Abstract

Over the last few years, we have witnessed tremendous progress on many subtasks of autonomous driving, including perception, motion forecasting, and motion planning. However, these systems often assume that the car is accurately localized against a high-definition map. In this paper we question this assumption, and investigate the issues that arise in state-of-the-art autonomy stacks under localization error. Based on our observations, we design a system that jointly performs perception, motion forecasting, and localization. Our architecture is able to reuse computation between both tasks, and is thus able to correct localization errors efficiently. We show experiments on a large-scale autonomy dataset, demonstrating the efficiency and accuracy of our proposed approach.

1. Introduction

Many tasks in robotics can be broken down into a series of subproblems that are easier to study in isolation and, at the same time, facilitate the interpretability of system failures [56]. In particular, it is common to subdivide the self-driving problem into five critical subtasks: (i) Localization: placing the car on a high-definition (HD) map with centimetre-level accuracy. (ii) Perception: estimating the number and location of dynamic objects in the scene. (iii) Prediction: forecasting the trajectories and actions that the observed dynamic objects might do in the next few seconds. (iv) Motion planning: coming up with a desired trajectory for the ego-vehicle, and (v) Control: activating the actuators (i.e. steering, breaks, throttle, etc.) to execute the planned motion.

Moreover, it is common to solve the above problems sequentially, such that the output of one sub-system is passed as input to the next, and the procedure is repeated iteratively over time. This classical approach lets researchers focus on well-defined problems that can be studied independently, and these areas tend to have well-understood metrics that measure progress on their respective sub-fields. For simplicity, researchers typically study autonomy subproblems under the assumption that its inputs are correct. For example, state-of-the-art perception-and-prediction (PnP) and motion planning (MP) systems often take HD maps as input, thereby assuming access to accurate online localization. We focus our attention on this assumption and begin by studying the effect of localization errors on modern autonomy pipelines. Here, we observe that localization errors can have serious consequences for PnP and MP systems, resulting in prediction errors and missed detections, as well as bad planning that leads to larger discrepancies with human trajectories and increased collision rates. Please refer to Figure 1 for an example of an autonomy error caused by inaccurate localization.

In contrast to the classical formulation, recent systems have been designed to perform multiple autonomy tasks jointly. This joint formulation often comes with a shared neural backbone that decreases computational and system complexity, while still producing interpretable outputs that make it easier to diagnose system failures. However, these approaches have so far been limited to jointly performing perception and prediction (PnP) [8, 9, 28, 30], PnP and motion planning (P3) [37, 51, 52], semantic segmentation and localization [36] or road segmentation and object detection [43].

In this paper, and informed by our analysis of the effects of localization error, we apply the joint design philosophy to the tasks of localization, perception, and prediction; we refer to this joint setting as $\text{LPnP}$. We design an $\text{LPnP}$ system that shares computation between the tasks, which makes it possible to perform localization with as little as 2 ms of computational overhead while still producing interpretable localization and PnP outputs.

We evaluate our proposed system on a large-scale dataset in terms of motion planning metrics, and show that the proposed approach matches the performance of a traditional system with separate localization and perception components, while being able to correct localization errors online, and having reduced run time and engineering complexity.

2. Related Work

We provide a brief overview of existing approaches for the tasks that we study (perception, prediction, and local-

Figure 1: **A scenario where a small amount of localization error results in a collision.** The top row visualizes the first time step, and the bottom row visualizes a later time step where a collision occurs. GT labels are black rectangles, and the pale blue rectangles are forecasted object trajectories. The SDV is the red rectangle, with its GT trajectory in a dark blue rectangle. The samples predicted by the motion planner are shown as orange lines. The 3 columns visualize different variants of the same scenario. (Left) The planned trajectory of the SDV when there is no localization error. (Middle) What the SDV “thinks” is happening, based on its estimated pose that has error \((x, y, \text{yaw}) = (10 \text{ cm}, 0 \text{ cm}, 1.5 \text{ deg}).\) (Right) What the SDV is actually doing when subject to the pose error; this is the same trajectory as shown in the middle image, but rigidly transformed so that the initial pose agrees with the GT pose. The collision (red circle) occurs because the yellow vehicle is not perceived at \(t = 0\) due to occlusion (by the cyan vehicle); the localization error then causes the SDV to go into the lane of opposite traffic which results in a collision.

