Mutation of a Putative Sperm Membrane Protein in *Caenorhabditis elegans* Prevents Sperm Differentiation but Not Its Associated Meiotic Divisions

Steven W. L'Hernault and P. Michele Arduengo
Department of Biology, Emory University, Atlanta, Georgia 30322

Abstract. Spermatogenesis in the nematode *Caenorhabditis elegans* uses unusual organelles, called the fibrous body-membranous organelle (FB-MO) complexes, to prepackage and deliver macromolecules to spermatids during cytokinesis that accompanies the second meiotic division. Mutations in the *spe-4* (spermatogenesis-defective) gene disrupt these organelles and prevent cytokinesis during spermatogenesis, but do not prevent completion of the meiotic nuclear divisions that normally accompany spermatid formation. We report an ultrastructural analysis of *spe-4* mutant sperm where the normally close association of the FB's with the MO's and the double layered membrane surrounding the FB's are both defective. The internal membrane structure of the MO's is also disrupted in *spe-4* mutant sperm. Although sperm morphogenesis in *spe-4* mutants arrests prior to the formation of spermatids, meiosis can apparently be completed so that haploid nuclei reside in an arrested spermatocyte. We have cloned the *spe-4* gene in order to understand its role during spermatogenesis and the molecular basis of how mutation of this gene disrupts this process.

DEVELOPMENT of sperm in the nematode *Caenorhabditis elegans* offers a number of advantages as a model system for studies of cellular morphogenesis. Spermatogenesis occurs via a series of steps that are cytologically distinct, and these stages occur sequentially along the length of the gonad. Additionally, many aspects of spermatogenesis will occur in vitro and many genes in which mutations specifically arrest spermatogenesis have been recovered. The mature spermatozoon that results from this differentiation pathway has a single pseudopod and moves by crawling on the substrate; nematode sperm lack both a flagellum and acrosome (for review see Kimble and Ward, 1988).

Unequal partitioning of cellular constituents during cell division can play an important role during development (for review see Davidson, 1986). In *C. elegans*, unequal cytoplasmic partitioning occurs at several stages during spermatogenesis. During meiosis II, for instance, part of the system that ensures the orderly segregation of components to the spermatid are unusual organelles called the fibrous-body membranous organelle (FB-MO) complexes. Several of the genes in which mutations disrupt aspects of spermatogenesis (*spermatogenesis-defective*) do so by affecting cytoplasmic partitioning (Hirsh and Vanderslice, 1976; Ward, 1986; Ward and Miwa, 1978; Argon and Ward, 1980; Edgar, 1982; Burke, 1983; Sigurdson et al., 1984; L'Hernault et al., 1988; Shakes, 1988, 1989a,b). Several *spe* mutants have defects in formation and/or function of the FB-MO complexes and a subset of these mutants also prevent formation of haploid spermatids (Ward et al., 1981; Shakes and Ward, 1989b; Varkey, J., and S. Ward, unpublished observations).

Mutations in the *spe-4* gene disrupt the coordination of cytokinesis with meiotic nuclear divisions during spermatogenesis so that a spermatocyte-like cell that contains four haploid nuclei forms instead of four spermatids (L'Hernault et al., 1988). In this paper, we present electron microscopic analysis showing that developing *spe-4* spermatocytes contain abnormal FB-MO complexes. An allele specific restriction fragment length polymorphism (RFLP) and transgenic rescue have been used to localize and clone the *spe-4* gene. Molecular analysis suggests that *spe-4* encodes a 465 amino acid integral membrane protein that is expressed during spermatogenesis. We suggest that, as a likely FB-MO complex protein, the *spe-4* product might play a role in spermatid formation during meiosis II.

called the terminal spermatocyte.

Phenotypic Analyses

These phenotypic analyses. Testes and sperm from all three analyzed as described previously (Nelson and -, 1980); SM contains Dpy males obtained from dpy-5 hermaphrodites; these and previous analyses (L'Hernault et al., 1988) were performed on F1 Dpy males produced by mating control experiments~ were examined; they were highly similar (see below). Control experiment~

Testes were released by hand-dissecting males in SM buffer, pH 7.8, and preparation were raised in liquid culture and synchronized by hypochlorite agar and seeded with

E. coli P90C treatment (Nelson et al., 1982). Animals with a female soma and containing nDp4 (Thomas, J., and H. R. Horvitz, unpublished observations), or otherwise during outcrossing of

a TR679 mut-2 (n457) background (Collins et al., 1987). Standard C. elegans nomenclature has been used throughout this paper (Horvitz et al., 1979). Genetic markers used are LGI, unc-13(e51, e091), unc-15(e73), dpy-5(e61), and dpy-6 (Rose and Baillie, 1980); LGIV, fem-1(hcl71s) (Nelson et al., 1978), fem-3(q23gf) (Barton et al., 1987); LGV, him-5(e1490) (Hodgkin et al., 1979). The mutation dpy-5 (Rose and Baillie, 1980), the translocation nDp4 (Thomas, J., and H. R. Horvitz, unpublished observations), or the mutation gid-1(q268) (Schedel, T., and J. Kimble, unpublished observations) were used to balance and maintain the heterozygous spe-4 strains used in this study.

