ABSTRACT

We estimate the conversion factor relating CO emission to H2 mass, αCO, in five Local Group galaxies that span approximately an order of magnitude in metallicity—M 31, M 33, the Large Magellanic Cloud (LMC), NGC 6822, and the Small Magellanic Cloud (SMC). We model the dust mass along the line of sight from infrared (IR) emission and then solve for the αCO that best allows a single gas-to-dust ratio (δGDR) to describe each system. This approach remains sensitive to CO-dark envelopes H2 surrounding molecular clouds. In M 31, M 33, and the LMC we find αCO ∼ 3–9 M⊙ pc−2 (K km s−1)−1, consistent with the Milky Way value within the uncertainties. The two lowest metallicity galaxies in our sample, NGC 6822 and the SMC (12 + log(O/H) ∼ 8.2 and 8.0), exhibit a much higher αCO. Our best estimates are αCO,NGC6822 ∼ 30 M⊙ pc−2 (K km s−1)−1 and αCO,SMC ∼ 70 M⊙ pc−2 (K km s−1)−1. These results are consistent with the conversion factor becoming a strong function of metallicity around 12 + log(O/H) ∼ 8.4–8.2. We favor an interpretation where decreased dust shielding leads to the dominance of CO-free envelopes around molecular clouds below this metallicity.

Key words: dust, extinction – galaxies: ISM – ISM: clouds – ISM: molecules – Local Group

1. INTRODUCTION

In the local universe, stars form out of clouds made of molecular hydrogen (H2; e.g., Fukui & Kawamura 2010). Understanding the processes that lead to star formation on large scales requires measuring the mass and distribution of this gas. Unfortunately, H2 lacks a dipole moment, most molecular gas is found under conditions too cold to excite quadrupole emission, and the high opacity of molecular clouds prevents UV absorption studies from probing the bulk of the gas. Estimates of a galaxy’s H2 distribution therefore rely on indirect tracers, most commonly the lower rotational transitions of CO. The conversion between CO intensity and H2 abundance has been the topic of a great deal of investigation. In particular, the effect of metallicity and the local radiation field on the CO-to-H2 mass conversion factor, αCO,12 have been studied for more than two decades.

Infrared (IR) dust emission is a powerful tool to address this problem. Dust is observed to be well mixed with gas (e.g., Bohlin et al. 1978; Boulanger et al. 1996) and may be mapped by its emission at IR wavelengths (e.g., Schlegel et al. 1998). By comparing IR emission, CO, and H1, one can constrain αCO (e.g., Thronson 1988; Israel 1997b). The procedure is to estimate the dust mass from IR emission, measure atomic gas (H1) and CO emission over a matched area, and then assume that the total gas mass (H2 + H1) is proportional to the dust mass, with the two related by a fixed gas-to-dust ratio. With measurements that span a range of relative CO, H1, and dust masses, it is possible to simultaneously constrain the gas-to-dust ratio and αCO. Key advantages of this approach are that it remains sensitive to any CO-free envelopes of H2 and that the calibration of αCO is pinned to the H1 within the system being studied.

This exercise has been applied to several dwarf irregular galaxies (Israel 1997a, 1997b; Leroy et al. 2007, 2009; Gratier et al. 2010; A. Bolatto et al. 2011, in preparation). In the low-metallicity Small Magellanic Cloud (SMC), the results suggest a very large αCO ∼ 90–270 M⊙ pc−2 (K km s−1)−1. An analogous application to the Milky Way yields αCO ∼ 4–9 M⊙ pc−2 (K km s−1)−1 (Bloemen et al. 1990; Dame et al. 2001), roughly compatible with determinations of αCO from fitting the diffuse γ-ray background (Strong & Mattox 1996; Abdo et al. 2010).

Most studies of αCO have focused on a single galaxy or high latitudes in the Milky Way, where confusion is minimal. Israel (1997b) worked with a varied galaxy sample but since his work the available IR and CO data for nearby galaxies have improved dramatically. This is largely thanks to the Spitzer Space Telescope, which recently finished its cool mission and produced high-quality maps of a number of Local Group galaxies. This is therefore a natural time to apply this technique to measure αCO across the Local Group in a self-consistent way.

In this paper, we combine maps of CO, H1, and IR emission to estimate αCO in five Local Group galaxies: the massive spiral M 31, the dwarf spiral M 33, the dwarf irregular NGC 6822, and...
the Large Magellanic Cloud (LMC), and the SMC. By treating all five systems self-consistently, we minimize uncertainty in the “zero point” of the approach. With the Herschel mission now underway and the execution of several complementary CO and H\textsc{i} surveys, this approach should be readily extensible to many nearby galaxies in the next few years.

2. THE MODEL

We assume that dust and gas are linearly related by a gas-to-dust ratio, \( \delta_{\text{GDR}} \), so that

\[
\delta_{\text{GDR}} \Sigma_{\text{dust}} = \Sigma_{\text{H}_2} + \Sigma_{\text{H}\textsc{i}},
\]

where \( \Sigma_{\text{dust}}, \Sigma_{\text{H}_2}, \) and \( \Sigma_{\text{H}\textsc{i}} \) are the mass surface densities of dust, \( \text{H}_2 \), and \( \text{H}\textsc{i} \) along a line of sight. Substituting \( \Sigma_{\text{H}_2} = \alpha_{\text{CO}} I_{\text{CO}} \), we have

\[
\delta_{\text{GDR}} \Sigma_{\text{dust}} = \alpha_{\text{CO}} I_{\text{CO}} + \Sigma_{\text{H}\textsc{i}},
\]

where the CO-to-\( \text{H}_2 \) conversion factor, \( \alpha_{\text{CO}} \), and gas-to-dust ratio, \( \delta_{\text{GDR}} \), are unknown and \( \Sigma_{\text{dust}}, I_{\text{CO}}, \) and \( \Sigma_{\text{H}\textsc{i}} \) are measured. After assembling \( \Sigma_{\text{dust}}, I_{\text{CO}}, \) and \( \Sigma_{\text{H}\textsc{i}} \) over many lines of sight in a region, we will use these data to solve for \( \alpha_{\text{CO}} \) that best allows a single \( \delta_{\text{GDR}} \) to describe the data.

2.1. \( \alpha_{\text{CO}} \): Definitions and Scales

The literature contains several working definitions of \( \alpha_{\text{CO}} \) that apply to different scales or phases of the gas. In this paper and Equation (2), we define \( \alpha_{\text{CO}} \) as the factor to convert from CO emission to total molecular gas mass on scales larger than individual clouds. Under this definition, \( \alpha_{\text{CO}} \) includes any \( \text{H}_2 \) associated with C* in the outer, poorly shielded parts of the clouds as well as gas immediately mixed with CO. Indeed, our goal is to measure whether such envelopes become dominant below some metallicity. Because this definition integrates over cloud structure, it is possible to derive a single \( \alpha_{\text{CO}} \) for a whole galaxy or part of a galaxy, and to view that \( \alpha_{\text{CO}} \) as a function of large-scale environmental factors. We choose this definition of \( \alpha_{\text{CO}} \) because it is directly applicable to CO measurements of distant galaxies on kiloparsec scales.