Object Detection and Motion Prediction: Detecting actors and predicting their future motion from sensor data is one of the fundamental tasks in autonomous driving. While object detection and motion forecasting can be modeled as independent tasks \([10, 11, 14, 34, 41, 49, 55]\), models that jointly perform both tasks \([9, 28, 30]\) have been shown to provide a number of benefits, such as fast inference, uncertainty propagation, and overall improved performance.

Localization: The objective of localization is to accurately and precisely determine the position of the ego-vehicle with respect to a pre-built map. Localization methods can be based on a wide variety of sensors, such as differential GPS in the form of Real-Time Kinematic systems \([19, 46]\), LiDAR \([4, 25, 29, 50]\), cameras \([18, 22, 39]\), RADAR \([3, 42]\) or combinations of such sensors \([31, 48, 57]\). While purely geometric algorithms for LiDAR localization such as iterative closest-point \([50]\) have been shown to be effective, recent work has shown that localizing by matching deep representations \([4, 12, 29, 57]\) can lead to improved robustness and scalability.

Multi-Task Learning: Compared to end-to-end approaches for autonomous agents which learn to directly map sensor readings to control output \([2, 5, 23]\), multi-task modular approaches have been shown to perform better empirically \([56]\), while also being more interpretable thanks to
human-readable intermediary representations like semantic segmentation, optical flow [56], object detections [52], occupancy forecasts [37] and planning cost maps [51]. Furthermore, Liang et al. [27] have shown the benefits of jointly performing mapping, object detection, and optical flow from LiDAR and camera data.

A wide range of approaches have been proposed to bring effective multi-task learning to the field of deep learning. While many deep learning approaches use a shared backbone with task-specific heads, and minimize a weighted sum of the loss terms of each sub-task [20, 21, 30, 43, 51], Sener and Koltun [40] showed that this may lead to suboptimal results as tasks compete for model capacity, and proposed a method where the weights of the sub-task losses are optimized at each step to bypass this issue. Side-Tuning [53] proposes an incremental approach where new tasks are added to existing neural networks in the form of additive side-modules that are easy to train, and have the advantage of leaving the weights of the original network unchanged, bypassing issues such as catastrophic forgetting.

Joint local and global feature extraction has also been studied as a form of multi-task learning in the context of localization [7, 12, 39], where multi-task networks extract global descriptors used for initial pose estimates and local features for geometric refinement of the initial estimates.

Planning Under Pose Uncertainty: The task of planning robust trajectories under pose uncertainty has been studied in the past, with previous methods formulating it as a continuous POMDP which can be solved with an iterative linear-quadratic-Gaussian method [45], or as an optimal control problem solved using model-predictive control [17]. More recently, Artuñedo et al. [1] focus on autonomous vehicles and incorporate the pose uncertainty in a probabilistic map representation that is then leveraged by a sampling-based planner. However, none of these approaches model other dynamic actors and the uncertainty in their respective motion, and do not study the complex interplay between pose uncertainty and state-of-the-art perception systems.

System-Level Analysis: A number of recent papers have studied the correlations between task-level metrics, such as object detection, and system-wide performance [35]. This line of work has shown that, while task-level metrics serve as good predictors of overall system performance, they are often unable to differentiate between similar errors that can however lead to very different system behaviors. Similarly, a related line of work analyzed the impact of sensor and inference latency on object detection in images [26] and LiDAR [13, 16]. At the same time, the simultaneous localization and mapping (SLAM) community [6, 33] has recently proposed extending SLAM evaluation beyond trajectory accuracy [15], towards system-level metrics like latency, power usage, and computational costs.

3. The Effects of Localization Error

Since state-of-the-art perception-prediction (PnP) and motion planning (MP) stacks make extensive use of accurate localization on high-definition maps (often assuming perfect localization [2, 8, 9, 51]), we study the effects of localization error on a state-of-the-art PnP and MP pipeline. We begin by describing how these modules work and how they use localization.