Worm Culture

Routine handling of worms was performed at 20°C in petri plates filled with agar and seeded with Escherichia coli OP50 (Brenner, 1974). Worms to be used for DNA preparation were raised on 9-cm agarose plates seeded with E. coli OP50 (Miller et al., 1977; Fire, 1986). Worms to be used for RNA preparation were raised in liquid culture and synchronized by hypochlorite treatment (Nelson et al., 1982). Animals with a female soma and containing oocytes, but no sperm, were recovered from cultures of fem-3(hcl17) that were raised at 25°C (Nelson et al., 1978). Animals with a female soma and containing sperm, but no oocytes, were recovered from cultures of fem-3(q23) that were raised at 25°C (Barton et al., 1987). Males from him-5 liquid cultures were prepared as described previously (Klass and Hirsh, 1981; Nelson et al., 1982).

Phenotypic Analyses

Testes were released by hand-dissecting males in SM buffer, pH 78, and analyzed as described previously (Nelson and Ward, 1980); SM contains 50 mM NaCl, 25 mM KCl, 5 mM CaCl2, 1 mM MgSO4, and 5 mM Hepes. Dpy males obtained from dpy-4 spe-4 dpy-5 balanced lines were used for these phenotypic analyses. Testes and sperm from all three spe-4 mutants were examined; they were highly similar (see below). Control experiemnts were performed on F1; Dpy males produced by mating dpy-5/+ males to dpy-5 hermaphrodites; these and previous analyses (L'Hernault et al., 1988) indicate that dpy-5 sperm are indistinguishable from N2 wild type. In this paper, the final cellular stage accumulated during spe-4 spermatogenesis is called the terminal spermatocyte.

Testes and sperm were prepared for transmission EM essentially as described previously (Shakes and Ward, 1980) except that samples were em-bedded for thin sectioning in LX112 (Ladd Research Industries Inc., Burlington, VA).

Nucleic Acid Methods

DNA was prepared from mixed populations of worms by a modification of previous procedures designed for worms grown on plates (Wood, 1988). RNA was isolated as previously described (Burke and Ward, 1983; Rosenquist and Kimble, 1988). General methods for manipulation of DNA and RNA were from Sambrook et al. (1989) and Ausubel et al. (1989). Plasmid DNA for worm microinjections was prepared and purified by chromatography on Qia gen resin according to the manufacturer's instructions (Qiagen Inc., Chatsworth, CA).

Southern and Northern blots were prepared using Hybond N (Amersham Corp., Arlington Heights, IL), and DNA probes were labeled by random hexamer priming as described by Sambrook et al. (1989). Hybridizations and subsequent washing protocols followed Church and Gilbert (1984) and were performed at 65°C.

Primer extension and RNA polymerase chain reaction (PCR) experiments were performed to determine the 5' end of the spe-4 transcript. The RNA used for either of these techniques was from male him-5 worms, fem-3 worms raised at 25°C (which have a female soma but a male germline), and, as a negative control, fem-3 worms raised at 25°C (which have a female soma and germline). Primer extension was performed by using a 5' end labeled antisense oligonucleotide of 30 bases (primer #2, Table I) that was annealed to either 1 µg of polyA+ or 20 µg of total RNA. Conditions used for primer extension were essentially as described in Sambrook et al. (1989). Sizes of primer extension DNA products were determined by comparison to DNA sequencing reactions in adjacent lanes on a 6% polyacrylamide/urea sequencing gel. RNA PCR was performed using the GeneAmp Thermostable rTh Reverse Transcriptase RNA PCR kit according to the manufacturer's instructions (Perkin Elmer Cetus, Norwalk, CT). Reverse transcriptase reactions included 250 ng total RNA primed with an antisense primer (Primer #3, Table I) and were incubated at 60°C for 10 min. PCR reagents and the sense primer (Primer #1, Table I) were then added to the first strand reverse transcription products and 35 cycles of PCR were performed, each with a 1-min 95°C denaturation step followed by a 1-min 53°C annealing/extension step. Resulting PCR products were fractionated by agarose gel electrophoresis.

Standard techniques were used for both DNA cloning and sequence analysis (Sambrook et al., 1989). Cosmids containing genomic DNA from the unc-13 to lin-10 interval of chromosome I were identified and recovered as part of the physical mapping of the C. elegans genome (Coulson et al., 1986, 1988) and generously provided by A. Coulson and J. Sulston (Medical Research Council, Laboratory of Molecular Biology, Cambridge, England). Restriction fragments from cosmids were fractionated on agarose gels, excised, and subcloned into Bluescript (Stratagene, La Jolla, CA) or M13mp8 (Manisch-Ferron et al., 1985). Two existing cDNA libraries prepared from polyA+ RNA from L4 stage enriched or mixed stage hermaphrodites (courtesy of J. Arhinger and J. Kimble, Laboratory of Molecular Biology, University of Wisconsin, Madison, WI; and R. Barstead and R. Waterston, Department of Genetics, Washington University School of Medicine, St. Louis, MO) were screened with genomic subclones. We recovered three cDNAs and the largest (from the R. Barstead and R. Waterston library) was completely sequenced.

PCR was performed with Taq polymerase (Perkin-Elmer/Cetus or

The Journal of Cell Biology, Volume 119, 1992 56
Promega) on DNA samples either to localize the deletion in the spe-4(q347) allele or to verify the presence of cloned DNA in transgenic worms. Samples containing either 100 ng of genomic or 1 ng of cosmid DNA were amplified by PCR with primers #4 and 5 (see Table I) in order to characterize the spe-4(q347) deletion. 100 µl reactions were set up under standard conditions (Promega). 25 cycles were performed in a Perkin-Elmer DNA Thermal Cycler under the following conditions: denaturation at 94°C for one min, annealing at 63°C for two min, and extension at 72°C for one min. PCR products were fractionated by agarose gel electrophoresis and gel bands containing the desired PCR product were excised and pooled, and the contained DNA was purified with GeneClean (Biotrol, La Jolla, CA) for direct sequencing.

