Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
Duration of viable SARS-CoV-2 shedding from respiratory tract in different human hosts and its impact on isolation discontinuation polices revision; a narrative review

ARTICLE INFO

Keywords: COVID-19, RT-PCR, Viral culture, Cycle threshold value, Transmission, Isolation

ABSTRACT

Background: The duration of viable viral shedding is important to be defined in regards of viral transmission in SARS-CoV-2 infection with the backdrop of the current worldwide effort for revising isolation polices and establishing the duration of infectiousness.

Methods: In this review we searched databases including Medline and google scholar for research articles published between January 2020 and January 2022. We included case reports, case series, cross sectional, cohort, and randomized control trials that reported the duration of shedding of viable SARS-CoV-2 virus. After evaluating the criteria for inclusion, 32 articles (2721 patients) were included.

Result: This review showed that the median for the last day of successful viral isolation was 11 (8.5–14.5 95% CI), 20 (9.0–57.5 95% CI), 20 (9.0–103 95% CI) for the general population, critical patients and immunocompromised individuals, respectively, with significant association between prolonged viral shedding, disease severity (P-Value 0.024) and immunosuppressive status (P-Value 0.023).

The corresponding higher cutoff of CtV to culturable virus ranged between 26.25 and 34.00 (95% confidence interval) with median of 30.5, and higher values were observed when critical (25.0–37.37 95% CI) and immunocompromised patients (20.0–37.82 95% CI) have been excluded, this deviation did not represent a statistical significance (P-Value 0.997 and 0.888) respectively.

Conclusion: Our review highlights that repeating SARS-CoV-2 viral RNA test solely in recovering patients has no importance in determining infectivity and emphasizes the individualization of de-isolation decisions based on the host factors and a combined symptom and testing-based approaches with the later benefiting most of correlation with recently introduced rapid antigen test. Our finding in the review also opposes the most recent CDC Guidance on shortening isolation duration in term of the last days of viable transmissible virus, therefore caution should be considered when revising such protocols.

Abbreviations: RT-PCR, Reverse transcription polymerase chain reaction; RAT, Rapid antigen test; CTv, Cycle threshold value.

Introduction

Historically, six strains of coronaviruses are believed to infect humans, of which four strains were identified from upper respiratory tract infection from patients with common cold (Su et al., 2016), the other two, are associated with more severe disease and mortality including severe acute respiratory syndrome (SARS-CoV) and Middle east respiratory syndrome (MERS-CoV) (Cui et al., 2019). The seventh coronavirus was identified as a cause of pneumonia outbreak in Wuhan, China in December 2019 (Zhu et al., 2020), the latter three are believed to be zoonotic in origin although the intermediate carrier of severe acute respiratory syndrome coronavirus – 2 (SARS-CoV-2) is not yet precisely known (Surveillances, 2020).

The main route for SARS-CoV-2 transmission is by close contact and respiratory droplet allowing high rate of infectivity, which poses a real challenge on health care systems that necessitates the need of contact tracing and testing. Real time reverse transcription polymerase chain reaction (RT-PCR) has become the standard of SARS-CoV-2 diagnosis because of its high sensitivity and specificity (Wiersinga et al., 2020; Li et al., 2020; Steinbrook, 2020; Shen et al., 2020).

SARS-CoV-2 RNA positivity by RT-PCR has been detected up to 12 weeks, but RT-PCR positivity might not represent the presence of viable virus (Sun et al., 2020). Confirmation of virus replication and infectivity requires viral culture, which is not practical in acute settings as the virus requires prolonged time to be isolated and specific laboratory settings with biosafety levels of 3 or more (Li et al., 2020).

Based on available published literature, the Center of Disease Control and Prevention (CDC) stated that discontinuing isolation can be considered after day 10 of symptoms onset, which can be extended to 20 days for severe cases or immunocompromised individual, awaiting more solid evidence regarding replication-competent virus shedding, which is still an area of debate (CDC. COVID-19 Interim Guidance, 2022). Currently, two years into the pandemic in the post vaccination and boosting era when the surge of Omicron variant predominated the active cases worldwide, the CDC shortened the quarantine period to five days CDC, Media Releases, 2021. While this step is rationalized and endorsed by some infectious diseases authorities IDSA, 2022, it is still not fully acceptable by medical communities. (AMA, 2022)

Method

Search strategy and selection criteria

We conducted a comprehensive search on both Medline and google scholar database up to January 2022, using keywords “COVID-19” Or “SARS-CoV-2” Or “Coronavirus” combined with “Culture” or “Virus Isolation” with the use of keywords’ Medical Subject Heading (MESH) And truncation. The total studies screened were 2540, of which 372 full text studies were assessed for eligibility.

The total studies included in the review were 32 after exclusion of 347 articles with seven additional studies included from references search. The main reason for exclusion included if the study method did not include viral culture, if the purpose of viral isolation was for sequencing, genotyping or phenotyping purpose, if the study reported viral culture form non-respiratory body fluid, or if the last day of successful isolation was not clearly mentioned in the study [Fig. 1.].

