT arrays. The cuts remove >99.5% of accidentals, measured
using single-scatter-like events with unphysical (>951 µs) drift time and events generated by random matching of isolated S1 and S2 populations.

**FIG. 2.** Signal efficiency as a function of NR energy for the trigger (blue), the threefold coincidence and >3 phd threshold on S1c (orange), single-scatter (SS) reconstruction and analysis cuts (green), and the search ROI in S1 and S2 (black). The inset shows the low-energy behavior, with the dotted line at 5.5 keV$_{nr}$ marking 50% efficiency. The error band (gray) is assessed using AmLi and tritium data as discussed in the text.

Data-driven signal efficiencies for the trigger, reconstruction, and analysis cuts are shown in Fig. 2. The DAQ trigger efficiency is determined from DD data by comparing the external trigger of the generator against the TPC S2 trigger logic, and is confirmed using randomly triggered events collected throughout the search. The reconstruction efficiency for low-energy NR events is evaluated by comparing the reconstruction results against a large set of events manually identified as single scatter in DD data. An additional reconstruction inefficiency due to S2 splitting for long drift times for low numbers of extracted electrons is accounted for with simulation. Analysis cut efficiency is not determined directly from neutron calibration data as they do not cover the spatial extent of the TPC and are contaminated by a high rate of single photons and electrons. Instead, the efficiency throughout the full analysis volume is evaluated using tritium data for analysis cuts targeting S1 pulses and the combination of tritium and AmLi data for those targeting S2 pulses. Composite NR-like waveforms are generated using tritium single scatters with their S2 pulses replaced by smaller pulses from other tritium or AmLi events (an “AmLi-tritium” dataset). The uncertainty on the NR signal efficiency is the larger of the ±1σ statistical fluctuation of the AmLi-tritium dataset and the difference between the AmLi-tritium dataset and a pure AmLi dataset. The uncertainty is 3% for nuclear recoil energies >3.5 keV$_{nr}$, increasing to 15% at 1 keV$_{nr}$.

![Graph](image)

**FIG. 3.** Data in reconstructed $r^2$ and $z$ after all analysis cuts. Black (gray) points show the data inside (outside) the FV. Red crosses and blue circles show events vetoed by a prompt LXe skin or OD signal, respectively. The solid line shows the FV definition, and the dashed line shows the extent of the active TPC. Field nonuniformities cause the reconstructed $r$ position of the active volume boundary to vary as a function of $z$. Events with drift time of approximately 50 µs are from recoils in the gas that produce S1 and S2 pulses with a fixed time separation.

Events with coincident activity in the TPC and skin or OD are removed to reduce backgrounds producing γ rays and neutrons. To mitigate backgrounds associated with γ rays, events with a prompt signal in the OD (skin) within ±0.3 µs (±0.5 µs) of the TPC S1 pulse are removed. Neutrons can thermalize in detector materials and those that capture on hydrogen or gadolinium in the OD can be tagged by an OD pulse of greater than ~200 keV within 1200 µs after the TPC S1. A selection on large skin pulses in the same time window additionally tags γ rays returning to the xenon from an OD capture process. AmLi calibration sources placed at the nine locations close to the TPC are used to determine a position-averaged neutron tagging efficiency of 89 ± 3% for TPC single-scatters in the nuclear recoil band. Background data is used to determine a false veto rate of 5% due to accidental activity in the OD during the coincidence window. Background neutrons may have a higher tagging efficiency due to their harder energy spectrum and coincident γ-ray emission.

Finally, events outside a central fiducial volume (FV) are removed to reject external and other backgrounds that concentrate near the TPC boundaries, as shown in Fig. 3. Events at high radius have reduced position reconstruction resolution due to reduced S2 light collection efficiency and charge-loss effects within a few millimeters of the polytetrafluoroethylene wall. The radial extent of the FV and the S2 threshold are chosen simultaneously using data outside the S1c ROI to eliminate events leaking into the FV due to poor position reconstruction.
resolution. Radially, the FV terminates at 4.0 cm in re-
constructed position from the TPC wall, with small ad-
ditional volumes removed in the top (5.2 cm for drift time
<200 µs) and bottom (5.0 cm for drift time >800 µs) cor-
ers to account for increased rates of background in those
locations. Events within 6.0 cm of the (x, y) positions of
two ladders of TPC field-cage resistors embedded in the
TPC wall are also removed. Vertically, events with drift
times <86 µs and >936.5 µs are rejected, corresponding
to 12.8 cm and 2.2 cm from the gate and cathode elec-
trodes, respectively. The number of remaining events
from the wall entering the FV is estimated to be < 0.01.
The xenon mass in the FV is estimated to be 5.5 ± 0.2 t
using tritium data and confirmed by geometric calcu-
lation.