PCR was also performed on small numbers of worms to characterize transgenic worms and various fertile and sterile spe-4 homozygous controls. Worms were first picked to individual plates to verify if they were fertile or laid unfertilized oocytes. Worms of the appropriate genotype were then pooled and processed for PCR by the techniques of Barstead and Waterston (1991). Aliquots containing the DNA from eight worms were subjected to 30 cycles of PCR with primer #6 and either primer #1 or #7 (see Table I for primer positions) under the following conditions: denaturation at 94°C for one min, annealing at 53°C for two min, and extension at 72°C for one min. The resulting PCR products were fractionated by agarose gel electrophoresis.

DNA was sequenced by the chain termination method (Sanger et al., 1977) using T7 DNA polymerase (Sequenase II, U.S. Biochemicals, Cleveland, OH), and both double stranded templates in Bluescript and single stranded M13 templates were used. Sequencing was initiated from oligonucleotides complementary to previously determined sequences. One cDNA and the entire genomic region from which it was derived plus flanking regions at both ends were sequenced, the former on the sense strand and the latter on both strands. Sequences were compiled and analyzed using GENEPRO (Riverside Scientific, Bainbridge Island, WA) and FASTA (Pearson and Lipman, 1988).

Germline Transformation of C. elegans

Transformation of C. elegans by microinjection of recombinant plasmid DNA was carried out essentially as described by Mello et al. (1991). This technique involves a single, high-volume injection into the central cytoplasmic syncytium of each of the two distal gonadal arms. Worms were microinjected with either 100 µg/ml pOA1, which is a Bluescript recombinant plasmid that contains the spe-4 gene (see Results) or 10 µg/ml pOA1 mixed with 100 µg/ml pRF4. The pRF4 plasmid contains rol-6(nu1000)/II, which confers a dominant rolling phenotype that aids in identifying worms that have been genetically transformed by the microinjection procedure (Mello et al., 1991). DNA for microinjection was suspended in 10 mM Tris-HCl, 1 mM EDTA (TE), pH 7.5.

The recessive nonconditional sterility exhibited by all spe-4 mutants required that we microinject heterozygous non-Spe hermaphrodites, and then test for the effect of the transforming DNA on their Spe progeny. The recipient strain for all microinjections was gld-l(q268)/unc-13[el109]spe-4(q347)[lin-10](el1439). Mutation of the lin-10 gene prevents formation of a functional vulva so that embryos hatch within a lin-10 mutant hermaphrodite, which is then devoured by its feeding progeny (Ferguson and Horvitz, 1983). This “bag of worms” phenotype associated with lin-10 requires functional sperm, so spe-4 lin-10 mutant hermaphrodites blot with oocytes, but never form embryos and do not “bag”. It was reasoned that transformation of spe-4 should result in the “bag of worms” phenotype appearing in the paralyzed (due to unc-13) unc-13 spe-4 lin-10 progeny of microinjected heterozygous parents. About 5% of lin-10 hermaphrodites do not become “bags of worms” because they form a functional vulva, and these animals permit outcrossing to test a spe-4 transgene in other genetic backgrounds. Outcrossing was performed with dpy[Spe-4(q347)] heterozygous males in order to establish transgenic strains in which the unc-13 lin-10 chromosomes were replaced by spe-4 chromosomes. Pedigree analysis and PCR were performed in order to ensure that these strains contained the transgene.

Results

Review of C. elegans Spermatogenesis

Development of sperm in C. elegans males has been described in detail (Wolf et al., 1978; Ward et al., 1981; Ward, 1986; Kimble and Ward, 1988) and these cellular events are reviewed in Fig. 1. The primary spermatocyte initially forms in syncytium with a cytoplasmic core called the rachis. Before the meiotic divisions, the primary spermatocyte buds off the rachis and completes development without any requirement for intimate association with other cells. As in most cells, nuclear divisions are closely coordinated with cytokinesis and other aspects of cytodifferentiation. The primary spermatocyte undergoes the two nuclear divisions of meiosis to give rise to four haploid spermatids. These spermatids form by budding off of a residual body, and spermatids only contain a subset of cellular constituents present in the secondary spermatocyte. Material within the residual body, which includes all the ribosomes and most of the actin and tubulin, is apparently resorbed (Wolf et al., 1978; Ward et al., 1981; Nelson et al., 1982; Ward, 1986). Sessile spermatids, since they lack ribosomes, complete differentiation into motile spermatzoa in the absence of cellular protein synthesis (Ward et al., 1983).

The asymmetric partitioning of cellular constituents to the spermatids as they bud off of the residual body partly occurs via specialized organelles called the FB-MO complexes, and the morphogenesis of these structures is reviewed in Fig. 2 (Wolf et al., 1978; Ward et al., 1981; Ward, 1986; Roberts et al., 1986). The MO's begin to form from the Golgi apparatus in pachytene spermatocytes, and the FB's form a short time later in close association with the MO's (Fig. 2 a). Growth of the fibrous body in the primary spermatocyte occurs within the confines of a MO-derived membrane env-
Figure 2. Summary of morphogenesis of the FB-MO complex. (a) The fibrous body (FB) develops in close association with, and is surrounded by the membranous organelle (MO) within the primary spermatocyte. The MO is separated by a collar (C) region into a head (speckled region at left) and body (region to the right of the collar); (b) the FB-MO complex reaches its largest size within mature spermatocytes. The double layered MO-derived membrane surrounds the striped fibers within the FB, and the fibers of the FB contain MSP; (c) the membranes surrounding the FB retract and fold up as the FB begins to disappear and disperse its contents during budding of spermatids from the residual body; (d) the head of each MO (arrow) moves to a position just below the plasma membrane (PM) of the spermatid, and the FB's disappear; (e) the head of the MO fuses at the collar to the plasma membrane and exocytoses its contents (speculor at the arrow) onto the cell surface. A permanent fusion pore remains at the point of each MO fusion (each cell has many MOs).