This is distinct from the ratio of CO to \( \text{H}_2 \) only for molecular gas mixed with CO. Dynamical measurements using CO emission at high spatial resolution may mainly probe this quantity with limited sensitivity to \( \text{H}_2 \) in an extended envelope not mixed with CO. The difference between this quantity and the quantity that we study has caused some confusion, leading to apparent contradictions between IR-based measurements and dynamical measurements. In fact, these may be largely attributed to the different regions being probed (Section 6).

Similarly, we do not define \( \alpha_{\text{CO}} \) as the ratio of \( \text{H}_2 \) to CO along a pencil beam. We have no reason to expect that this quantity, or any ratio that places many elements across a cloud, remains reasonably constant across part of a galaxy. In contrast, comparisons of dust and CO emission imply dramatic variations in the CO-to-\( \text{H}_2 \) ratio within individual clouds (Pineda et al. 2008).

Our spatial resolution ranges from 45 to 180 pc (Table 1). For these resolutions, giant molecular clouds (GMCs) will mostly lie within one or two resolution elements (e.g., Heyer et al. 2009). This is ideal for our definition of \( \alpha_{\text{CO}} \). We wish to integrate over the structure of these clouds to make a single \( \alpha_{\text{CO}} \) a more appropriate assumption.

| Target | Metallicity | Resolution |
|--------|-------------|------------|
| LMC 8.43 240 60 | M 31 Inner | 9.0 | 170 |

3. DATA

To carry out this experiment we require maps of IR (to estimate \( \Sigma_{\text{dust}} \)), CO, and H\textsc{i} emission. Such maps have been published for M 31, M 33, NGC 6822, the LMC, and the SMC. We refer to the original papers for details of the observations, reduction, and data.

For M 31, we use the CO map taken by Nieten et al. (2006) using the IRAM 30 m telescope. This map has already been masked by Nieten et al. (2006) and so contains only positive signal. We trace H\textsc{i} using the 21 cm map of Brinks & Shane (1984), obtained with the Westerbork Synthesis Radio Telescope (WSRT). Gordon et al. (2006) present Spitzer maps at 24, 70, and 160 \( \mu \text{m} \).

For M 33, we take CO data from Rosolowsky et al. (2007), which combine BIMA (Engargiola et al. 2003) and FCRAO data (Heyer et al. 2004). We use the WSRT map by Deul & van der Hulst (1987). We use Spitzer data reduced following Gordon et al. (2005) and presented by Verley et al. (2007) and Tabatabaei et al. (2007).

We use the first CO map of the LMC obtained by NANTEN (Fukui et al. 1999), the Australia Telescope Compact Array (ATCA) + Parkes H\textsc{i} map of Kim et al. (1998, 2003), and IR maps from the Spitzer SAGE legacy program (Meixner et al. 2006; Bernard et al. 2008).

We also use the NANTEN CO map of the SMC (Mizuno et al. 2001), the ATCA + Parkes H\textsc{i} map by Stanimirovic et al. (1999). The SMC IR maps are a combination of data from the SAGE-SMC legacy program (Gordon et al. 2009; K. D. Gordon et al. 2011, in preparation) and the S3MC survey (Bolatto et al. 2007).

For NGC 6822, we use the IRAM 30 m CO map by Gratier et al. (2010), the SINGS Spitzer maps presented by Cannon et al. (2006), and the Very Large Array H\textsc{i} map of de Blok & Walter (2003). Gratier et al. (2010) mapped the CO \( J = 2 \rightarrow 1 \) line for this galaxy, while the rest of our maps are of CO \( J = 1 \rightarrow 0 \). We follow Gratier et al. (2010) in assuming a line ratio of 0.7; we phrase all of our results in terms of CO \( J = 1 \rightarrow 0 \) intensity assuming this ratio. We mask the CO map, keeping only emission above \( \sim 3\sigma \) at the original 15′ resolution.
For each galaxy, we convolve all data to the resolution of the coarsest data set and align them on a common astrometric grid. In M 31, M 33, and NGC 6822, we are limited by the resolution of the Spitzer 160 μm data and so convolve all data to have a 45′ (FWHM) Gaussian point-spread function (PSF). In the LMC, the NANTEN CO data limit our resolution to >2′; because signal to noise in the CO map is also a concern, we convolve all data to 4′ resolution. The NANTEN CO data also set the resolution in the SMC, where we convolve all data to 2.6 resolution.

In the LMC and SMC, we subtract a foreground from the IR maps. Following Bot et al. (2004), we remove a scaled version of the Milky Way H I over these lines of sight (for the exact approach, see Leroy et al. 2009). In M 33 and M 31, the reduction imposes the condition that the intensity is 0 away from the galaxy, making a cirrus subtraction unnecessary. In NGC 6822, Cannon et al. (2006) already removed a Galactic foreground.

The statistical uncertainty in the CO maps is about 0.30 K km s$^{-1}$ in M 31, 0.35 K km s$^{-1}$ in M 33, 0.30 K km s$^{-1}$ in the LMC, 0.01 K km s$^{-1}$ in NGC 6822, and 0.08 K km s$^{-1}$ in the SMC (though in each case this varies somewhat with position). The statistical noise in the H I maps is very roughly 1 – 3 $M_\odot$ pc$^{-2}$ with the uncertainty dominated by imperfect knowledge of the H I opacity and the reconstruction of extended emission. The noise in the IR maps is ~0.2 MJy sr$^{-1}$ at 70 μm and ~0.7 MJy sr$^{-1}$ at 160 μm. The zero point in the IR maps is uncertain by ~0.1 MJy sr$^{-1}$ at 70 μm and ~0.5 MJy sr$^{-1}$ at 160 μm.

Throughout this paper, IR intensity has units of MJy sr$^{-1}$, color-corrected to the IRAS scale. H I surface density has units of $M_\odot$ pc$^{-2}$ and includes a factor of 1.36 to account for helium. In the SMC and the LMC, H I includes an opacity correction based on Dickey et al. (2000). In M 31, M 33, and NGC 6822, we have assumed that the H I is optically thin. CO $J = 1 \rightarrow 0$ intensity has units of K km s$^{-1}$ and is related to H2 surface density, in units of $M_\odot$ pc$^{-2}$, by a factor $\alpha_{CO}$ that includes helium (so that $\Sigma_{H_2} = \alpha_{CO} I_{CO}$); if $X_{CO} = 2 \times 10^{-20}$ cm$^{-2}$ (K km s$^{-1}$)$^{-1}$ then $\alpha_{CO} \equiv 4.4 M_\odot$ pc$^{-2}$ (K km s$^{-1}$)$^{-1}$.