Data analysis

We reviewed the articles to extract the following information from each: First Author, setting, name of the journal, date of article first available online, study sample size, number of cases with successful viral isolation, last day of positive culture, type of sample, cycle threshold Value (CTv) and inclusion of immunocompromised individuals or critically ill patients (Supplementary Table 1). The data was analyzed using SPSS. Median, grouped median, mean values and 95% confidence interval of the analyzed values were calculated using Anova-T test with bootstrapping to number of samples. The level of significance was established based on linear-by-linear association and 2-sided P-value of 0.05 or less.

Results

The systematic search included 2540 possible relevant articles. After evaluating the criteria for inclusion, 32 articles (2721 patients) were included (Supplementary Table 1). Of the 32 articles included, 7 were done in united states, 7 in France, 3 in Canada, 3 in China, 2 in Japan and 1 in each of the following countries (Australia, Germany, Italy, Netherland, South Korea, Spain, Switzerland, Taiwan, Turkey and United Kingdom), 17 articles (53.13%) were available online in 2020, 13 (40.62%) in 2021 and 2 (6.25) in 2022.

Regarding the type of patients included in the study, immunocompromised were included in 12 articles (37.5%), patients with critical disease were included in 15 articles (46.9%) while the remaining 20 (62.5%) and 17 (53.1%) studies excluded or did not specify the inclusion of immunocompromised individuals and critical cases, respectively.

In regard to the type of samples used when assessing viral culture, 29 studies (90.6%) used nasopharyngeal swab, 11 (34.38%) used oropharyngeal swab, sputum samples were used in 5 (15.6) articles and endotracheal aspirates in 3 (9.38%) articles. 1 (3.13%) study tested samples directly from saliva and a combination of methods were used in 14 (43.75%) of the studies included.

In regards to the last day of virus isolation by culture, most of the data retrieved from systematic review of the above-mentioned articles showed that the last day of successful viral isolation ranged somewhere between 8.5 and 14.50 days (95% confidence interval (CI)) with median of 11 days and mean of 28.75 days.

The duration of viral viability appears to be more prolonged in critical patients with median (9.0–57.5 95 %CI) and grouped median (9.0–53.0 95 %CI) of 20 days and mean of 47.5 days and shorter if those patients were not specified of excluded with median and grouped median of 9 days (8.0–13.98 95 %CI) and mean of 10 days, with estimated 2-sided statistical significance of 0.024

A similar pattern is also observed when immunocompromised individuals were included in the reviewed article with calculated median (9.0–103 95 %CI) and grouped median (9.0–85.98 95 %CI) of 20 days and mean of 54.36 days which noticed to be shorter with median (8.0–13.98 95 %CI) and grouped median (8.2–13.33 95 %CI) of 9 days
and mean of 11.67 if this category of patient was not specified or excluded (P-Value 0.023).

When looking at the relation of CTV and positive viral culture, the corresponding higher border of CTV to culturable virus ranged between 26.25 and 34.00 (95% confidence interval) with median of 30.5, grouped median of 30.67 and mean of 30.82, although this range was slightly wider when critical cases (25.0–37.37 95% CI) and immunocompromised patients (20.0–37.82 95% CI) have been excluded with median of 32.5, but this deviation did not represent a statistical significance or linear-by-linear association (P-Value 0.997 and 0.888) respectively (Supplementary Table 2).

Discussion

This narrative review provides data on the understanding of SARS-CoV-2 infectivity. The findings show that 95% of samples are no longer viable after day 15 in the general population, with a median of 11 days, and with a mean of 28.75 days. When applying this review on critical patients and immunocompromised individuals, the viable viral shedding could last up to 2 and 4 months, respectively, with a median of 20 days. These findings correlate with the initial suggestions made from the Center of Disease Control, that the duration of infectiousness lasts up to 10 days for mild to moderate cases and up to 20 days in severe cases or severely immunocompromised hosts, and materializes liberal shortening of the period of quarantine into an exclamatory question (CDC. Media releases, 2021; CDC. COVID-19 Interim Guidance, 2022).

To date, the diagnosis of COVID-19 has relied on the detection of SARS-CoV-2 through molecular detection (Wiersinga et al., 2020; Li et al., 2020; Steinbrook, 2020; Shen et al., 2020). While this method is the gold standard by the World Health Organization (WHO) as it is both rapid and highly sensitive (Asrani et al., 2021), there are important limitations in the context of both duration and rate of positivity. Noticeably, this discrepancy has been reflected in some reviewed studies that showed that patients with SARS-CoV-2 continue to have prolonged viral shedding even up to 60 days, no live virus was isolated by culture method beyond 18 days (Million et al., 2020). Similarly, out of 84 positive RT-PCR for SARS-CoV-2 in healthcare workers, only one sample produces a cytopathic effect on the 11th day of incubation (Longtin et al., 2022). The use of RT-PCR as a follow-up method for SARS-CoV-2 infection might represent dead viral particles and has led to infer misleading information regarding the duration of infectivity of patients, defining cases and isolation policies. This subsequently increases the burden on healthcare utilities and human resources, and needs to be further interpreted with caution to minimize its impact (Asrani et al., 2021; Widders et al., 2020).