Figure 3. Aberrant morphogenesis of the FB-MO complexes in spe-4 mutants. (A and B) Developing FB-MO complexes in dpy-5 (control); (A) and spe-4(q347) dpy-5 (B) primary spermatocytes. The association of FB's with MO's and the presence of a double layered membrane surrounding the FB observed in controls is not seen in spe-4. (D and H) Division of spe-4 spermatocytes. Both micrographs depict cells with at least two nuclei (there could be two more nuclei in each of these cells in another section plane). Sometimes more than one nucleus resides in a cell that is not attempting to divide (D; q347) and other times the cell is obviously constricted (H; hcb1). Note distended MO's that are not associated with FB's; the latter are not membrane bound. Also note the granular "necklace" (arrowheads) surrounding the nuclei, and vacuoles (V) that are not observed in wild type and are presumed to be MO-derived in D. (G) Higher magnification view of an example of abnormal MO's in spe-4(q347) terminal spermatocytes. (C) Control spermatids budding from the residual body (not evident in this section plane) in which the FB's are still at least partly membrane bound and (F) after completion of budding and completion of FB disassembly. Note the prominent MO's near the cell surface. (E) Region of a spermatozoon showing a MO that has fused with the cell surface. A permanent fusion pore (arrow) is evident. Bars: (A-D, F, and H) 1 μm; (E and G) 0.5 μm.

In spe-4 mutants, meiotic divisions, cytokinesis, and cytoklative differentiation during spermatogenesis are not coordinated, resulting in a spermatocyte-like cell that contains four haploid nuclei (Fig. 1; also see L'Hernault et al., 1988). To understand the basis of this phenotype, we performed an ultrastructural analysis to examine the terminal phenotype of these spe-4 spermatocytes and to determine how they differed from wild type. In wild type primary spermatocytes, the FB's develop in close association with the MO's and are enveloped by a double layered membrane as they form (Fig. 3 a). In spe-4 primary spermatocytes, the membrane surrounding the FB's, when it is present, does not appear to be a double layered structure (Fig. 3 b). MO's in spe-4 spermatocytes appear swollen and they either are not associated with FB's or, when they are, this association is not as prominent as in wild type (Fig. 3 a). Development of spe-4 spermatocytes continues until a cell that is apparently arrested without completing spermatid formation is observed (Fig. 3, d and h). Occasionally, these cells will attempt to divide (Fig. 3 h) but, frequently, no evidence of cellular division is observed (Fig. 3 d). In spe-4 mutant testes, many cells with these ultrastructural abnormalities accumulate, suggesting that this is the terminal phenotype. The MO's can be grossly swollen in the terminal spermatocyte and still lack any obvious association with FB's (Fig. 3, d, g, and h). The FB's present in spe-4 terminal spermatocytes are frequently not surrounded by membrane (Fig. 3, d and h) but, occasionally, small patches of membrane that never completely surround the FB are observed (data not shown). In contrast, during wild type spermatogenesis, FB-MO complexes segregate to spermatids.
during meiosis II (Fig. 3 c) and the FB's disassemble while the MO's move to the cell surfaces (Fig. 3 f). The wild type FB's remain surrounded by a double membrane until the spermatid buds off the residual body (Wolf et al., 1978; Ward et al., 1981; Roberts et al., 1986). The MO's then fuse with the cell surface and undergo exocytosis during formation of the mature spermatoozon (Fig. 3 e). We have not observed spe-4 terminal spermatocytes (Fig. 3, d, g, and h) that contained any MO's like those found in wild-type spermatids (Fig. 3, c and f) or spermatozoa (Fig. 3 e).

**Genetics**

The spe-4 gene has been mapped to chromosome I and shown to complement sDf5 but failed to complement sDf6 (L'Hernault et al., 1988). This placed spe-4 near the unc-15 unc-13 interval, which is <0.025 map unit, and to the right of unc-15 (Rose and Bailtie, 1980) (Fig. 4 a). We recovered Unc recombinants from spe-4(hc78)/unc-15(e73) unc-13(e51) animals and 2/2 unc-15 animals were Spe while 0/3 unc-13 animals were Spe, which also suggests that spe-4 is to the right of unc-15. Two factor mapping in cis was then performed on unc-13(e1091)spe-4(q347)/+ + . 10 complete broods comprised of 2,951 animals were analyzed; only one of 730 unc-13 animals was fertile and all 2,221 wild types were fertile. This suggests that spe-4 is ~0.7 map unit from unc-13, based on the previously described two factor mapping equation (Fig. 4 a; Brenner, 1974). The correspondence of the genetic map with the physical map can vary in different regions of the C. elegans genome (e.g., Greenwald et al., 1987) but in the unc-15 unc-13 interval, 1 map unit is ~3,200 kb of DNA (Maruyama and Brenner, 1991). This meant that spe-4 was possibly within 225 kb of unc-13.