4. METHOD

Our goal is to identify regions where both H I and H2 contribute significantly to the interstellar medium (ISM), use the IR intensity in these regions to estimate the dust column, and then harness the assumption that gas and dust are linearly related to solve for $\alpha_{CO}$.

4.1. Sampling and Target Region

This experiment leverages our knowledge of H I column to infer $\alpha_{CO}$. It thus works best in regions where both H I and H2 are important to the ISM mass budget. If we target areas where H I dominates then $\alpha_{CO}$ has little or no impact on $\delta_{GDR}$ while if we target areas with only H2 then $\alpha_{CO}$ and $\delta_{GDR}$ are degenerate.

For our targets and resolution, being dominated by H2 is not a concern for any reasonable $\alpha_{CO}$. On the other hand, each target has large areas where the ISM is overwhelmingly H I. Especially in M 31 and M 33, much of the H I is at large radius and appears to have a different $\delta_{GDR}$ from the inner galaxy (Nieten et al. 2006). We mostly avoid these H I-only regions, instead targeting the part of each galaxy near where CO is detected. This gives us a range of total gas surface densities and relative contributions by H2 and H I, allowing us to constrain $\alpha_{CO}$ and $\delta_{GDR}$.

We define our target region by a ~3σ intensity cut in the convolved CO map, $I_{CO} \geq 1$ K km s$^{-1}$ in M 31, M 33, and the LMC, $I_{CO} \geq 0.25$ K km s$^{-1}$ in the SMC, and $I_{CO} \geq 0.03$ K km s$^{-1}$ in NGC 6822. We reject small regions (area < a resolution element) as likely noise spikes and then consider all area within about one resolution element of the remaining emission. Finally, we require a line of sight to have significant IR emission to be included; this is $I_{160} \geq 5$ MJy sr$^{-1}$ in NGC 6822, $I_{160} \geq 10$ MJy sr$^{-1}$ in all other targets. The result resembles loosely circling bright CO emission by hand. Figure 1 shows the target regions in contour on top of the 160 μm map.

In M 31, M 33, and the SMC treating the whole galaxy at once causes problems with our model, which assumes a constant $\alpha_{CO}$ and $\delta_{GDR}$ across the area studied. Previous work arrived at similar conclusions. Nieten et al. (2006) observed $\delta_{GDR}$ to be higher in the inner part of M 31 than the 10 kpc ring containing most of the CO. In M 33, bright CO extends a fair distance out into the disk, but based on radial profiles of H I, CO, and 160 μm intensity it is immediately clear that this galaxy, too, has a strong radial gradient in $\delta_{GDR}$. The SMC’s CO emission is clustered into three distinct regions that show evidence for local variations in their $\delta_{GDR}$, $\alpha_{CO}$, and GMC properties (Leroy et al. 2007; Muller et al. 2010).
To isolate regions with fixed $\alpha_{\text{CO}}$ and $\delta_{\text{GDR}}$, we separate each galaxy into several zones. We treat the “inner” part of M 31 separately from the 10 kpc ring and further divide the ring into a “north” and “south” part. We exclude 60′ around the minor axis (in the plane of the galaxy) of M 31 (see Section 4.3). We break M 33 into three parts: a “west” region, a “north” region, and an “east” region. Our regions in the SMC deliberately exclude two clouds near the center of the galaxy identified in Leroy et al. (2007) to have high CO-to-IR ratios; including these clouds leads to even worse solutions for this part of the SMC. Black lines and labels in Figure 1 indicate the divisions for each galaxy.

After the target regions are defined, we sample each map using a hexagonal grid spaced by 1/2 the resolution (i.e., 22.5′′ in M 31, 20′′ in M 33, 2′′ in the LMC, 22.5′′ in NGC 6822, and 1′/3 in the SMC). This yields a matched, approximately Nyquist-sampled set of measurements of $I_{70}, I_{160}, I_{\text{CO}},$ and $\Sigma_{\text{HII}}$

### 4.2. Estimating Dust Along the Line of Sight

We follow the approach of Draine & Li (2007) and Draine et al. (2007) to estimate the amount of dust along the line of sight. These papers present models that can be used to estimate the dust mass and incident radiation field from IR intensities. Following Draine et al. (2007) and Muñoz-Mateos et al. (2009), we search a grid of models illuminated by different radiation fields to find the best-fit dust mass surface density, $\Sigma_{\text{dust}}$, for each set of IR intensities. A slight difference between our fits and those papers is that we quote the geometric mean of the dust mass across the region of parameter space where $\chi^2 < \chi^2_{\text{min}} + 1$ (i.e., within 1 of the $\chi^2$ for the best-fit model). We present the results of our own direct grid-search fits, but during analysis made extensive use of the work of Muñoz-Mateos et al. (2009), who parameterized the results of model fitting over a wide range of parameter space have been as functions of the IR intensity at 24, 70, and 160 μm.

We only need a linear tracer of dust mass to solve for $\alpha_{\text{CO}}$, the normalization affects $\delta_{\text{GDR}}$ but not $\alpha_{\text{CO}}$. While values of $\delta_{\text{GDR}}$ that we find are interesting on their own, the overall normalization of the Draine & Li (2007) models do not affect our results for $\alpha_{\text{CO}}$. Before settling on the Draine & Li (2007) models, we also used modified blackbody fits with a range of emissivities to estimate the dust opacity, $\tau_{160}$. We obtained very similar results for $\alpha_{\text{CO}}$ using that approach, in the end preferring the Draine & Li (2007) models mainly for their more straightforward handling of the 70 μm band, which can include significant out-of-equilibrium emission. When we derive the uncertainties associated with our assumptions (Section 4.4 and Appendix B), we adopt either a modified blackbody or the Draine & Li (2007) models with equal probability. When using a modified blackbody fit, we include a variable fraction of 70 μm emission from an out-of-equilibrium population and emissivity power-law index in the calculation.

### M 31

M 31 is quiescent compared to our other targets. It has a very low $I_{70}/I_{160}$, implying very low radiation fields or colder dust temperatures (Gordon et al. 2006). Montalto et al. (2009) showed that with only Spitzer data the radiation field illuminating the dust is unconstrained. In addition to poor constraints on the model, these low $I_{70}/I_{160}$ make ratio maps extremely sensitive to artifacts or contamination by point sources. M 31, of all our targets, will benefit most from the additional spectral energy distribution (SED) coverage offered by Herschel. Our approach in the meantime is to treat all points in M 31 as though they had the median IR color across the whole galaxy. We implement the recommendation by Draine et al. (2007) that in the absence of submillimeter data, the radiation field be limited to 0.7 times the local value. This treatment effectively assumes that value everywhere in M 31 and uses the $I_{160}$ μm to estimate the dust mass. We note this uncertainty in Table 2.

### NGC 6822

NGC 6822 shows the faintest IR emission of any of our targets. As a result, many of the variations in $I_{70}/I_{160}$ appear driven by noise and artifacts rather than $T_{\text{dust}}$ variations. Gratier et al. (2010) noted the difficulty of deriving...