Perception-Prediction (PnP): PnP models are tasked with perceiving actors and predicting their future trajectories to ensure that motion planning has access to safety-critical information about the scene for the entire duration of the planning horizon. We study the state-of-the-art Implicit Latent Variable Model [8] (ILVM), the latest of a family of methods that use deep neural networks with voxelized LiDAR inputs to jointly perform detection and prediction [9, 30, 51]. ILVM encodes the whole scene in a latent random variable and uses a deterministic decoder to efficiently sample multiple scene-consistent trajectories for all the actors in the scene. Besides LiDAR, the ILVM backbone takes as input a multi-channel image with semantic aspects of the rasterized map (e.g., one channel encodes walkways, another encodes lanes, and so on, for a total of 13 layers [8]), which the model is expected to use to improve detection and forecasting. While the LiDAR scans are always processed in the vehicle frame, the scans and the map are aligned using the pose of the car. Thus, localization error results in a misalignment between the semantic map and the LiDAR scan.

Motion Planning (MP): Given a map and a set of dynamic agents and their future behaviours, the task of the motion planner is to provide a route that is safe, comfortable, and physically realizable to the control module. We study the state-of-the-art Path Lateral Time (PLT) motion planner [38], a method that samples physically-realizable trajectories, evaluates them, and selects the one with the minimal cost. The costing function employed is a combination of safety (e.g., avoid collision, stay in lane, obey traffic lights), comfort (e.g., penalizing jerk and hard braking) as well as a routing cost that encourages the vehicle to follow a path that will arrive to the destination. In this case, bad localization gives the planner a wrong idea about the layout of the static parts of the scene.

3.1. Experimental setup

LP3 Dataset: Evaluating the localization, perception, prediction, and motion planning tasks requires a dataset that contains accurately-localized self-driving scenarios, together with the corresponding HD appearance maps (to evaluate
localization), as well as annotations of dynamic objects in the scene, their tracks, and their future trajectories (to evaluate P3). To the best of our knowledge, no current public dataset satisfies all these criteria. Therefore, we use our own LP3 dataset. The LP3 dataset is a subset of the ATG4D dataset [8, 9, 51], that also has appearance maps available. The dataset is comprised of 1858 sequences of 25 seconds each, all captured in a large North American city.

Besides bounding boxes for vehicles, pedestrians and bicycles in the scene, the LP3 dataset provides semantic map annotations, such as lanes, traffic signs and sidewalks. Importantly, LP3 also provides a map appearance layer comprised of the LiDAR intensity of the static elements of the scene as captured by multiple passes of LiDAR scans through the area (please refer to the top left of Figure 3 for an example). Our LP3 dataset makes it possible to evaluate methods that jointly perform appearance-based LiDAR localization and PnP, and to quantify the effect of these tasks on planning metrics.

Simulating Localization Error: We simulate localization error and study its effects on downstream autonomy tasks. Given a maximum amount of noise $m \in \mathbb{R}$ (which we call maximum jitter), we perturb the ground truth pose on evaluation frames by sampling translational or rotational noise from a uniform distribution $\varepsilon \sim \mathcal{U}(-m, m)$. To understand the effects of different types of localization error, we evaluate translational noise and rotational noise independently.

Metrics: For perception, we focus on the mean average precision metric with at least 70% overlap between the predicted and the ground truth boxes (mAP@0.7) [9]. For prediction, we report the mean scene final displacement error (mean SFDE), which is the average difference between the ground truth and the predicted trajectories for actors in the scene, after 5 seconds (i.e., the planning horizon) [8]. For motion planning, we run the planner for the ego-vehicle at the beginning of the segments, and let the trajectory unfold for 5 seconds. We then measure the percent of segments for which there is a collision, and the $\ell_2$ distance between the predicted trajectory and the trajectory followed by the human driver after 5 seconds.

Results: We show the effects of perturbing the pose of the ego-vehicle on PnP in the top row of Figure 2. We observe that the performance of ILVM is barely affected by translational jitter up to 25 cm, and rotational jitter up to $0.5^\circ$. Larger amounts of translational noise have little effect ($\sim 2\% \text{ mAP}, 0.05 \text{ mean SFDE}$) up to 80 cm, while the effect is more pronounced for rotational error ($\sim 7\% \text{ mAP}, 0.3 \text{ mean SFDE}$) up to $3^\circ$.