**Molecular Localization of spe-4**

The physical map of chromosome I is nearly complete in the region where spe-4 is located (Coulsou et al., 1986, 1988), and we obtained a number of cosmid clones that are located in this region. Genomic DNA was prepared from C. elegans strains heterozygous for one of the three spe-4 alleles, transferred to Southern blots, and probed with several recombinant cosmid cosmids containing a portion of chromosome I in order to search for a RFLP. Two of these cosmids, C44E1 (Fig. 4 a) and ZK524 (data not shown), identified a RFLP associated with the spontaneous spe-4 allele q347 (Fig. 5 a); these two cosmids are partially overlapping. RFLP's associated with q347 were also observed when genomic DNA was digested with any of five other restriction enzymes, and a restriction map of the spe-4 region deduced from genomic DNA. The lines under the map are cDNA (pMA7) or cloned, genomic restriction fragments that were sequenced (pMA2 and pMA6) or used for transgenic rescue (pOA1).
prepared

Figure 5. (A) DNA polymorphisms in spe-4. DNA was prepared from wild type N2 and the heterozygous balanced spe-4 strains sDf5/spe-4(hc78), sDf5/spe-4(hc81), and sDf5/spe-4(q347). 5 µg of DNA was digested with EcoRV, subjected to electrophoresis in a 0.7% agarose gel, transferred onto Hybond N, and hybridized to 32P-labeled cosmid C44E1. The arrowhead indicates the polymorphic restriction fragment associated with spe-4(q347). The arrow indicates the corresponding wild type restriction fragment. (B) Northern hybridization with a spe-4-specific probe. Total RNA was prepared from fem-1(hcl7) or fem-3(q23) worms reared at 25°C. Under these growth conditions, both of these mutant strains have female somatic tissues but the germline contains oo- but no sperm, while the germline of fem-1(hcl7) contains oocytes, but no sperm, while the germline of fem-3(q23) contains sperm but no oocytes. 20 µg of total RNA was subjected to electrophoresis in a 1.4% agarose gel containing formaldehyde, transferred to nylon and hybridized to the spe-4 genomic clone pMA2 (see Fig. 4 for the position of pMA2). The probe detects one ~1.5-kb spermatogenesis specific RNA. The sex nonspecific 5.9-kb mRNA encoded by unc-13 (Maruyama and Brenner, 1991) is present in these fem-1 and fem-3 RNA samples and has been detected with unc-13 specific probes (data not shown). For both A and B, size standards are indicated along the left margin of each figure.

These three recombinant plasmids were used as probes, DNA sequencing templates, and/or constructs for creation of transgenic worms, as described below. The right breakpoint of cosmid C44E1 lies between the rightmost EcoRI and EcoRV restriction sites depicted in Fig. 4 b (data not shown). This places the spe-4 gene at the right end of the C44E1 recombinant insert and to the right of unc-13, which begins closer to the other end of this cosmid (Maruyama and Brenner, 1991). Both unc-13 and spe-4 are transcribed left to right, and a near full length unc-13 cDNA does not hybridize to either pMA2 or pMA6 (data not shown).

The ultrastructural phenotype of spe-4 mutants suggests that a polypeptide within sperm might be affected by mutation of this gene. These data suggest that spe-4 transcription might occur only within animals engaged in spermatogenesis. This was examined by performing Northern hybridizations to blots containing RNA from worms that either contained sperm (genotype: fem-3[q23gf] raised at 25°C) or lacked sperm (genotype: fem-1[hcl78] raised at 25°C). An ~1.5-kb RNA was found only in fem-3 RNA when this blot was probed with a wild type 1.8-kb restriction fragment that included the region affected by the q347 deletion (pMA2, see Fig. 4 b for its position). Both fem-1[hcl7] and fem-3[q23] have female somatic tissues and, since they differ only in their germline, this suggests that pMA2 contains part of a gene that is spermatogenesis or sperm specific (Fig. 5 b). Complementary DNA clones corresponding to the ~1.5-kb RNA were isolated by screening C. elegans libraries with a pMA2 insert probe. Insert size and Southern hybridization experiments (data not shown) indicated that the largest cDNA, pMA7, was near full length (see below), and within a region encompassed by subclones pMA2 and pMA6 (Fig. 4 b).

The above-mentioned genetic and molecular data all are consistent with a spe-4 location near and to the right of unc-13 on chromosome I. We sought to confirm the location of spe-4 by microinjecting worms with a recombinant plasmid that contained DNA from the presumed spe-4 region. A total of 34 gld-1/lunc-13 spe-4 lin-10 heterozygous hermaphrodites were microinjected with the recombinant plasmid pOA1 (for the position of pOA1, see Fig. 4 b); 18 of these 34 hermaphrodites were co-injected with the rol-6 plasmid pRF4 as a dominant behavioral marker (see Materials and Methods). Fertility was restored to spe-4 worms microinjected with pOA1, and the results of these experiments are summarized in Table II. The pOA1 plasmid contains a 3.8-kb EcoRV restriction fragment that includes the entire putative spe-4 transcription unit, ~450 bp 5' to the transcription start and ~1,200 bp 3' to the proposed polyadenylation signal (see below). Three independently derived stable transformed lines were created and, in one case, a transgenic line (ebEx3) was outcrossed to replace both unc-13 spe-4 lin-10 chromosomes with spe-4 chromosomes. This outcross was performed in order to eliminate the lin-10 gene because its vulvaless phenotype results in broods that are much smaller than non-

Table II: Characterization of Three spe-4 Transgenes

Stable transgenic strains bearing the extrachromosomal arrays ebEx1, ebEx2, or ebEx3 were recovered from unc-13(e1091) spe-4(q347) lin-10(e1439)I hermaphrodites that were microinjected with plasmid DNA. Inheritance of these transgenes and the brood sizes of transgenic hermaphrodites were compared to non-transgenic control strains. These transgenes all contain the spe-4 plasmid pOA1, and ebEx2 and ebEx3 also contain the rol-6(sul-404)II plasmid pRF4 dominant selectable marker (see Materials and Methods). Brood sizes were determined for the bracketed number of hermaphrodites (n) and are presented as the mean number of progeny with the standard deviation (SD). ebEx3 was crossed into a spe-4(q347) or wild type chromosome I background in order to examine the brood size of non-Lin non-Unc hermaphrodites carrying this transgene.