Figure 4 shows the distribution in log$_{10}$S2c−S1c of the
335 events [53] passing all selections, along with con-
tours representing a 30 GeV/c$^2$ WIMP, a flat NR distri-
bution, and the background model. The signal model as-
sumes spin-independent scattering from WIMPs with an
isotropic Maxwell–Boltzmann velocity distribution, pa-
rameterized as in Ref. [54], with inputs from Refs. [55–
60]. The WIMP model has an approximately exponen-
tially decreasing energy spectrum with shape that de-
pends on the mass of the WIMP [55].

The background model in this analysis consists of nine
components, grouped according to their spectra in the
ROI or the uncertainty on their rate. Table I lists the
expected number of events from each component.

The dominant ER signal in the search comes from
radioactive decay of impurities dispersed in the xenon.
$^{214}$Pb from the $^{222}$Rn decay chain, $^{212}$Pb from $^{220}$Rn, and
$^{85}$Kr have broad energy spectra that are nearly flat in en-
ergy across the ROI and are summed into an overall β
background. The concentrations of $^{124}$Xe (3.26 µBq/kg) and
$^{212}$Pb (0.14 µBq/kg) are determined by fitting to energy peaks outside the ROI. The xenon was puri-
ﬁed of krypton above ground using gas chromatogra-
phy [62], and an in situ mass spectroscopy measurement
of 144 ± 22 ppq $^{85}$Kr (g/g) informs the $^{85}$Kr rate esti-
mate. The β component is further combined with a small (<1 %) and similarly flat ER contribution from γ
rays originating in the detector components [63] and cav-
ern walls [64]. Solar neutrinos are also predicted to con-
tribute a nearly flat ER spectrum in the ROI, with a rate calculated using Refs. [54, 65–67]. As the predic-
tion is very precise, neutrinos are kept separate from the
detector β background in this model. The naturally oc-
curring isotopes of $^{124}$Xe (double electron capture) and
$^{136}$Xe (double β decay) contribute ER events, and the predictions are driven by the known isotopic abundances,
lifetimes, and decay schemes [68–70].

Cosmogenic activation of the xenon prior to under-
ground deployment produces short-lived isotopes that de-
cayed during this first run, notably $^{127}$Xe (36.3 d) and
$^{37}$Ar (35.0 d) [71–73]. Atomic de-excitations following
$^{127}$Xe L- or M-shell electron captures fall within the ROI
if the ensuing $^{127}$I nuclear de-excitation γ ray(s) escapes
the TPC. The rate of $^{127}$Xe electron captures is con-
strained by the rate of K-shell atomic de-excitations,
which are outside the ROI. The skin is effective at tag-
ing the $^{127}$I nuclear de-excitation γ ray(s), reducing this

TABLE I. Number of events from various sources in the
60 d × 5.5 t exposure [61]. The middle column shows the
predicted number of events with uncertainties as described in the
text. The uncertainties are used as constraint terms in a com-
bined fit of the background model plus a 30 GeV/c$^2$ WIMP
signal to the selected data, the result of which is shown in the
right column. $^{37}$Ar and detector neutrons have non-Gaussian
prior constraints and are totaled separately. Values at zero
have no lower uncertainty due to the physical boundary.

| Source                   | Expected Events | Fit Result |
|--------------------------|-----------------|------------|
| β decays + Det. ER       | 215 ± 36        | 222 ± 16   |

$^{37}$Ar [0, 288] 52.5 ± 9.9
Detector neutrons 0.4 ± 0.2 0.0 ± 0.2
Total – 333 ± 17
background by a factor of 5. The number of $^{37}$Ar events is estimated by calculating the exposure of the xenon to cosmic rays before it was brought underground, then correcting for the decay time before the search [74]. A flat constraint of 0 to three times the estimate of 96 events is imposed because of large uncertainties on the prediction.

The NR background has contributions from radiogenic neutrons and coherent elastic neutrino-nucleus scattering (CEνNS) from $^8$B solar neutrinos. The prediction for the CEνNS rate, calculated as in Refs. [54, 65–67], is small due to the S2>600 phd requirement. The rate of radiogenic neutrons in the ROI is constrained using the distribution of single scatters in the FV tagged by the OD and then applying the measured neutron tagging efficiency from the AmLi calibration sources (89 ± 3 %). A likelihood fit of the NR component in the OD-tagged data is consistent with observing zero events, leading to a data-driven constraint of 0.0 $^{+0.2}_{−0.1}$ applied to the search. This rate agrees with simulations based on detector material radioassay [63].

Finally, the expected distribution of accidentals is determined by generating composite single-scatter event waveforms from isolated S1 and S2 pulses and applying the WIMP analysis selections. The selection efficiency is then applied to unphysical drift time single-scatter-like events to constrain the accidentals rate.