**Notes.**

- $^a$ Best fit. Units of $M_\odot$ pc$^{-2}$ (K km s$^{-1}$)$^{-1}$ including helium.
- $^b$ Estimated 1σ uncertainty in log$_{10} \alpha_{\text{CO}}$ for each source of uncertainty. “Stat.”—statistical (from Monte Carlo); “Rob.”—robustness to removal of data (from bootstrapping); “Assump.”—variation of assumptions.
- $^c$ Linear correlation coefficient relating $\Sigma_{\text{gas}}$ and $\Sigma_{\text{dust}}$ for best-fit $\alpha_{\text{CO}}$. Uncertainty gives 1σ scatter for random re-pairings of data.
- $^d$ 1σ scatter in log$_{10} \delta_{\text{GDR}}$ in dex for best-fit $\alpha_{\text{CO}}$.
- $^e$ Based on the fit of $\Sigma_{\text{HII}}$ to $\Sigma_{\text{dust}}$ at low $\Sigma_{\text{dust}}$. 

---
dust temperatures for each line of sight. Based on plots of $I_{70}$ versus $I_{160}$, we identify two main “colors” in our data. We assign each line of sight the median color for its group, with the cut at $I_{70}/I_{160} = 0.6$. We note this uncertainty in Table 2.

4.3. Diffuse H\textsc{I}

Gas with different $\delta_{\text{GDR}}$ may be superposed along the line of sight, in which case our assumption of a single $\delta_{\text{GDR}}$ no longer applies. In some cases, we expect there to be a diffuse H\textsc{I} component with little or no associated dust along the line of sight. Such a component requires that we introduce an additional term into Equation (2) so that $\Sigma_{\text{gas}}$ remains finite once $\Sigma_{\text{dust}} \sim 0$.

The simplest example of this is an edge-on spiral galaxy with a strong radial gradient in $\delta_{\text{GDR}}$. M 31 is inclined and does show a gradient in $\delta_{\text{GDR}}$ (Nieten et al. 2006). The pile-up of many different radii along a single line of sight will be most severe along the minor axis and Equation (2) does not appear to describe these data as well as those along the major axis. Because we have plenty of data, we simply exclude 60° around the minor axes from our analysis. This improves the stability of our solution. No other correction appears necessary.

The SMC has an extended distribution of H\textsc{I} that may also be very elongated along the line of sight. In this H\textsc{I} envelope and away from the main star-forming regions (in the “Wing” and “Tail”), $\delta_{\text{GDR}}$ is observed to be high (Bot et al. 2004; Leroy et al. 2007; Gordon et al. 2009). Similar results are found for other dwarf irregulars (Walter et al. 2007; Draine et al. 2007). Given the very high column densities found in the SMC, it is plausible that low $\delta_{\text{GDR}}$ H\textsc{I} lies along the line of sight.

To account for an envelope of dust-poor H\textsc{I}, we subtract a diffuse component from the SMC H\textsc{I} map before fitting for $\alpha_{\text{CO}}$. We estimate this component via an ordinary least squares bisector fit relating $\Sigma_{\text{dust}}$ and $\Sigma_{\text{H}1}$ at low $\Sigma_{\text{dust}}$, where H\textsc{I} is likely to represent most of the gas. This line implies a value of $\Sigma_{\text{H}1}$, where $\Sigma_{\text{dust}} = 0$, which we take as our estimate of the diffuse H\textsc{I}. We estimate a diffuse component of $\Sigma_{\text{H}1} = 40, 20, \text{ and } 60 M_\odot \text{ pc}^{-2}$ for the western, northern, and eastern parts of the SMC. Similar fits to the other targets suggest a diffuse H\textsc{I} component with magnitude below $10 M_\odot \text{ pc}^{-2}$, usually consistent with zero. Our uncertainty estimates include a 20% (1σ) uncertainty on this diffuse component in the SMC and $\pm 5 M_\odot \text{ pc}^{-2}$ in the case of galaxies other than the SMC.

This subtraction of diffuse H\textsc{I} differs from Leroy et al. (2007, 2009, though the latter applied this approach in some of the analysis). The effect on $\alpha_{\text{CO}}$ is largest in the “east” section of the SMC, which is embedded in the mostly diffuse Wing.

4.4. Solution

Appendices A and B lay out our method of solution and uncertainty estimates in detail. We identify the best-fit $\alpha_{\text{CO}}$ for each data set as the value that minimizes the point-to-point (rms) scatter in log$_{10} \delta_{\text{GDR}}$. We estimate the uncertainty from three sources: (1) statistical noise, (2) robustness to removal of individual data, and (3) assumptions. These are reported in Table 2 and we take the overall uncertainty to be the sum of all three terms in quadrature.

4.5. Limitations of the Model

Our model has several important limitations. It cannot recover a pervasive, CO-free H$_2$ component like that suggested for the LMC by Bernard et al. (2008). To derive such a component, we would need to make strong assumptions about $\delta_{\text{GDR}}$. We derive $\alpha_{\text{CO}}$ for H$_2$ associated with CO emission on $\sim 100$ pc scales, essentially $\alpha_{\text{CO}}$ for GMCs and their envelopes. Based on UV spectroscopy (e.g., Tumlinson et al. 2002), we consider a pervasive H$_2$ phase unlikely, but our experiment makes no test of this idea one way or the other.

We assume that $\delta_{\text{GDR}}$ does not vary between the atomic and molecular ISM. In fact, observations and theory suggest the $\delta_{\text{GDR}}$ does correlate with density. The depletion of heavy elements from the gas phase increases with increasing density (Jenkins 2009), though absorption measurements cannot probe to very high densities. Meanwhile, accounting for the observed dust abundance appears to require buildup of dust in molecular clouds (Dwek 1998; Zhukovska et al. 2008; Draine 2009). A lower $\delta_{\text{GDR}}$ in dense, molecular gas directly, linearly scales our derived $\alpha_{\text{CO}}$. Dust already accounts for $\sim 50\%$ of the relevant heavy elements, so this effect cannot exceed a factor of $\sim 2$ in magnitude. In fact, the effect should be even less severe because we already study mainly the peaks of the gas distribution, where we expect H\textsc{I} to also have high densities.

Our dust modeling also implicitly assumes that the dust emissivity does not vary between the atomic and molecular gas. Observations suggest that dust properties do change between the diffuse and dense ISM, with an enhanced emissivity in dense gas. The best evidence for this comes from a $\sim 30\%$–$50\%$ increase in far-IR optical depth relative to optical extinction at high columns ($\sim 1$ mag; e.g., Arce & Goodman 1999; Dutra et al. 2003; Cambrésy et al. 2005). Direct comparison of virial masses to submillimeter emission suggests a similar enhancement (Bot et al. 2007). The origin of this enhanced emissivity is thought to be a change in the size distribution of dust, with “fluffy,” low-albedo grains created in dense environments (Dwek 1997; Stepanyuk et al. 2003; Cambrésy et al. 2005). As with $\delta_{\text{GDR}}$ variations, emissivity variations directly scale the derived $\alpha_{\text{CO}}$.