We show the effects of perturbing the ego-vehicle pose on motion planning in the bottom row of Figure 2. Similar to PnP, MP performance does not degrade much until there is translational noise above 25 cm (or rotational noise above $0.5^\circ$). We also observe that large translation errors have small effects relative to rotational noise for both collision rate and distance to human route. While this is somewhat expected (as rotational error can cause straight paths to run into sidewalks or incoming traffic), it is interesting to formally quantify these effects.

4. Joint Localization, Perception, & Prediction

We now formulate a model that performs joint localization and PnP (LPnP). First, we lay out the key challenges that we would like our system to overcome, and then explain
Figure 3: The architecture of the combined localization and perception-prediction model.

4.1. System Desiderata

Low Latency: In order to provide a safe ride, a self-driving car must react quickly to changes in its environment. In practice, this means that we must minimize the time from perception to action. In a naïve, cascaded autonomy system, the running time of each component adds up linearly, which may result in unacceptable latency.

To reduce the latency of the localization system, it is common to use Bayesian filtering to provide high-frequency pose updates. In this case, a belief about the pose is maintained over time and updated through the continuous integration of different levels of evidence from wheel autoencoders, IMUs, or camera and LiDAR sensing. In this context, the external sensing step (e.g., carried out via iterative closest point alignment between the LiDAR reading and an HD map) typically carries the strongest evidence, but is also the most expensive part of the system. Therefore, it is critical to keep the latency of the sensing step of the localization filter low.

Learning-Based Localization: Localization systems with learned components are typically better at discerning semantic aspects of the scene that are traditionally hard to discriminate with purely geometric features (e.g., growing vegetation, tree stumps, and dynamic objects), and have the potential of being more invariant to appearance changes due to season, weather, and illumination [32]. Therefore, we would like to incorporate a learning-based localization component in our system. Moreover, since PnP systems are typically heavily driven by learning, it should be possible to incorporate learning-based localization by sharing computation between the two modules, resulting in reduced overhead to the overall LpNP system.

Simple Training and Deployment: We would like our joint LpNP system to be easier to train and deploy than its classical counterpart. Given the large amounts of ML infrastructure invested around PnP systems (e.g., on dataset curation, labelling, active learning, and monitoring), it makes sense to design a localization subsystem that can be trained as a smaller addition to a larger PnP model. This should also make it easier to iterate on lightweight localization modules without the need to retrain the more computationally expensive PnP component.

4.2. Designing an LpNP System

We now explain our model design choices, highlighting the ways they overcome the aforementioned challenges and achieve our design goals. We show an overview of the proposed architecture in Figure 3.

Input Representation: Our system receives LiDAR as input, which is then converted to a bird’s-eye view (BEV) voxelization with the channels of the 2D input corresponding to the height dimension [49]. Despite PnP and localization models both relying on some form of voxelized LiDAR input, perception-prediction models often use a coarser LiDAR resolution (e.g., 20cm [30, 51]) to accommodate larger regions, while matching-based localizers typically require a finer-grained resolution to localize with higher precision [4].
Using only a fine resolution voxelization for an LPnP model would be simplest, but imposes large run-time efficiency costs. Therefore, to accommodate these resolution differences, our method simultaneously rasterizes the incoming LiDAR point cloud \( x \) into two tensors of different resolutions, \( \tilde{x}_{\text{coarse}} \) for perception and \( \tilde{x}_{\text{fine}} \) for localization.

**Perception and Prediction:** For our PnP subsystem, we rely on ILVM [8], whose robustness to localization error we quantified in Section 3 – this corresponds to the lower part of Figure 3. The proposed PnP approach contains four main submodules. (i) A lightweight network processes a rasterized semantic map centred at the current vehicle pose. We pass our estimated pose to this module. (ii) Another neural backbone \( h \) extracts features from a coarsely voxelized LiDAR sweep \( \tilde{x}_{\text{coarse}} \). These two features maps are concatenated and passed to (iii) a detector-predictor that encodes the scene into a latent variable \( Z \), and (iv) a graph neural network where each node represents a detected actor, and which deterministically decodes samples from \( Z \) into samples of the joint posterior distribution over all actor trajectories.