* ~6% of the worms that inherit ebEx3 are mosaics that are either sterile rollers, fertile non-rollers, or express the rolling phenotype in only a portion of their cuticle.

ND, not determined.

Lin hermaphrodites (Table II). Construction of this strain relied on following the dominant rolling phenotype associated with transgenes that include a rol-6(sul-404)II mutant plasmid, such as ebEx3 (Mello et al., 1991). The continued presence of spe-4 wild type sequence within the ebEx3 transgene following this cross was directly demonstrated by PCR in which an amplified product formed only when spe-4 sequences were continuous with at least a portion of the Blue-script cloning vector (Fig. 6). The resulting ebEx3/spe-4 hermaphrodites had an average brood size that was ~81% of ebEx3/+ non-spe-4 controls (Table II). Detailed examination of the progeny of ebEx3/spe-4 hermaphrodites indicated that this transgene behaves like an extrachromosomal array that is mitotically unstable (Table II), which could explain why ebEx3/spe-4 did not have a wild type brood size. Consequently, it appears that pOA1 contains most, or perhaps all, sequence information required to restore fertility to spe-4 hermaphrodites.

Sequence of the spe-4 Gene

We determined the sequence of cDNA pMA7 on the sense strand and the corresponding, as well as flanking, genomic region on both strands (Fig. 7). Comparison of the genomic and cDNA sequences reveals that the spe-4 gene is composed of eight exons, and that pMA7 has a 10 nucleotide polyA tail at its 3′ end. The polyA tail is preceded by an imperfect match to the AATAAA consensus polyadenylation signal (Proudfoot and Brownlee, 1976). Primer extension indicates that the 5′ end of the spe-4 transcript is 23 nucleotides longer than cDNA pMA7 (Fig. 8 a). This experiment predicts that the 5′ end of the spe-4 transcript is at position 1 (Fig. 7), assuming no additional intron splicing. A sense primer (primer #1, Table I) at this presumed 5′ end was then used to show that it could prime PCR sense strand products following reverse transcription PCR with an antisense primer (primer #3, see Table I). The resulting product of this PCR closely corresponds in size to the predicted 236-bp fragment (Fig. 8 b), indicating that nucleotides 1-23 of the genomic sequence are found in the spe-4 mRNA and are not interrupted by an intron. Furthermore, both primer extension and reverse transcription PCR confirm that the transcription of spe-4 occurs only in animals engaged in spermatogenesis.

The data discussed above establish the transcription initiation point and indicate that the spe-4 transcript is 1,484 nucleotides without the polyA 3′ tail (Fig. 7). The first ATG at position 16 shows excellent agreement with the consensus translation start for C. elegans (Perry, M. D., G. H. Hertz, 1991). The continued presence of sper-4 wild type sequence within the ebEx3 transgene following this cross was directly demonstrated by PCR in which an amplified product formed only when spe-4 sequences were continuous with at least a portion of the Blue-script cloning vector (Fig. 6). The resulting ebEx3/spe-4 hermaphrodites had an average brood size that was ~81% of ebEx3/+ non-spe-4 controls (Table II). Detailed examination of the progeny of ebEx3/spe-4 hermaphrodites indicated that this transgene behaves like an extrachromosomal array that is mitotically unstable (Table II), which could explain why ebEx3/spe-4 did not have a wild type brood size. Consequently, it appears that pOA1 contains most, or perhaps all, sequence information required to restore fertility to spe-4 hermaphrodites.

L'Hernault and Arduengo C. Elegans Sperm Membrane Protein
and W. B. Wood, personal communication) and, if one assumes that it is used, the predicted polypeptide is 465 amino acids. The spe-4 gene contains seven introns and six of these are short (42-71 nucleotides) as is typical for C. elegans genes (Blumenthal and Thomas, 1988). The open reading frame (ORF) defined by cDNA pMA7 and primer extension extends to the 5' end of the transcript and shows excellent agreement to a C. elegans codon usage table provided by C. Fields (personal communication; Fig. 9).

Restriction mapping and sequencing of the cDNA pMA7 suggested that the deletion present in spe-4(q347) probably affected the spe-4 encoded protein. Additional restriction mapping revealed that exon five contained a KpnI site that was lacking in spe-4(q347) (Fig. 10 a). PCR primers were

---

**Figure 8.** Primer extension and reverse transcription PCR of spe-4 transcripts. For both techniques, the template total RNA was either fem-3 (which has a female soma and makes sperm but not oocytes), him-5 males (male soma and germline) or, as a negative control, fem-1 (female soma and germline). (a) Identification of the 5' end of the spe-4 transcript by primer extension. The three rightmost lanes contain the products of a primer extension reaction using a 32P end-labeled oligonucleotide (primer #2, see Table I) hybridized to 20 µg of total RNA. The size of the DNA products of reverse transcription was determined by comparison to DNA sequencing reactions primed with primer #2 and shown in the four leftmost lanes. These primer extension results indicate that the 5' end is an A (the sense strand complement of the T at the arrow), which is position +1 in Fig. 7. Note that both fem-3 and him-5 (which have sperm) form products (arrowheads) while no product is formed from fem-1 females (which lack sperm). (b) Confirmation of the 5' end of the spe-4 transcript by reverse transcription PCR. Reverse transcription was performed on 250 ng of total RNA hybridized to primer #3. Primer #1, designed to be at the 5' transcription start as determined by primer extension (see Fig. 8 a), was then added, PCR was performed, and the three rightmost lanes of this ethidium bromide stained 1.5% agarose gel contain 5% of the products of these reactions. Note that both fem-3 and him-5 (which have sperm) form the expected 236-bp product (arrowhead) while no product is formed from fem-1 females (which lack sperm). The size standards for b are a 100-bp DNA ladder, and the positions of the 100-, 200-, and 300-bp fragments appear along the left margin of the figure.