Our best estimate is that emissivity and $\delta_{\text{GDR}}$ variations bias our measured $\alpha_{\text{CO}}$ high by a factor of $\sim 1.5$–2.0. Because this estimate distills a variety literature results, none of them definitive, applying such a correction after the fact would simply confuse our results. More importantly, we have no handle on how these factors vary with environment, though we expect weaker effects at low metallicity, where shielding is weaker. We highlight a quantitative understanding of $\delta_{\text{GDR}}$ and dust emissivity vary with environment as the most important systematics that must be addressed to improve dust-based derivations of $\alpha_{\text{CO}}$.

Finally, our data cannot rule out a pervasive population of very cold dust. We consider this unlikely and neglect it throughout the paper (e.g., see Draine et al. 2007). If such a population exists, the Herschel Space Observatory will identify it and our picture of dust will change dramatically over the next few years. However, we note that preliminary results suggest that dust masses are not dramatically affected by the inclusion of Herschel data (Gordon et al. 2010). Other systematics in using dust to trace H$_2$ have been discussed at length elsewhere (Israel 1997a, 1997b; Schnee et al. 2005; Leroy et al. 2007, with references to many other works therein) and we do not repeat them here. Our best estimate is that none of these represent a major concern. Almost all will be addressed by the inclusion of long-wavelength Herschel data (and are already improved relative to IRAS by using Spitzer’s 160 μm band).

5. RESULTS

Figure 2 plots scatter in log$_{10} \delta_{\text{GDR}}$ as a function of $\alpha_{\text{CO}}$ for our targets. In the background, a normalized histogram
Figure 2. Scatter in log10 $\delta_{\text{GDR}}$ as a function of $\alpha_{\text{CO}}$; each dot shows a calculation for a trial $\alpha_{\text{CO}}$. The shaded histograms in the background show the distribution of best-fit $\alpha_{\text{CO}}$ achieved across bootstrapping and variation of assumptions; they give some indication of the likelihood of a given $\alpha_{\text{CO}}$ describing the data.

indicates the distribution of best-fit $\alpha_{\text{CO}}$ derived across the uncertainty exercises nos. 2 (bootstrapping) and 3 (variation of assumptions). We find clear minima in each data set, which we report in Table 2 with associated uncertainties. We also quote the linear correlation coefficient between gas and dust and the scatter in log10 $\delta_{\text{GDR}}$ for the best-fit $\alpha_{\text{CO}}$. Both quantities indicate the degree to which our model describes the system.

The scatter plots in Figures 3–5 show gas (y-axis) as a function of dust (x-axis) for each target. In the left column, $\Sigma_{\text{gas}}$ is calculated from H1 alone, the middle column shows $\Sigma_{\text{gas}} = \alpha_{\text{CO}} I_{\text{CO}}$ for our best-fit $\alpha_{\text{CO}}$, and the right column shows total gas ($\Sigma_{\text{gas}} = \Sigma_{\text{H1}} + \alpha_{\text{CO}} I_{\text{CO}}$). In each case, the last column is a better match to a line through the origin (i.e., a single $\delta_{\text{GDR}}$) than the first two.

The southern part of M 31 exemplifies the signal that we look for. H1 correlates well with dust at low $\Sigma_{\text{dust}}$. At the high end, $\Sigma_{\text{dust}}$ increases without a corresponding increase in H1 (left panel). CO correlates well with $\Sigma_{\text{dust}}$ at high $\Sigma_{\text{dust}}$ but drops to low values (or zero) while there is still significant dust, so that the x-intercept of the CO–$\Sigma_{\text{dust}}$ relationship is not zero (middle panel). The gas becomes mostly molecular above a certain $\Sigma_{\text{dust}}$ and is mostly atomic below this. Our best $\alpha_{\text{CO}}$ stitches these regimes together, allowing a single $\delta_{\text{GDR}}$ to span all data.

5.1. Comments on Solutions

Before arriving at these results, we varied our methodology significantly. We tried different dust treatments, methods of solution, sampling regions, and treatments of diffuse H1. Most variations yield similar results to what we present here but a few cases are worth comment.

First, the northern part of the SMC is not well described by our model even after we excluded the high CO-to-IR clouds. Several distinct groups of data appear in the scatter plots for this region, suggesting local variations in $\delta_{\text{GDR}}$ or $\alpha_{\text{CO}}$. The data for this region are already good (Muller et al. 2010), so improved modeling—multiple dust and H1 components, local variations in $\alpha_{\text{CO}}$ and $\delta_{\text{GDR}}$—seems like the most acute need. In the meantime, our solution minimizes $\delta_{\text{GDR}}$ and yields a result consistent with the other SMC regions.

NGC 6822 yields reasonable solutions but is somewhat unstable to the choice of methodology. Adjusting the dust treatment, background subtraction, or weighting can change the best-fit $\alpha_{\text{CO}}$ by ~50%. This instability results mostly from the low signal-to-noise ratio and dynamic range in the data. These, in turn, are low because of the large distance of NGC 6822 compared to the SMC or the LMC, which makes observations challenging. The resulting low intensities also make confusion with the Milky Way an issue (Cannon et al. 2006). Improved resolution from Herschel or ALMA should allow a greater range of $\Sigma_{\text{dust}}$ as individual clouds are resolved. This will enable a stronger constraints on $\alpha_{\text{CO}}$.

The inner part of M 31 is also somewhat unstable to the choice of methodology—especially region definition and fitting method. Best-fit solutions can range from $\alpha_{\text{CO}} \sim 1$ to 5. The most likely cause is variations in $\delta_{\text{GDR}}$ and $\alpha_{\text{CO}}$ within the region studied—the data do not appear to be a plane in CO–H1–dust space. Both improved modeling and better IR SED coverage will help this case.

We emphasize that our approach to the SMC is conservative. We subtract a diffuse H1 foreground, correct for high optical depth H1, and solve for $\delta_{\text{GDR}}$ in the star-forming regions only—rendering us insensitive to any pervasive CO-free H2 component. All of these choices lower $\alpha_{\text{CO}}$, bringing it closer to the other galaxies, but the SMC still exhibits notably high $\alpha_{\text{CO}}$. The more straightforward approaches employed in Israel (1997a), Leroy et al. (2007), and Leroy et al. (2009) yield even higher $\alpha_{\text{CO}}$.

5.2. $\alpha_{\text{CO}}$ versus Metallicity

Figure 6 shows $\alpha_{\text{CO}}$ (left) and $\delta_{\text{GDR}}$ (right) as a function of metallicity. Table 2 gives the adopted metallicity for each target, which unfortunately represent a major source of uncertainty. Literature values span several tenths of a dex for most of our systems and internal variations in $12 + \log(O/H)$ often exist even where strong gradients are absent. We show a 0.2 dex uncertainty in $12 + \log(O/H)$ in our plots to reflect this uncertainty.