**Localization:** We approach localization using the recently proposed framework of ground intensity localization with deep LiDAR embeddings [4]. The idea behind ground intensity localization [25] is to align the (sparse) observed LiDAR sweep \( x \) with a pre-built (dense) map of the LiDAR intensity patterns of the static scene, \( m \). This localizer learns deep functions that produce spatial embeddings of both the map \( f(m) \) and LiDAR sweep \( g(\tilde{x}_{\text{fine}}) \) before alignment. Following existing work [4] we parameterize the vehicle pose using three degrees of freedom (DoF), \( x, y, \) and yaw, represented as \( \xi \in \mathbb{R}^3 \).

Given a small set of pre-defined translational and rotational offsets, we compute the dot product between the transformed sweep and the map embeddings, and choose the pose candidate \( \xi^* \) from a pre-defined set (near the original pose estimate) with the highest correlation as the maximum-likelihood estimate of the vehicle pose:

\[
\xi^* = \arg\max_{\xi} \pi(g(\tilde{x}_{\text{fine}}), \xi) \cdot f(m) \triangleq \arg\max_{\xi} \mathbf{p}(\xi) \quad (1)
\]

where \( \pi \) is a function that warps its first argument based on the 3-DoF offset \( \xi \) and \( \cdot \) represents the dot product operator. In practice, this matching is done more efficiently by observing that the dot products can be computed in parallel with respect to the translational portion of the pose candidates by using a larger-region \( m \) and performing a single cross-correlation rather than multiple dot products for each DoF in the rotation dimension. Each cross-correlation can be performed very efficiently in the Fourier domain to allow real-time operation [4].

**Multi-Resolution Feature Sharing:** An important advantage of localizing using LiDAR matching is that in contrast to, e.g., point cloud-based localizers [12], it uses the same BEV input representation as PnP enabling a substantial amount of computation to be shared between both systems. However, as discussed earlier, the inputs to the PnP and localization backbones use different resolutions, which can make information fusion difficult. We address this issue by upsampling a crop of the LiDAR feature map computed by the coarse perception backbone to match the resolution of the finer features in the localization backbone. We then add the feature maps together using a weighted sum to produce the final localization embedding, as depicted in Fig. 3. This allows localization LiDAR embeddings to be computed with very little run-time or memory overhead compared to the base perception-prediction network.

**4.3. Learning**

We optimize the full model using side-tuning [54]. We first train the heavier perception-prediction module, and then add the LiDAR branch of the localizer as a side-tuned module. In the second stage, we freeze the weights of the perception-prediction network (yellow modules in Fig. 3), and only learn the map and online branches of the localizer (purple modules in Fig 3). There are three benefits to this approach: first, there is no risk of catastrophic forgetting in the perception-prediction task, which can be problematic as it typically requires 3–5× more computation to train than the localizer alone; second, we do not need to balance the loss terms of the localization vs. perception-prediction, eliminating the need for an additional hyperparameter; third, training the localization network can be done much faster than the full system, since the PnP header no longer needs to be evaluated and fewer gradients needs to be stored.

**Perception and Prediction:** We train the PnP component using supervised learning by minimizing a loss which combines object detection with motion forecasting, while accounting for the multimodal nature of the trajectory predictions. The PnP loss is therefore structured as

\[
\mathcal{L}_{\text{PnP}} = \mathcal{L}_{\text{DET}} + \alpha \mathcal{L}_{\text{PRED}},
\]

where \( \mathcal{L}_{\text{DET}} \) optimizes a binary cross entropy term for the object detections and one based on smooth-\( \ell_1 \) for the box regression parameters [49], \( \mathcal{L}_{\text{PRED}} \) optimizes the ELBO of the log-likelihood of the inferred \( t \) trajectories over \( t \) time steps, conditioned on the input [8], and \( \alpha \) represents a scalar weighting term selected empirically.