**FIG. 5.** The 90% confidence limit (black line) for the spin-independent WIMP cross section vs. WIMP mass. The gray dot-dash line shows the limit before applying the power constraint described in the text. The green and yellow bands are the 1σ and 2σ sensitivity bands. The dotted line shows the median of the sensitivity projection. Also shown are the PandaX-4T [26], XENON1T [25], LUX [28], and DEAP-3600 [75] limits.

**FIG. 6.** Reconstructed energy spectrum of the best-fit model. Data points are shown in black. The blue line shows total summed background. The darker blue band shows the model uncertainty and the lighter blue band the combined model and statistical uncertainty. Background components are shown in colors as given in the legend. Background components from $^8$B solar neutrinos and accidents are included in the fit but are too small to be visible in the plot.

Statistical inference of WIMP scattering cross section and mass is performed with an extended unbinned profile likelihood statistic in the log$_{10}$S2c−S1c observable space, with a two-sided construction of the 90% confidence bounds [54]. Background and signal component shapes are modeled in the observable space using the GEANT4-based package BACCARAT [76, 77] and a custom simulation of the LZ detector response using the tuned NEST model. The background component uncertainties are included as constraint terms in a combined fit of the background model to the data, the result of which is also shown in Table I.

Above the smallest tested WIMP mass of 9 GeV/c$^2$, the best-fit number of WIMP events is zero, and the data are thus consistent with the background-only hypothesis. Figure 5 shows the 90% confidence level upper limit on the spin-independent WIMP-nucleon cross section $\sigma_{SI}$ as a function of mass. For WIMP masses between 13 GeV/c$^2$ and 36 GeV/c$^2$, background fluctuations produce a limit that is substantially smaller than the median expected limit, as shown by the dot-dashed line in Fig. 5. For these masses, the limit is constrained to a cross section such that the power of the alternate hypothesis is $\pi_{crit} = 0.16$ [78]. This restricts the fluctuation to 1σ below the median expected limit. The introduction of the power constraint also introduces overcoverage, i.e., the coverage of the limit with the power constraint is greater than 90%. The minimum of the limit curve is $\sigma_{SI} = 9.2 \times 10^{-48}$ cm$^2$ at $m_\chi = 36$ GeV/c$^2$. The minimum of the unconstrained limit curve is $6.2 \times 10^{-48}$ cm$^2$ at 26 GeV/c$^2$, and the minimum of the median expected limit is $1.9 \times 10^{-47}$ cm$^2$ at 43 GeV/c$^2$. The background model and data as a function of reconstructed energy are shown in Fig. 6, and the data agree with the background-only model with a p-value of 0.96. LZ also reports the most sensitive limit on spin-dependent neutron scatter-
The LZ experiment has achieved the highest sensitivity to spin-independent WIMP-nucleon scattering for masses greater than 9 GeV/c^2 due to the successful operation of an integrated detector system containing the largest dual-phase xenon TPC to date. LZ is continuing operations at SURF and will undertake further detector and analysis optimization to search for a broad range of rare-event physics searches, including WIMPs, neutrinoless double-beta decay, solar neutrinos, and solar axions [80–82] over an estimated 1000 day exposure.

Appendix - Spin Dependent Results

WIMP-nucleon scattering can also have a spin-dependent interaction in which two limiting cases are considered: that WIMPs scatter only on protons or only on neutrons. Two isotopes of xenon have non-zero nuclear spin, 129Xe (spin 1/2, 26.4% natural abundance) and 131Xe (spin 3/2, 21.2% natural abundance) [85]. As both have an unpaired neutron, the search is most sensitive to WIMP-neutron scattering. Sensitivity to a spin-dependent WIMP-proton interaction arises from mixing between proton and neutron spin states in isotopes with an unpaired neutron, albeit with increased uncertainty on the predicted signal rate [86–91]. Signal models for both the neutron and proton cases are constructed using the nuclear structure factors with uncertainties from Refs. [88, 90, 91]. This analysis quotes nominal limits which correspond to the mean structure functions from [90] and is chosen to facilitate a like-for-like comparison to previous limits from Xe-based experiments. An uncertainty is constructed for each mχ by calculating the limit corresponding to the minimum and maximum interaction rate at each energy across the three models; this uncertainty also applies to the previous xenon results. The details of data selection, background modeling, and statistical inference are identical to those reported in the main text.