Figure 6 shows that $\delta_{\text{GDR}}$ is a clear function of metallicity, increasing with decreasing metallicity. This clear, one-to-one dependence of $\delta_{\text{GDR}}$ on metallicity provides a consistency check on our solutions for $\alpha_{\text{CO}}$. The data are roughly consistent with a linear relation (i.e., a fixed fraction of metals in dust), though a fit yields a slightly sublinear slope, $\log_{10} \delta_{\text{GDR}} = (9.4 \pm 1.1) - (0.85 \pm 0.13)(12 + \log(O/H))$. Our focus on star-forming regions likely biases us toward high $\delta_{\text{GDR}}$; studies of
Figure 3. Scatter plots showing $\Sigma_{\text{gas}}$ as a function of $\Sigma_{\text{dust}}$ for M 31. The columns show the relationship between dust (x-axis) and (left) $\text{H}_\text{i}$, (middle) $\text{H}_2$ derived from CO using our best-fit $\alpha_{\text{CO}}$, and (right) total ($\text{H}_\text{i} + \text{H}_2$) gas. Our best-fit $\alpha_{\text{CO}}$ yields reasonable linear scalings between total gas and dust in each system (the red line shows the median $\delta_{\text{GDR}}$), usually a clear improvement on the relationship between dust and either phase alone.

(A color version of this figure is available in the online journal.)

all material find a steeper relation (Lisenfeld & Ferrara 1998; Muñoz-Mateos et al. 2009).

In the left panel of Figure 6, we plot the best-fit $\alpha_{\text{CO}}$ as a function of metallicity. A gray area shows the commonly accepted range of values for the Milky Way (Bloemen et al. 1986; Solomon et al. 1987; Strong & Mattox 1996; Dame et al. 2001; Heyer et al. 2009). A dashed line shows the $\alpha_{\text{CO}}$ argued by Draine et al. (2007) to offer the best consistency between dust and gas measurements in SINGS galaxies. The molecular ring in M 31, both parts of M 33, and the LMC span a factor of $\sim 2$–$3$ in metallicity but show little clear gradient in $\alpha_{\text{CO}}$. All three appear broadly consistent with the Milky Way. We find higher $\alpha_{\text{CO}}$ in NGC 6822 and the SMC, but the rise relative to the higher metallicity systems much steeper than linear. Figure 6 therefore suggests a jump from “normal” to “high” $\alpha_{\text{CO}}$ at metallicity $\sim 1/4$ the solar value rather than a steady dependence of $\alpha_{\text{CO}}$ on metallicity. At the high-metallicity end, the inner part of M 31 does suggest a low $\alpha_{\text{CO}}$. It is unclear how much weight to ascribe to this point and whether the low $\alpha_{\text{CO}}$ is primarily a product of metallicity: the solution is somewhat unstable and a number of other conditions differ between the bulge of M 31 and our other targets. However, the point does highlight that lower-than-Galactic $\alpha_{\text{CO}}$ has often been observed, especially in extreme, dust-rich systems (e.g., Downes & Solomon 1998).

6. DISCUSSION

First, we emphasize a very basic result: combining $\text{H}_\text{i}$, CO, and IR emission we obtain reasonable solutions for $\alpha_{\text{CO}}$ across the Local Group. In M 31, M 33, and the LMC $\alpha_{\text{CO}}$ appears consistent, within the uncertainties, with the Milky Way. In most targets, our $\alpha_{\text{CO}}$ agree well with previous determinations using other methods. Despite its simplicity and the potential importance of systematic effects, the approach outlined here produces consistent results. A lack of quantitative constraints on how the emissivity and $\delta_{\text{GDR}}$ change between the atomic and molecular ISM (ideally measured at several metallicities) remains the most significant obstacle to derive robust absolute values of $\alpha_{\text{CO}}$ from this approach. We cite circumstantial evidence that these effects combined may cause us to overestimate $\alpha_{\text{CO}}$ everywhere by a factor of $\sim 1.5$–$2$ but emphasize the need for better constraints to improve the precision of this approach. In the meantime we have, we believe, an internally robust measurement of $\alpha_{\text{CO}}$ spanning an order of magnitude in metallicity.
6.1. CO-dark Gas at Low Metallicities

Does a rapid increase in $\alpha_{\text{CO}}$ over a narrow range in metallicity make physical sense? The metallicity dependence of $\alpha_{\text{CO}}$ is likely driven by “CO-dark” $\text{H}_2$ at low extinctions. In regions with low metallicity, a significant mass of $\text{H}_2$ is found in the outer parts of clouds where the carbon is mostly C$^+$ rather than CO (e.g., Maloney & Black 1988; Israel 1997b; Bolatto et al. 1999). Both Glover & Mac Low (2010) and Wolfire et al. (2010) recently studied this problem by modeling molecular clouds. They find that the dust extinction is the key parameter determining the fraction of CO-dark gas or $\alpha_{\text{CO}}$. For clouds with mean extinction $A_V \sim 8$ mag, such as those in the Milky Way, Wolfire et al. (2010) find a fraction of CO-dark gas $f_{\text{DG}} \sim 30\%$, in rough agreement with several observations of nearby clouds (Grenier et al. 2005; Abdo et al. 2010). At intermediate metallicities, the CO-dark $\text{H}_2$ is not dominant, so that even a significant fractional change does not impact $\alpha_{\text{CO}}$ very much. For example, in the calculations by Wolfire et al. (2010) going from the metallicity of M 31 to that of the LMC causes a doubling of the CO-dark gas fraction, from $f_{\text{DG}} \approx 20\%$ to $f_{\text{DG}} \approx 40\%$, but the corresponding effect on $\alpha_{\text{CO}}$ is only a factor of $\sim 1.3$, easily within the uncertainties of our study. As the mean extinction through the cloud decreases due to the effects of metallicity on the gas-to-dust ratio the increase in the fraction of CO-dark $\text{H}_2$ makes it the dominant molecular component, at which point $\alpha_{\text{CO}}$ is very rapidly driven upward.

Our measurements suggest that CO-dark gas becomes an important component in the metallicity range $12 + \log(\text{O/H}) \sim 8.2–8.4$. With such a small sample, we cannot be sure that this is a general result, but it is in good agreement with the expectation from Wolfire et al. (2010). Above these metallicities, variations in the fraction of CO-dark gas will still exist, but their influence on the value of $\alpha_{\text{CO}}$ will be small. Excitation of the molecular gas (particularly due to temperature variations) will be likely the dominant factor setting $\alpha_{\text{CO}}$ in molecule-rich systems. This is probably the cause of the low $\alpha_{\text{CO}}$ observed in LIRGs and ULIRGs (e.g., Downes & Solomon 1998), which have solar or slightly subsolar metallicities (e.g., Rupke et al. 2008). Within galaxies, the radiation field incident on the molecular gas may also play a role, a fact emphasized by Israel (1997a). Unfortunately, the size scales involved make this extragalactic measurement difficult. While Israel (1997a) found strong quantitative support for the influence of the radiation field on $\alpha_{\text{CO}}$, Pineda et al. (2009) and Hughes et al. (2010) recently failed to detect this effect in carefully controlled experiments in the LMC.
6.2. Comparison with the Literature

Many authors have measured $\alpha_{\text{CO}}$ using a variety of techniques. We will not attempt to summarize the literature, but focus on comparisons to two sets of measurements: (1) previous applications of IR-based techniques and (2) high spatial resolution measurements of dynamical masses using CO emission.