---

**Figure 9.** Analysis of ORFs within the pMA7 cDNA sequence and the ORF that extends from the 5' end of pMA7 to position -108 in the genomic sequence (see Fig. 7). All six potential reading frames are displayed by the GENEPRO program (Riverside Scientific), which can evaluate the codon usage within ORFs. Any potential ORFs that start with a methionine are indicated by a thick dashed horizontal bar. Superimposed on the horizontal bars are a series of dots. Each dot represents a comparison of the codon used at that position in the ORF and a table of codon usage provided by C. Fields (Institute for Genomic Research, Gaithersburg, MD). The vertical position of dots relative to the horizontal dashed bar indicates similarity to the C. elegans codon usage table. Dots above the bar are more similar to the table values than dots below the bar. The ORF in reading frame one (indicated on the ordinate) is open to the left border of the plot and the first ATG methionine codon (the start of the thick, dashed bar) is the proposed translational start. This ATG (arrow; also see position 16 in Fig. 7) is followed by a single long ORF (1395 nucleotides, 465 amino acid residues) that shows excellent agreement with C. elegans codon usage (note the large number of dots above the thick, dashed line). This ORF terminates in a TGA stop codon (at arrowhead; also see position 1,411 in Fig. 7).
Further characterization of the genomic region affected by spe-4(q347).

(A) 5 μg of genomic DNA from N2(wild-type), sDf5/spe-4(hc78), sDjff/spe-4(hc81), or sDj75/spe-4(q347) was double-digested with EcoRI and KpnI and subjected to electrophoresis on a 1% agarose gel, transferred to nylon, and hybridized to an oligolabeled large EcoRI insert fragment of the cDNA pMA7. The probe is homologous to two EcoRI/KpnI restriction fragments that are both ~1.3 kb (arrow). Deletion of the single KpnI site between these two EcoRI sites by the spe-4(q347) mutation results in a fusion fragment of ~2.4 kb (arrowhead).

(B) PCR strategy to obtain the sequence of the region deleted by the spe-4(q347) mutation. PCR was performed as described in Materials and Methods. The PCR primers were #4 and #5 (see Table I). An ethidium bromide stained 1.5% agarose gel that had been loaded with 10% of the PCR products of 1 ng C44E1 recombinant cosmid DNA, 100 ng genomic DNA, or a "no added template" DNA control is shown. The cosmids and all samples of C. elegans genomic DNA produced the wild type product (arrowhead) while strains containing spe-4(q347), in addition, produced a smaller fragment (arrow). We used two different heterozygous spe-4(q347) strains in order to ensure that the balancer chromosome (sDjff or nDp4) was not the template for this smaller fragment (arrow). For both A and B, size standards are indicated along the left margin of each figure.

Discussion

We have presented phenotypic, genetic, and molecular analyses of spe-4, a gene involved in sperm morphogenesis. We have discovered that the genetic lesion within a spontaneous allele is a small deletion, and, after localizing this deletion on the physical map of chromosome I, have cloned the spe-4 gene. This cloned DNA can rescue spe-4-associated sterility in germline transformation experiments. Transcription of the spe-4 gene results in an ~1.5-kb polyA+ mRNA that is produced only in animals engaged in spermatogenesis. This spe-4 mRNA encodes a protein that is not homologous to the wild type 465 amino acids would result.

A hydropathy plot (Kyte and Doolittle, 1982) of the spe-4 protein indicates that it is likely to be an integral membrane protein. There are at least seven regions that could span the membrane using the conservative window of 19 residues and the first, third, and sixth regions are followed by a sequence of charged residues. As compared with other membrane proteins, the deduced amino acid sequence near the NH2 terminus and the position of the first proposed membrane spanning region suggests that the spe-4 polypeptide lacks a cleavable NH2 terminal signal sequence (von Heijne, 1985). The region from residues 211–394 is hydrophilic, as it contains many charged and polar residues, and presumably faces either the extracellular space or the lumen of a vesicle. There are a total of five potential N-linked glycosylation sites in the spe-4 protein at positions 27, 159, 172, 313, and 334; we do not know if these sites are used but the last two are located within the above-mentioned hydrophilic region (Fig. 11). The spe-4 protein has no significant homology to other proteins in either the GENPEPT (update 71) or SWISS-PROT (update 21) databases. The most significant matches were to membrane spanning domains within several other integral membrane proteins (data not shown).
previously characterized proteins, but hydropathy analysis indicates that it is probably an integral transmembrane protein that passes through the lipid bilayer multiple times.