Above the smallest tested WIMP mass of 9 GeV/c^2, the best-fit number of WIMP events is zero for both neutron and proton cases, and the data are thus consistent with the background-only hypothesis. Figure 7 shows the 90% confidence level nominal upper limit (black line) and nuclear structure function uncertainty on the limit (grey band) on the WIMP-neutron spin-dependent cross section as a function of mass. The minimum of the limit curve is at mχ = 30 GeV/c^2 at a cross section
FIG. 7. The 90% confidence limit (black line) and uncertainty bands (gray) coming from xenon nuclear correction factors for the spin-dependent WIMP-neutron cross section vs. WIMP mass using the mean of the nuclear structure factors from [90] and range across [88, 90, 91]. Also shown are the PandaX-II [92], LUX [93], and XENON1T [94] limits. A similar uncertainty band as shown on this result applies to the other Xe-based limits.

FIG. 8. The 90% confidence limit (black line) and uncertainty bands (gray) coming from xenon nuclear correction factors for the spin-dependent WIMP-proton cross section vs. WIMP mass using the mean of the nuclear structure factors from [90] and range across [88, 90, 91]. Also shown are the PICO-60 [24], PandaX-II [92], LUX [93], and XENON1T [94] limits. A similar uncertainty band as shown on this result applies to the other Xe-based limits. The PICO-60 result relies on WIMP-scattering on the spin of the unpaired proton of 19F with minimal uncertainty.

of $\sigma_{SD}^p = 1.49 \times 10^{-42} \text{cm}^2$; a power constraint is applied between $13 \text{GeV}/c^2$ and $36 \text{GeV}/c^2$. Figure 8 shows the 90% confidence level nominal upper limit and uncertainty on the WIMP-proton spin-dependent cross section as a function of mass. The minimum of the limit curve is at $m_\chi = 32 \text{GeV}/c^2$ at a cross section of $\sigma_{SD}^p = 4.2 \times 10^{-41} \text{cm}^2$; a power constraint is applied between $13 \text{GeV}/c^2$ and $32 \text{GeV}/c^2$. The minimum and maximum limits which form the nuclear structure factor uncertainty are also power-constrained over the relevant mass range for both the neutron and proton cases.

Supplemental Materials

Detailed Event Rates

TABLE S1. Number of events remaining after each stage of event selection criteria described in the main text.

| Selection description          | Events after selection |
|-------------------------------|------------------------|
| All triggers                  | $1.1 \times 10^8$      |
| Analysis time hold-offs       | $6.0 \times 10^7$      |
| Single scatter                | $1.0 \times 10^7$      |
| Region-of-interest            | $1.8 \times 10^5$      |
| Analysis cuts for accidentals | $3.1 \times 10^4$      |
| Fiducial volume               | 416                    |
| OD and Skin vetoes            | 335                    |

Tuned Detector and Xenon Response Model Details

The LZ detector and xenon response models are implemented in a NEST-based application that includes effects such as curved electron drift paths from field non-uniformities, finite position reconstruction resolution in the transverse ($x, y$) and longitudinal $z$ directions, and position-dependence in S1 and S2 areas. The key numerical parameters of the NEST model are provided in Table S2. Additionally, a header file for NEST 2.3.7 that will reproduce the ER and NR response models used in this analysis is available online at https://doi.org/10.1103/PhysRevLett.131.041002. Note that the extraction field number is known to be an effective value due to multiple models for this effect in NEST, and this parameter is tuned such that the extraction efficiency matches the LZ data.

In addition to the parameters below, the width of the predicted ER and NR bands had to be reduced to match LZ calibration data and, as mentioned in the main text, the NEST recombination skewness model was turned off. There are detailed instructions for implementing these changes in the provided header file.

TABLE S2. NEST tuning parameters. Parameters in the top half of the table are input parameters, while bottom half parameters result from NEST calculations.

| Parameter                  | Value               |
|----------------------------|---------------------|
| $g_1^{gas}$                | 0.0921 phd/photon   |
| $g_1$                      | 0.1136 phd/photon   |
| Effective gas extraction field | 8.42 kV/cm          |
| Single electron            | 58.5 phd            |
| Extraction Efficiency      | 80.5 %              |
| $g_2$                      | 47.07 phd/electron  |

Limits in terms of number of WIMP events

The main text reports the limit in the standard form of WIMP cross section vs WIMP mass. In the supplemental material, we provide an alternative view of the result, reporting the limit as the number of WIMP events, for the spin-independent case, as shown in Fig. S1. As described in the main text, the limit is constrained by the power constraint method between 13 GeV/c$^2$ and 36 GeV/c$^2$. Both the limit before the power constraint and the limit after the power constraint are shown, as well as the expected sensitivity.

In unified interval analyses such as this, statistical fluctuations in the data create statistical fluctuations in the limit, including to values below the median sensitivity of the experiment; a further discussion of this effect is found in Section VI of [S95]. We report the median expected limit, as well as the 1 and 2σ bands around the median, as
recommended, to mitigate the cognitive impact of these fluctuations. When comparing experiments or interpreting the compatibility of theory with this result, we recommend consideration of the median expected limit as well.