We measure high $\alpha_{\text{CO}}$ in the SMC and NGC 6822. This agrees with a larger trend in which IR photometry and spectroscopy suggest high $\alpha_{\text{CO}}$ in the range $12 + \log(O/H) \lesssim 8.0$–$8.2$. Israel (1997a) saw this in a number of irregulars. Rubio et al. (2004), Leroy et al. (2007), and Leroy et al. (2009) found similar results in the SMC, though as we note in Section 5.1 we actually solve for a somewhat lower $\alpha_{\text{CO}}$ than these studies—a fact we attribute to our focus on deriving $\delta_{\text{GDR}}$ from the H\textsc{i} immediate associated with the star-forming region. Gratier et al. (2010) found the same high $\alpha_{\text{CO}}$ for NGC 6822 using several approaches. Using far-infrared spectroscopy, Madden et al. (1997) found indications of high $\alpha_{\text{CO}}$ in IC 10, a Local Group galaxy with metallicity similar to NGC 6822 (we do not include IC 10 in this study because it lies near the Galactic plane and has considerable IR foregrounds). Pak et al. (1998) reached similar conclusions in the SMC. Dust continuum modeling by Bernard et al. (2008) and Roman-Duval et al. (2010) found a mixed picture in the LMC, also consistent with our findings. Note that in contrast

![Figure 5](image-url)
with this broad agreement, recent work on diffuse lines of sight in the Milky Way (Liszt et al. 2010) suggests that the ratio of CO brightness to H₂ column density is not a strong function of column density.

Figure 7 compares $\alpha_{\text{CO}}$ as a function of metallicity between this study and the literature. The points in red indicate IR-based measurements. In detail, our measurements (circles) yield lower $\alpha_{\text{CO}}$ than previous IR-based studies. We suspect this is mainly because we solve for $\alpha_{\text{CO}}$ without assuming $\delta_{\text{GDR}}$ or measuring it far away from the region of interest. One likely sense of systematic variations in $\delta_{\text{GDR}}$ is that $\delta_{\text{GDR}}$ is likely to be higher in the dense gas close to molecular complexes, which tend to reside mainly in the stellar disk, than in a diffuse, extended H I disk (e.g., Stanimirovic et al. 1999; Draine et al. 2007; Muñoz-Mateos et al. 2009). If $\delta_{\text{GDR}}$ is taken to be too high, Equation (2) yields a corresponding overestimate of $\alpha_{\text{CO}}$. In the SMC, our attempt to remove a diffuse H I component along the line of sight also leads to lower $\alpha_{\text{CO}}$ (Section 5.1), though it is less clear that our approach is correct in that case. Regardless of the cause, by simultaneously solving for $\alpha_{\text{CO}}$ and $\delta_{\text{GDR}}$ in the regions of interest in a uniform way across a heterogeneous sample we improve on literature studies of individual galaxies.

A long standing discrepancy exists between IR-based results and high-resolution virial mass measurements based on CO observations. Using virial masses, Wilson (1995), Rosolowsky et al. (2003), and Bolatto et al. (2008) all found weak or absent trends in $X_{\text{CO}}$ as a function of metallicity. The blue points in Figure 7 show virial mass results from CO observations with resolution better than 30 pc. The two approaches agree up to about the metallicity of M 33 or the LMC, and then strongly diverge in the SMC. This divergence is most easily understood if the additional H₂ traced by IR lies in an extended envelope outside the main CO-emitting region (Bolatto et al. 2008). Such an envelope can reconcile the virial mass and dust measurements and naturally explains the scale dependence of $\alpha_{\text{CO}}$ observed by Rubio et al. (1993) in the SMC. These envelopes could perhaps still have an effect on the velocity dispersion of the material inside it (and consequently the measured virial mass) via surface pressure. Structures with virial parameters $\alpha \leq 1$, however, are often observed inside local molecular clouds, suggesting that at least in some instances the velocity dispersion does not appreciably show the impact of the surrounding material. An alternative view is argued by Bot et al. (2007, 2010), who observed discrepancies between dust-based masses and virial masses even at fairly small scales. They suggest that magnetic support becomes very strong at low metallicities, perhaps because of higher ionization fractions inside clouds.

7. SUMMARY

We combine CO, H I, and IR measurements to solve for the CO-to-H₂ conversion factor, $\alpha_{\text{CO}}$, in M 33, M 31, NGC 6822, the LMC, and the SMC. We estimate the dust mass from IR intensities and then identify the $\alpha_{\text{CO}}$ that produces the best linear relation between total (H I + H₂) gas and dust. We accomplish this finding the $\alpha_{\text{CO}}$ and $\delta_{\text{GDR}}$ that minimize the scatter about Equation (2). We find that $\alpha_{\text{CO}}$ is approximately constant (within a factor of two) in M 31, M 33, and the LMC, with a value $\alpha_{\text{CO}} \approx 6 M_{\odot} pc^{-2} (K \text{ km s}^{-1})^{-1}$. By contrast NGC 6822 and the SMC, the lowest metallicity galaxies in the sample show a drastically higher $\alpha_{\text{CO}}$, ~30 and 70. The resulting gas-to-dust ratio, $\delta_{\text{GDR}}$, scales approximately linear with metallicity.

We attribute the behavior of $\alpha_{\text{CO}}$ to the transition from the regime where most H₂ is bright in CO to a regime where CO is mostly photodissociated and the bulk of the molecular reservoir is CO-dark. In our sample, this transition occurs around $12 + \log(O/H) \sim 8.4-8.2$. With only a limited number of systems, an actual numerical prescription for $\alpha_{\text{CO}}$ is beyond the scope of the paper. These results agree qualitatively with a large body of existing work using IR-based techniques, though quantitatively we find lower $\alpha_{\text{CO}}$ than previous work (e.g., Israel 1997a), probably because we restrict our analysis to CO-emitting regions.

We thank the anonymous referee for a constructive report and helpful suggestions. We gratefully acknowledge Elias Brinks, John Cannon, and Fabian Walter for sharing their data on M 31 and NGC 6822. We also thank Julia Roman-Duval, Michele
Figure 7. $\alpha_{\text{CO}}$ as a function of metallicity. Blue measurements show $\alpha_{\text{CO}}$ from virial mass calculations using high-resolution ($\lesssim 30$ pc FWHM) CO mapping. Red measurements show $\alpha_{\text{CO}}$ from infrared observations. The “ULIRGs” label indicates roughly the region of parameter space occupied by the dense, excited gas in merger-induced starbursts (Downes & Solomon 1998).