The sterile phenotype of spe-4 mutants is caused by their failure to form normal spermatids and, consequently, functional spermatozoa. All three spe-4 alleles are completely penetrant for this sterile phenotype and form terminal spermatocytes in which meiotic nuclear divisions have occurred without the usually concomitant cell divisions. The major subcellular defect revealed by ultrastructural analyses of spe-4 mutant spermatocytes is disruption of the FB-MO complexes. These structures, which are first observed in spermatocytes prior to the first meiotic division, apparently play a role that is unique to nematode sperm. Unlike flagellated sperm, where spermatids contain ribosomes engaged in translation and a lengthy time interval separates the second meiotic division from loss of ribosomes to the residual body (for review see Olds-Clarke, 1988), nematode spermatids do not contain ribosomes because they are discarded into the residual body as these cells form (Wolf et al., 1978; Ward et al., 1981). Consequently, all protein components that are necessary for subsequent differentiation into spermatozoa must be placed within the spermatid as it forms. The FB-MO complexes ensure that macromolecules synthesized in spermatocytes are segregated to spermatids during the cytokinesis that accompanies the second meiotic division. Components within the FB-MO complexes include proteins that are necessary for differentiation of spermatids (Ward and Klass, 1982; Roberts et al., 1986).

Ultrastructural localization of gold-conjugated mAbs specific for sperm antigens has been used to elucidate many details of how FB-MO complexes form during C. elegans spermatogenesis (Roberts et al., 1986). One of these antibodies recognizes MSP, and it localizes to the fibers that are within the FB. A second antibody (Ward et al., 1986) recognizes proteins within membranes of the FB-MO's and the sperm plasma membrane. These studies reveal that MO's appear prior to the FB's, and each FB forms in close association with an MO and becomes surrounded by MO-derived membrane as it grows by adding new MSP containing fibers. In contrast, our work suggests that a close association of FB's with MO's does not occur in either spe-4 primary or terminal spermatocytes. It has been suggested that the wild type FB represents a membrane enclosed site where fibers can form because the localized high concentration of soluble MSP favors polymerization (=fiber) formation. Our work has established that fiber integrity in spe-4 mutants requires neither continuous association of an FB with a MO nor the presence of a surrounding membrane. Detailed study of the early morphogenesis of FB's in spe-4 mutants should reveal how FB's form and if there is ever association of MO's with FB's.

FB-MO complexes contain several proteins that are required by the C. elegans spermatozoon, and they are segregated to the spermatid during meiosis II when this cell separates from the residual body. The membrane around each FB retracts towards its associated MO, the fibers of the FB disassemble, releasing their MSP contents to the cytoplasm (Ward and Klass, 1982; Roberts et al., 1986) and the MO moves to the cell surface. The MO then fuses with the cell surface and forms a permanent fusion pore as it releases its contents onto the cell surface by exocytosis during conversion of spermatids to spermatozoa (Ward et al., 1978; Nelson and Ward, 1980; Ward et al., 1981). MSP localizes within the pseudopod where it appears to play a cytoskeletal role (Roberts, 1983; Roberts et al., 1989; Seisenwald et al., 1989). Unfortunately, it is presently not possible to determine whether the spe-4 protein functions in gametes because mutations in this gene arrest cellular morphogenesis prior to spermatid formation. Recovery of appropriate temperature sensitive spe-4 mutations might allow spermatids to form...
under permissive conditions. These spermatids could then be shifted to restrictive conditions in order to mutationally disrupt the spe-4 protein and examine its role within spermatids and during the conversion of spermatids into spermatocytes.

Several genes that affect FB-MO ultrastructure have been identified (e.g., Ward et al., 1981; J. Varkey and S. Ward, personal communication), and one of these genes (spe-10) is expressed in a manner that is characteristic of wild type MO's, they become large and vacuolated. The MOs within spe-10 spermatids and the stable FBs that lack surrounding membranes are both similar in appearance to the MOs and FBs observed within spe-4 terminal spermatocytes. The mutant phenotypes of spe-4 and spe-10 both suggest that the spermatids are forming; normally, an FB does not become associated with an MO until after spermatid formation. These FBs do not disassemble their fibrous contents and they end up in the residual body, rather than the spermatid. The MOs are segregated to the spermatid where, instead of developing a terminal spermatid after completion of polypeptide synthesis. These spermatids could then

permits their passage into the ER membrane (reviewed by Singer, 1990). The proposed signal sequence in the protein has at least seven regions that meet this criterion. In general, the signal sequence, and the protein should retain its NH2 terminus after completion of polypeptide synthesis. Molecular data together with the ultrastructural analyses discussed above suggest spe-4 encodes an integral mem-
brane protein that resides within membranes that are part of the FB-MO complex. It is also possible that the spe-4 encoded protein resides within other membranes in sperm. To address this question, we are raising antisera to the spe-4 encoded protein that has been synthesized in bacteria. Electron microscopic localization of the spe-4 antigen with specific antibodies should allow unambiguous determination of its subcellular localization in wild type spermatocytes and spermatids.

We thank Tim Schell for providing spe-4(q347) and many helpful discussions, Alan Coulson and John Sulston for providing cosmids, Ichiro Maruyama for helpful discussions and his restriction map of cosmid C44E1, and Tom Roberts, Barry Yedvobnick, Hilary Ellis, and Guy Be-

nier for their interest and advice. We would also like to thank Nancy L'Hernault, who provided assistance with EM, Ollie Appleby for technical assistance, and Henk Maier for microinjection advice.

This work was supported by grants from the National Institutes of Health (GM0697) and the Emory University Research Committee to S. W. L'Hernault. Some of the stocks used in this work were obtained from the Caenorhabditis Genetics Center, which is supported by a contract grant (1101-AG-2113) between the National Institutes of Health and the University of Missouri.

Received for publication 27 January 1992 and in revised form 1 July 1992.