Vero cells were used primarily for the identification of causative viruses of the disease and evaluating vaccine effectiveness for such viruses. Recently, Vero E6 cell line was found to enhance SARS-CoV-2 infection in vitro growth by exposing the virus to selective pressure. Although the use of cell culture to define the virus infectivity has been criticized as it may overexpresses the viral growth and not truly represent the viral pathogenesis and transmutability in the human host (Wurutz et al., 2021; Basile et al., 2020; Ramirez et al., 2021), the study of viral growth in human airway epithelium revealed comparable viral dynamics and rebutted this theory (Milewska et al., 2020). Importantly, not all studies using cell culture for SARS-CoV-2 identification reported the viral cytopathic effect, which serves as an important role for delineating viruses' pathogenicity (Longtin et al., 2022). However, the ability to use viral culture to determine infectivity remains challenging due to unavailable resources and the labor-intensive nature of the pandemic.

A relationship is apparent between the lower CTV threshold and positive SARS-CoV-2 viral culture (La Scola et al., 2020), with higher cutoff of 34 based on most of the published articles (Million et al., 2020; La Scola et al., 2020; Lescurre et al., 2020; Gautret et al., 2020). In this review the analysis showed that 95% of the viable samples have the higher cutoff of CTV less than 35 (25.25–34.6) for the total cohort representing the general population with a median of 30.5. These findings are supported by similar reviews that correlated lower CTV to infectivity, although, on the contrary, correlation to disease severity was not established statically in our review (Rao et al., 2020). Therefore, according to available evidence; infection prevention and control guidelines may take into account that CTV equal or above 35 may be safely discharged and no longer require isolation.

As confirmed by multiple reviews, disease severity and immunosuppressive status are widely accepted as independent risks for prolonged viral shedding (van Kampen et al., 2021 Jan 11; Feng et al., 2020). This observation has been confirmed by our review which found that a viable virus can be isolated from this group of patients for up to 2–4 months with a median of 20 days. While the lengthened duration in critical patients is attributed to multiple factors, including the mechanical ventilation dynamics, the nature of samples and the use of immunomodulators (Xu et al., 20202020) in immunosuppressed host, this finding is proposed to be secondary to delayed seroconversion due to underlying immunosuppressive disease or therapy (Buder et al., 2021; Murphy and Dzik, 2020 Nov 12). However, the decision of discontinuing isolation in such an entity of patients remains an ample challenge. Though a combination of test based along with symptoms-based approaches could help guide the decision-making process in such entities of patients as proposed by Alshukairi et al. (Alshukairi et al., 2021 Jul).

The recent introduction of point of care testing including rapid antigen test (RAT), for example the Panbio™ COVID-19 Ag Rapid Test Device (Abbott Diagnostic GmbH, Jena, Germany) started to be widely available as it is self-operated, easily interpreted and highly specific, furthermore, it is more sensitive with lower CTV (less than 25), which is more determinate of infectiousness, as some recent reports suggested that PCR-positive/RAT-negative individuals are less likely to have transmissible diseases, its use in correlation with SARS-CoV-2 RT-PCR might serve as important de-isolation tool, specifically in patient with prolonged molecular test positivity (Strömmer et al., 2020 Dec 28; Fenollar et al., 2021 Jan 21; Albert et al., 2021 Mar).

There were several limitations in this systematic review, most of the studies were of low to moderate quality, importantly, the articles’ data were heterogeneous in regards to disease severity and patient population. Also, some studies did not specifically report the relationship between CTV and successful virus isolation by culture, but correlated it rather to RT-PCR. Despite a huge effort done from the start of the pandemic, further studies regarding SARS-CoV-2 transmissibility dynamics are needed, especially in post-vaccination era.

Conclusion

We are providing data on the dynamics of SARS-CoV-2 infectivity. Our review showed that 95% of samples are no longer viable after day 15 in the general population with a median of 11 days. On the other hand, the viable viral shedding could last up to 2 and 3–4 months in critical patients and immunocompromised individuals, respectively, with a median of 20 days. The prolonged viral shedding observed in our study opposes the most recent CDC Guidance on shortening isolation duration. Therefore, caution should be considered when revising such protocols.

This review also clearly shows that repeat testing SARS-CoV-2 viral RNA in recovering patients has no importance in determining infectivity. This emphasizes the use of a multi-tier approach for isolation discontinuation which incorporates patient host factors, disease symptomatology and severity. Thus, benefiting most from a combination of molecular and serological testing to guide clinical decisions and infection control policies rather than the sole use of molecular testing.