APPENDIX A
METHOD OF SOLUTION

For a given $\alpha_{\text{CO}}$, we can compute the total gas surface density ($\Sigma_{\text{gas}} = \Sigma_{\text{H}_2} + \Sigma_{\text{H}_i}$) for each line of sight. With the corresponding $\Sigma_{\text{dust}}$, each point implies a value of $\delta_{\text{GDR}}$. We have assumed (Equation (2)) that a single $\delta_{\text{GDR}}$ describes each data set. A simple way to identify the $\alpha_{\text{CO}}$ that best fits this model is to try many $\alpha_{\text{CO}}$ and select the one that minimizes the scatter in $\log_{10} \delta_{\text{GDR}}$. First, we pick a set of $\alpha_{\text{CO}}$ that brackets the true value. For each $\alpha_{\text{CO}}$, we calculate $\Sigma_{\text{gas}}$ and combine it with $\Sigma_{\text{dust}}$ to measure the rms scatter in $\log_{10} \delta_{\text{GDR}}$. This yields clear minima in each data set, which we identify as our best-fit $\alpha_{\text{CO}}$.

We experimented with several other approaches, including plane fits with errors in all three axes. The results agree with what we report here except that the plane fit is less stable in the inner part of M 31, NGC 6822, and the northern part of the SMC. The presence of significant intrinsic scatter in the relation makes the weighting of data subjective and so the plane fit is not significantly more rigorous than using the scatter as a goodness-of-fit metric. We also experimented with maximization of the linear and rank correlation coefficients relating dust and gas. Most of these approaches yield similar results. Our uncertainty estimates include substituting the median absolute deviation for the rms in the goodness of fit.

This method can fail in a data set without a good mix of $\text{H}_2$ and $\text{H}_i$-dominated lines of sight. For example, in a data set with 100 overwhelmingly $\text{H}_i$ lines of sight and three mostly molecular lines of sight, the $\text{H}_i$-dominated data will drive the scatter in $\log_{10} \delta_{\text{GDR}}$ leaving little sensitivity to $\alpha_{\text{CO}}$. In such a case, we would like to weight the high $\text{H}_2$ lines of sight more heavily. In practice, our definition of sampling regions addresses this concern and we weight all points equally.

APPENDIX B
UNCERTAINTIES

We gauge the uncertainty in the best-fit $\alpha_{\text{CO}}$ in three ways. (1) We vary details of the calculation (the calibration and background for each map, the dust model, and the goodness-of-fit statistic) across their plausible range, repeating our solution for each new set of assumptions. (2) We solve for $\alpha_{\text{CO}}$ in a simulated noisy data set where we know the true $\alpha_{\text{CO}}$ by construction. (3) We repeat the original solution while bootstraping, solving for $\alpha_{\text{CO}}$ using data drawn from the original sample (with the same number of elements) allowing repeats. We thus assess the sensitivity of $\alpha_{\text{CO}}$ to our assumptions, statistical uncertainty, and robustness. We bookkeep each as a gain-style uncertainty (i.e., rms in $\log_{10} \alpha_{\text{CO}}$) and then take our overall uncertainty to be the sum of all three terms in quadrature.

In the first test, we carry out 100 iterations. Although the Draine & Li (2007) models have been applied successfully to the SMC (Sandstrom et al. 2010), adopting them represents a key assumption. Therefore, in each iteration we randomly select with equal probability to use either the Draine & Li (2007) dust models or a modified blackbody with $\beta = 1–2$ and assuming 50% of the 70 $\mu$m emission to come from out-of-equilibrium very small grain emission, a value appropriate for the SMC.
(Leroy et al. 2009). We also select our goodness-of-fit statistic to be with equal probability either the rms scatter (as in the main result) in $\log_{10} \delta_{\text{GDR}}$, the fractional scatter in $\delta_{\text{GDR}}$, or the median absolute deviation in $\log_{10} \delta_{\text{GDR}}$. We randomize the zero point of the IR maps and the absolute calibration of each data set within their plausible value. Finally, we adjust the zero point of the H I map, either varying the assumed zero point by $\pm 20\%$ (in the SMC) or $\pm 5 M_\odot$ pc$^{-2}$ (in the other galaxies). In detail, we vary the zero points of the IR maps by typically $\pm 0.1$ and $0.5$ at 70 and 160 $\mu$m ($1\sigma$, this depends slightly on the target). We adjust overall scale of the CO and H I data by $\pm 15\%$ ($1\sigma$) and the IR maps by $\pm 10\%$. When we use a modified blackbody we pick $\beta$ randomly from the range 1–2 (always using a single value) and take a fraction $0.5 \pm 0.1$ of the 70 $\mu$m emission to come from out-of-equilibrium emission and so neglect it in the calculation. Each realization corresponds to a reasonable set of assumptions and yields a valid solution for $\alpha_{\text{CO}}$ and $\delta_{\text{GDR}}$, but we emphasize that the results presented in the main text represent our best estimates.

In the second test, we take $\Sigma_{\text{H}1}$ and $I_{\text{CO}}$ for each data set. We assume an $\alpha_{\text{CO}}$, add intrinsic scatter to the relation, add noise, and then solve for $\alpha_{\text{CO}}$. We first take the real H I and CO data and assume the best-fit values of $\alpha_{\text{CO}}$ from Table 2 to be correct. We convert $I_{\text{CO}}$ to $\Sigma_{\text{H}2}$ and then apply the measured $\delta_{\text{GDR}}$ to derive a $\Sigma_{\text{dust}}$ for each point. At this point, we have a plane in CO-H I dust space that is perfectly described by a single $\alpha_{\text{CO}}$ and $\delta_{\text{GDR}}$. We add lognormal scatter to each quantity (equally distributed among the three axes) and finally apply noise to each axis. This yields a realistic approximation of real data for which we know the true $\alpha_{\text{CO}}$. We do not know the intrinsic scatter a priori, so we try a range of values from 0 to 0.4 dex, applying $1/\sqrt{3}$ times this value to each axis. We repeat the exercise several times for each scatter, resampling the original data (allowing repeats) and re-generating the noise.

Figure 8 shows the result of this test. The y-axis gives the best-fit $\alpha_{\text{CO}}$ divided by $\alpha_{\text{CO}}$ assumed for the simulation. The x-axis shows the amount of intrinsic scatter applied when making the simulated data. Each point shows the mean and scatter for $\sim 50$ tests. The statistical uncertainty reported in Table 2 is the rms scatter (in the log) about the true $\alpha_{\text{CO}}$ for all trials with intrinsic scatter $<0.2$ dex, a realistic value based on Table 2. It thus incorporates both the mild bias and scatter seen in Figure 8.