**Localization:** Learning \( f \) and \( g \) end-to-end produces representations that are invariant to LiDAR intensity calibration, and ignore aspects of the scene irrelevant to localization.
Learning is performed by treating localization as a classification task and minimizing the cross-entropy between the discrete distribution of $p(\xi)$ and the ground truth pose offset $p^{GT}$ expressed using one-hot encoding [4]:

$$L_{loc} = - \sum_{\xi} p(\xi) \log(p(\xi)^{GT}).$$

The online and map embedding networks $f$ and $g$ use an architecture based on the PnP map raster backbone and do not share weights. In Section 5 we also show that it is possibly to significantly improve run time by downsizing $g$ while keeping $f$ fixed with little impact on overall performance. We refer to this architecture as a Pixor backbone [49].

5. Experiments

We design our experiments to test the accuracy of our multi-task model on the joint localization and PnP (LPnP) task. We also show how these improvements translate to safe and comfortable rides based on motion planning metrics. We refer to the task of doing localization, PnP, and motion planning as LP3.

Dataset and Metrics: We use the LP3 dataset (c.f. Sec. 3), for all our experiments. To evaluate localization accuracy, following prior work [47], we report the percentage of frames on which the localizer matches the ground truth exactly, and where it matches the ground truth or a neighbouring offset as recall @ 1 (r@1) and recall @ 2 (r@2) respectively. In our setting, the former metric corresponds to exactly matching the ground truth, up to our state space resolution (5cm and 0.5°), while the latter corresponds to being inside a 15cm × 15cm × 1.5° region centered at the ground truth. For PnP, we focus on mAP@0.7 for detection and mean SFDE for prediction, as in Sec. 3. For motion planning, besides collision rate and $\ell_2$ distance to human trajectory (see Sec. 3), we also measure lateral acceleration, jerk, and progress towards the planning goal.

Experimental Setup: There are multiple ways to design an experiment that tests a localizer. One alternative is to start the state estimation at the identity and later align the produced trajectory with the ground truth (as is often done in SLAM [44]). Alternatively, online localization often initializes the robot pose at the ground truth location, and measures how far a localizer can travel before obtaining an incorrect pose [4, 31, 57]. By definition, these setups assume that the initial pose is correct, and do not test the ability to recover from localization failure – which is crucial for self-driving. Instead, we assume a self-driving scenario where the localization of the pose is initially incorrect. As such, we perturb the true pose of the vehicle and thus measure the ability of the localizer to recover from this failure, as well as the ability of PnP and MP to deal with localization failure. The perturbations are performed following the same uniform noise policy described in Section 3.1 with 0.5 metres for translation and 1.5 degrees for rotation.

Implementation Details: We train our model for 5 epochs using the Adam [24] optimizer using 16 GPUs. The coarse LiDAR tensor $x_{coarse}$ is rasterized at 20cm/voxel, while the fine tensor $x_{fine}$ uses 5cm/voxel. The spatial region corresponding to the coarse LiDAR voxelization is $144m \times 80m \times 3.2m$, while the spatial region corresponding to the fine LiDAR voxelization is $48.05m \times 24.05m \times 3.2m$. Reducing the spatial extent of the high-resolution rasterization reduces the run time of the system without sacrificing performance. The localization search range covers $\pm 0.5m$ relative to the initial vehicle pose estimate in the $x$ and $y$ dimension, discretized at 5cm intervals, and $[-1.5^{\circ}, -1.0^{\circ}, -0.5^{\circ}, 0.0^{\circ}, 0.5^{\circ}, 1.0^{\circ}, 1.5^{\circ}]$ in the yaw dimension.

Results: In Table 1, we evaluate localization and PnP performance through motion planning metrics. Notably, despite significant variation in localization metrics, both of our localization models perform similarly well when evaluated in terms of the motion planning metrics. These results further confirm the observations from our jitter experiments (Figure 2): both PnP and a short-term rollout of PLT perform similarly well when subject to a modest amount of localization error. This means that besides localization accuracy (which is important from an interpretability perspective), we have plenty of room to optimize for latency and simplicity when designing the localization component of an LPnP architecture. Our tiny Pixor backbone only takes 2ms of overhead on top of the PnP subsystem, while providing a robust learned localization signal to the autonomy system.

Ablation Study: We perform an ablation study on the capacity of the online LiDAR embedding network to evaluate the trade-off between matching performance and inference time. The results are shown in Fig. 4. Faster inference is achieved by shallower and narrower networks (fewer channels) for the online LiDAR embedding. The calculated inference time does not include the map embedding branch, which can be pre-computed offline. The largest model corresponds to a similar architecture to the PnP rasterized HD map backbone (which is itself a smaller version of the PnP LiDAR backbone), while the faster and smaller models have fewer layers or fewer channels in each layer. The four largest models have 11 convolutional layers and a factor of $C = 1/2^0, 1/2^1, 1/2^2, 1/2^4$ the number of channels as the largest model. The smallest (fifth largest) has $C = 1/2^4$ and five layers rather than 11, which corresponds to one layer around each of the three pooling/upsampling stages followed by a final layer.
Table 1: **Motion planning evaluation using pose estimate and actor predictions.** For the PnP and Planning poses: GT denotes ground truth (the pose was not altered); N denotes that localization noise was added (translation and rotation sampled uniformly at random from $[-0.5m,+0.5m]$ and $[-1.5\degree,+1.5\degree]$, respectively). Big Pixor refers to the largest width Pixor Embedding Net from Fig 4, and Tiny Pixor refers to the smallest. Bold denotes the best results (within an epsilon threshold) and underlines second best results.

| Model                        | PnP pose (GT, N, L) | Planning Pose (GT, N, L) | r@1 ↑ (%) | r@2 ↑ (%) | Collision ↓ (\% up to 5s) | $\ell_2$ human ↓ (m @ 5s) | Lat. acc. ↓ (m/s) | Jerk ↓ (m/s$^2$) | Progress ↑ (m @ 5s) |
|------------------------------|---------------------|--------------------------|-----------|-----------|--------------------------|--------------------------|-------------------|-------------------|-------------------|
| ILVM GT                      | GT                  | -                        | -         | -         | 2.915                    | 4.64                    | 2.13              | 1.82              | 24.95             |

**Figure 4: Localizer Embedding Network Size vs. Performance** The localization performance and runtime of the single-task and multi-task methods. Faster inference is achieved by narrower and shallower networks for the online LiDAR embedding.

Table 2: **Localization inference time comparison.** While being nearly identical in terms of matching accuracy when comparing models with recall @ 2 performance similar to [4], the proposed approach is much faster, due to a more efficient architecture and sharing computation with the perception backbone.

| Model                        | Time (ms) | r@1 | r@2 |
|------------------------------|-----------|-----|-----|
| LiDAR Localizer [4]          | 25.92      | 0.52| 0.95|
| LiDAR Localizer (Pixor-based)| 2.79       | 0.47| 0.95|
| Joint LnP (Ours)             | 1.95       | 0.49| 0.95|

While reducing model size leads to a small drop in matching accuracy, this does not end up affecting motion planning, as shown in Table 1, while at the same time reducing the online embedding computation time four-fold.

Finally, Table 2 compares our proposed online LiDAR embedding networks to the state of the art. The U-Net-based approach from [4] was shown to outperform classic approaches like ICP-based localization, especially in challenging environments such as highways. Our results show that the original performance can already be matched with a much faster network architecture, while leveraging the perception feature maps allows even smaller models to perform at the same level. All inference times are measured on an NVIDIA RTX5000 GPU.

6. **Conclusion**

While prior research in autonomous driving has explored either full end-to-end learning or the joint study of tasks such as object detection and motion forecasting, the task of localization has not received as much attention in the context of perception and planning systems, in spite of the strong reliance of self-driving vehicles on HD maps for these tasks. In this paper, we studied how localization errors affect state-of-the-art perception, prediction, and motion-planning systems. Our analysis showed that while perception is robust to relatively small localization errors, motion planning performance suffers more, especially in case of yaw errors, motivating the need to detect and correct such issues. We subsequently proposed a multi-task learning solution capable of jointly localizing against an HD map while also performing object detection and motion forecasting, and showed that localization errors can be successfully detected and corrected with very little computational cost—less than 2ms of GPU time.
